

# 2001 Fundamentals

## Contributors

## Preface

## Technical Committees and Task Groups

### THEORY

- F01. Thermodynamics and Refrigeration Cycles
- F02. Fluid Flow
- F03. Heat Transfer
- F04. Two-Phase Flow
- F05. Mass Transfer
- F06. Psychrometrics
- F07. Sound and Vibration

### GENERAL ENGINEERING INFORMATION

- F08. Thermal Comfort
- F09. Indoor Environmental Health
- F10. Environmental Control for Animals and Plants
- F11. Physiological Factors in Drying and Storing Farm Crops
- F12. Air Contaminants
- F13. Odors

### LOAD AND ENERGY CALCULATIONS

- F26. Ventilation and Infiltration
- F27. Climatic Design Information
- F28. Residential Cooling and Heating Load Calculations
- F29. Nonresidential Cooling and Heating Load Calculation Procedures
- F30. Fenestration
- F31. Energy Estimating and Modeling Methods

### DUCT AND PIPE DESIGN

- F32. Space Air Diffusion
- F33. HVAC Computational Fluid Dynamics
- F34. Duct Design
- F35. Pipe Sizing

- F14. Measurement and Instruments
- F15. Fundamentals of Control
- F16. Airflow Around Buildings

### BASIC MATERIALS

- F17. Energy Resources
- F18. Combustion and Fuels
- F19. Refrigerants
- F20. Thermophysical Properties of Refrigerants
- F21. Physical Properties of Secondary Coolants (Brines)
- F22. Sorbents and Desiccants
- F23. Thermal and Moisture Control in Insulated Assemblies — Fundamentals
- F24. Thermal and Moisture Control in Insulated Assemblies—Applications
- F25. Thermal and Water Vapor Transmission Data

### GENERAL

- F36. Abbreviations and Symbols
- F37. Units and Conversions
- F38. Physical Properties of Materials

### ADDITIONS AND CORRECTIONS

### INDEX

Composite index to the 1998 Refrigeration, 1999 HVAC Applications, 2000 HVAC Systems and Equipment, and 2001 Fundamentals volumes

# CONTRIBUTORS

In addition to the Technical Committees, the following individuals contributed significantly to this volume. The appropriate chapter numbers follow each contributor's name.

# ASHRAE Research: Improving the Quality of Life

The American Society of Heating, Refrigerating and Air-Conditioning Engineers is the world's foremost technical society in the fields of heating, ventilation, air conditioning, and refrigeration. Its members worldwide ideas, identify needs, support research, and write the industry's standards for testing and practice. The result is that engineers are better able to keep indoor environments safe and productive while protecting and preserving the outdoors for generations to come.

One of the ways that ASHRAE supports its members' and industry's need for information is through ASHRAE Research. Thousands of individuals and companies support ASHRAE Research

annually, enabling ASHRAE to report new data about material properties and building physics and to promote the application of innovative technologies.

The chapters in ASHRAE Handbooks are updated through the experience of members of ASHRAE technical committees and through results of ASHRAE Research reported at ASHRAE meetings and published in ASHRAE special publications and in *ASHRAE Transactions*.

For information about ASHRAE Research or to become a member contact, ASHRAE, 1791 Tullie Circle, Atlanta, GA 30329; telephone: 404-636-8400; [www.ashrae.org](http://www.ashrae.org).

## The 2001 ASHRAE Handbook

The Fundamentals volume covers basic principles and provides data for the practice of HVAC&R technology. Although design data change little over time, research sponsored by ASHRAE and others continues to generate new information that meets the evolving needs of the people and industries that rely on HVAC&R technology to improve the quality of life. The ASHRAE technical committees that prepare chapters strive to provide new information, clarify existing information, delete obsolete materials and reorganize chapters to make the Handbook more understandable and easier to use. In this volume, some of the changes and additions are as follows:

- Chapter 1, Thermodynamics and Refrigeration Cycles, includes new sections on ideal thermal and absorption cycles, multiple stage cycles, and thermodynamic representation of absorption cycles. The section on ammonia water cycles has been expanded.
- Chapter 12, Air Contaminants, has undergone major revisions. Material has been added from the 1999 *ASHRAE Handbook*, Chapter 44, Control of Gaseous Indoor Air Contaminants. Health-related material with standards and guidelines for exposure has been moved to Chapter 9, Indoor Environmental Health.
- Chapter 15, Fundamentals of Control now includes new or revised figures on discharge air temperature control, step input process, and pilot positioners. New are sections on networking and fuzzy logic, revised descriptions on dampers and modulating control, and text on chilled mirror humidity sensors and dispersive infrared technology.
- Chapter 17, Energy Resources, contains new sections on sustainability and designing for effective energy resource use.
- Chapter 19, Refrigerants, provides information on phaseout of CFC and HCFC refrigerants and includes new data on R-143a and R-404A, R-407C, R-410A, R-507, R-508A, and R-508B blends.
- Chapter 20, Thermophysical Properties of Refrigerants, has new data on R-143a and R-245fa. Though most CFC Refrigerants have been removed from the chapter, R-12 has been retained to assist in making comparisons. Revised formulations have been used for many of the HFC refrigerants, conforming to international standards where applicable.
- Chapter 23, Thermal and Moisture Control in Insulated Assemblies—Fundamentals, now has a reorganized section on economic insulation thickness, a revised surface condensation section, and a new section on moisture analysis models.
- Chapter 26, Ventilation and Infiltration, includes rewritten stack pressure and wind pressure sections. New residential sections discuss averaging time variant ventilation, superposition methods, the enhanced (AIM-2) model, air leakage through automatic doors, and central air handler blowers in ventilation systems. The nonresidential ventilation section has also been rewritten, and now includes a commercial building envelope leakage measurements summary.

- Chapter 27, Climatic Design Information, now contains new monthly, warm-season design values for some United States locations. These values aid in consideration of seasonal variations in solar geometry and intensity, building occupancy, and use patterns.
- Chapter 29, Nonresidential Cooling and Heating Load Calculations, now contains enhanced data on internal loads, an expanded description of the heat balance method, and the new, simplified radiant time series (RTS) method.
- Chapter 30, Fenestration, now has revised solar heat gain and visible transmittance sections, including information on the solar heat gain coefficients (SHGC) method. The chapter now also has a rewritten section on solar-optical properties of glazings, an expanded daylighting section, and a new section on occupant comfort and acceptance.
- Chapter 31, Energy Estimating and Modeling Methods, now contains improved model forms for both design and existing building performance analysis. A new section describes a simplified method for calculating heat flow through building foundations and basements. Sections on secondary equipment and bin-energy method calculations have added information, while the section on data-driven models has been rewritten and now illustrates the variable-base degree-day method.
- Chapter 32, Space Air Diffusion, has been reorganized to be more user-friendly. The section on principles of jet behavior now includes simpler equations with clearer tables and figures. Temperature profiles now accompany characteristics of different outlets, with stagnant regions identified. The section on underfloor air distribution and task/ambient conditioning includes updates from recent ASHRAE-sponsored research projects.
- Chapter 33, HVAC Computational Fluid Dynamics, is a new chapter that provides an introduction to computational methods in flow modeling, including a description of computational fluid dynamics (CFD) with discussion of theory and capabilities.
- Chapter 34, Duct Design, includes revisions to duct sealing requirements from ASHRAE *Standard* 90.1, and has been expanded to include additional common fittings, previously included in electronic form in ASHRAE's Duct Fitting Database.

This Handbook is published both as a bound print volume and in electronic format on a CD-ROM. It is available in two editions—one contains inch-pound (I-P) units of measurement, and the other contains the International System of Units (SI).

Look for corrections to the 1998, 1999, and 2000 Handbooks on the Internet at <http://www.ashrae.org>. Any changes in this volume will be reported in the 2002 *ASHRAE Handbook* and on the ASHRAE web site.

If you have suggestions for improving a chapter or you would like more information on how you can help revise a chapter, e-mail [ashrae@ashrae.org](mailto:ashrae@ashrae.org); write to Handbook Editor, ASHRAE, 1791 Tullie Circle, Atlanta, GA 30329; or fax 404-321-5478.

# ASHRAE TECHNICAL COMMITTEES AND TASK GROUPS

---

## SECTION 1.0—FUNDAMENTALS AND GENERAL

- 1.1 Thermodynamics and Psychrometrics
- 1.2 Instruments and Measurements
- 1.3 Heat Transfer and Fluid Flow
- 1.4 Control Theory and Application
- 1.5 Computer Applications
- 1.6 Terminology
- 1.7 Operation and Maintenance Management
- 1.8 Owning and Operating Costs
- 1.9 Electrical Systems
- 1.10 Energy Resources

## SECTION 2.0—ENVIRONMENTAL QUALITY

- 2.1 Physiology and Human Environment
- 2.2 Plant and Animal Environment
- 2.3 Gaseous Air Contaminants and Gas Contaminant Removal Equipment
- 2.4 Particulate Air Contaminants and Particulate Contaminant Removal Equipment
- 2.6 Sound and Vibration Control
- 2.7 Seismic and Wind Restraint Design
- TG Buildings' Impacts on the Environment
- TG Global Climate Change

## SECTION 3.0—MATERIALS AND PROCESSES

- 3.1 Refrigerants and Secondary Coolants
- 3.2 Refrigerant System Chemistry
- 3.3 Refrigerant Contaminant Control
- 3.4 Lubrication
- 3.5 Desiccant and Sorption Technology
- 3.6 Water Treatment
- 3.8 Refrigerant Containment

## SECTION 4.0—LOAD CALCULATIONS AND ENERGY REQUIREMENTS

- 4.1 Load Calculation Data and Procedures
- 4.2 Weather Information
- 4.3 Ventilation Requirements and Infiltration
- 4.4 Building Materials and Building Envelope Performance
- 4.5 Fenestration
- 4.6 Building Operation Dynamics
- 4.7 Energy Calculations
- 4.10 Indoor Environmental Modeling
- 4.11 Smart Building Systems
- 4.12 Integrated Building Design
- TG Mechanical Systems Insulation

## SECTION 5.0—VENTILATION AND AIR DISTRIBUTION

- 5.1 Fans
- 5.2 Duct Design
- 5.3 Room Air Distribution
- 5.4 Industrial Process Air Cleaning (Air Pollution Control)
- 5.5 Air-to-Air Energy Recovery
- 5.6 Control of Fire and Smoke
- 5.7 Evaporative Cooling
- 5.8 Industrial Ventilation
- 5.9 Enclosed Vehicular Facilities
- 5.10 Kitchen Ventilation

## SECTION 6.0—HEATING EQUIPMENT, HEATING AND COOLING SYSTEMS AND APPLICATIONS

- 6.1 Hydronic and Steam Equipment and Systems
- 6.2 District Energy
- 6.3 Central Forced Air Heating and Cooling Systems
- 6.4 In Space Convection Heating
- 6.5 Radiant Space Heating and Cooling
- 6.6 Service Water Heating
- 6.7 Solar Energy Utilization
- 6.8 Geothermal Energy Utilization
- 6.9 Thermal Storage
- 6.10 Fuels and Combustion

## SECTION 7.0—PACKAGED AIR-CONDITIONING AND REFRIGERATION EQUIPMENT

- 7.1 Residential Refrigerators and Food Freezers
- 7.4 Combustion Engine Driven Heating and Cooling Equipment
- 7.5 Mechanical Dehumidification Equipment and Heat Pipes
- 7.6 Unitary and Room Air Conditioners and Heat Pumps

## SECTION 8.0—AIR-CONDITIONING AND REFRIGERATION SYSTEM COMPONENTS

- 8.1 Positive Displacement Compressors
- 8.2 Centrifugal Machines
- 8.3 Absorption and Heat Operated Machines
- 8.4 Air-to-Refrigerant Heat Transfer Equipment
- 8.5 Liquid-to-Refrigerant Heat Exchangers
- 8.6 Cooling Towers and Evaporative Condensers
- 8.7 Humidifying Equipment
- 8.8 Refrigerant System Controls and Accessories
- 8.10 Pumps and Hydronic Piping
- 8.11 Electric Motors and Motor Control

## SECTION 9.0—AIR-CONDITIONING SYSTEMS AND APPLICATIONS

- 9.1 Large Building Air-Conditioning Systems
- 9.2 Industrial Air Conditioning
- 9.3 Transportation Air Conditioning
- 9.4 Applied Heat Pump/Heat Recovery Systems
- 9.5 Cogeneration Systems
- 9.6 Systems Energy Utilization
- 9.7 Testing and Balancing
- 9.8 Large Building Air-Conditioning Applications
- 9.9 Building Commissioning
- 9.10 Laboratory Systems
- 9.11 Clean Spaces
- 9.12 Tall Buildings
- TG Combustion Gas Turbine Inlet Air Cooling Systems

## SECTION 10.0—REFRIGERATION SYSTEMS

- 10.1 Custom Engineered Refrigeration Systems
  - 10.2 Automatic Icemaking Plants and Skating Rinks
  - 10.3 Refrigerant Piping, Controls, and Accessories
  - 10.4 Ultra-Low Temperature Systems and Cryogenics
  - 10.5 Refrigerated Distribution and Storage Facilities
  - 10.6 Transport Refrigeration
  - 10.7 Commercial Food and Beverage Cooling Display and Storage
  - 10.8 Refrigeration Load Calculations
  - 10.9 Refrigeration Application for Foods and Beverages
  - TG Mineral Oil Circulation

---	--

**T**HERMODYNAMICS is the study of energy, its transformations, and its relation to states of matter. This chapter covers the application of thermodynamics to refrigeration cycles. The first part reviews the first and second laws of thermodynamics and presents methods for calculating thermodynamic properties. The second and third parts address compression and absorption refrigeration cycles, the two most common methods of thermal energy transfer.

### THERMODYNAMICS

A **thermodynamic system** is a region in space or a quantity of matter bounded by a closed surface. The surroundings include everything external to the system, and the system is separated from the surroundings by the system boundaries. These boundaries can be movable or fixed, real or imaginary.

The concepts that operate in any thermodynamic system are **entropy** and **energy**. Entropy measures the molecular disorder of a system. The more mixed a system, the greater its entropy; conversely, an orderly or unmixed configuration is one of low entropy. Energy has the capacity for producing an effect and can be categorized into either stored or transient forms as described in the following sections.

#### Stored Energy

**Thermal (internal) energy** is the energy possessed by a system caused by the motion of the molecules and/or intermolecular forces.

**Potential energy** is the energy possessed by a system caused by the attractive forces existing between molecules, or the elevation of the system.

$$PE = mgz \quad (1)$$

where

- $m$  = mass
- $g$  = local acceleration of gravity
- $z$  = elevation above horizontal reference plane

**Kinetic energy** is the energy possessed by a system caused by the velocity of the molecules and is expressed as

$$KE = mV^2/2 \quad (2)$$

where  $V$  is the velocity of a fluid stream crossing the system boundary.

**Chemical energy** is energy possessed by the system caused by the arrangement of atoms composing the molecules.

**Nuclear (atomic) energy** is energy possessed by the system from the cohesive forces holding protons and neutrons together as the atom's nucleus.

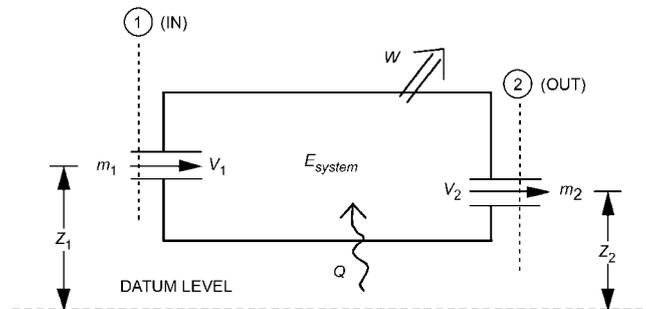

#### Energy in Transition

**Heat ( $Q$ )** is the mechanism that transfers energy across the boundary of systems with differing temperatures, always toward the lower temperature. Heat is positive when energy is added to the system (see Figure 1).

**Work** is the mechanism that transfers energy across the boundary of systems with differing pressures (or force of any kind), always toward the lower pressure. If the total effect produced in the system can be reduced to the raising of a weight, then nothing but work has crossed the boundary. Work is positive when energy is removed from the system (see Figure 1).

**Mechanical or shaft work ( $W$ )** is the energy delivered or absorbed by a mechanism, such as a turbine, air compressor, or internal combustion engine.

**Flow work** is energy carried into or transmitted across the system boundary because a pumping process occurs somewhere outside the system, causing fluid to enter the system. It can be more easily understood as the work done by the fluid just outside the

**Fig. 1** Energy Flows in General Thermodynamic System

The preparation of the first and second parts of this chapter is assigned to TC 1.1, Thermodynamics and Psychrometrics. The third part is assigned to TC 8.3, Absorption and Heat-Operated Machines.

system on the adjacent fluid entering the system to force or push it into the system. Flow work also occurs as fluid leaves the system.

$$\text{Flow Work (per unit mass)} = pv \quad (3)$$

where  $p$  is the pressure and  $v$  is the specific volume, or the volume displaced per unit mass.

A **property** of a system is any observable characteristic of the system. The **state** of a system is defined by listing its properties. The most common thermodynamic properties are temperature  $T$ , pressure  $p$ , and specific volume  $v$  or density  $\rho$ . Additional thermodynamic properties include entropy, stored forms of energy, and enthalpy.

Frequently, thermodynamic properties combine to form other properties. **Enthalpy** ( $h$ ), a result of combining properties, is defined as

$$h \equiv u + pv \quad (4)$$

where  $u$  is internal energy per unit mass.

Each property in a given state has only one definite value, and any property always has the same value for a given state, regardless of how the substance arrived at that state.

A **process** is a change in state that can be defined as any change in the properties of a system. A process is described by specifying the initial and final equilibrium states, the path (if identifiable), and the interactions that take place across system boundaries during the process.

A **cycle** is a process or a series of processes wherein the initial and final states of the system are identical. Therefore, at the conclusion of a cycle, all the properties have the same value they had at the beginning.

A **pure substance** has a homogeneous and invariable chemical composition. It can exist in more than one phase, but the chemical composition is the same in all phases.

If a substance exists as liquid at the saturation temperature and pressure, it is called **saturated liquid**. If the temperature of the liquid is lower than the saturation temperature for the existing pressure, it is called either a **subcooled liquid** (the temperature is lower than the saturation temperature for the given pressure) or a **compressed liquid** (the pressure is greater than the saturation pressure for the given temperature).

When a substance exists as part liquid and part vapor at the saturation temperature, its quality is defined as the ratio of the mass of vapor to the total mass. Quality has meaning only when the substance is in a saturated state; i.e., at saturation pressure and temperature.

If a substance exists as vapor at the saturation temperature, it is called **saturated vapor**. (Sometimes the term **dry saturated vapor** is used to emphasize that the quality is 100%.) When the vapor is at a temperature greater than the saturation temperature, it is **superheated vapor**. The pressure and temperature of superheated vapor are independent properties, since the temperature can increase while the pressure remains constant. Gases are highly superheated vapors.

## FIRST LAW OF THERMODYNAMICS

The first law of thermodynamics is often called the **law of the conservation of energy**. The following form of the first law equation is valid only in the absence of a nuclear or chemical reaction.

Based on the first law or the law of conservation of energy for any system, open or closed, there is an energy balance as

$$\left[ \begin{array}{c} \text{Net Amount of Energy} \\ \text{Added to System} \end{array} \right] = \left[ \begin{array}{c} \text{Net Increase in Stored} \\ \text{Energy of System} \end{array} \right]$$

or

$$\text{Energy In} - \text{Energy Out} = \text{Increase in Energy in System}$$

Figure 1 illustrates energy flows into and out of a thermodynamic system. For the general case of multiple mass flows in and out of the system, the energy balance can be written

$$\begin{aligned} & \sum m_{in} \left( u + pv + \frac{V^2}{2} + gz \right)_{in} \\ & - \sum m_{out} \left( u + pv + \frac{V^2}{2} + gz \right)_{out} + Q - W \\ & = \left[ m_f \left( u + \frac{V^2}{2} + gz \right)_f - m_i \left( u + \frac{V^2}{2} + gz \right)_i \right]_{system} \end{aligned} \quad (5)$$

where subscripts  $i$  and  $f$  refer to the initial and final states, respectively.

The steady-flow process is important in engineering applications. Steady flow signifies that all quantities associated with the system do not vary with time. Consequently,

$$\begin{aligned} & \sum_{\text{all streams leaving}} \dot{m} \left( h + \frac{V^2}{2} + gz \right) \\ & - \sum_{\text{all streams entering}} \dot{m} \left( h + \frac{V^2}{2} + gz \right) + \dot{Q} - \dot{W} = 0 \end{aligned} \quad (6)$$

where  $h = u + pv$  as described in Equation (4).

A second common application is the closed stationary system for which the first law equation reduces to

$$Q - W = [m(u_f - u_i)]_{system} \quad (7)$$

## SECOND LAW OF THERMODYNAMICS

The second law of thermodynamics differentiates and quantifies processes that only proceed in a certain direction (irreversible) from those that are reversible. The second law may be described in several ways. One method uses the concept of entropy flow in an open system and the irreversibility associated with the process. The concept of irreversibility provides added insight into the operation of cycles. For example, the larger the irreversibility in a refrigeration cycle operating with a given refrigeration load between two fixed temperature levels, the larger the amount of work required to operate the cycle. Irreversibilities include pressure drops in lines and heat exchangers, heat transfer between fluids of different temperature, and mechanical friction. Reducing total irreversibility in a cycle improves the cycle performance. In the limit of no irreversibilities, a cycle will attain its maximum ideal efficiency.

In an open system, the second law of thermodynamics can be described in terms of entropy as

$$dS_{system} = \frac{\delta Q}{T} + \delta m_i s_i - \delta m_e s_e + dI \quad (8)$$

where

$dS_{system}$  = total change within system in time  $dt$  during process

$\delta m_i s_i$  = entropy increase caused by mass entering (incoming)

$\delta m_e s_e$  = entropy decrease caused by mass leaving (exiting)

$\delta Q/T$  = entropy change caused by reversible heat transfer between system and surroundings

$dI$  = entropy caused by irreversibilities (always positive)

Equation (8) accounts for all entropy changes in the system. Rearranged, this equation becomes

$$\delta Q = T[(\delta m_e s_e - \delta m_i s_i) + dS_{sys} - dI] \quad (9)$$

In integrated form, if inlet and outlet properties, mass flow, and interactions with the surroundings do not vary with time, the general equation for the second law is

$$(S_f - S_i)_{system} = \int_{rev} \frac{\delta Q}{T} + \sum (ms)_{in} - \sum (ms)_{out} + I \quad (10)$$

In many applications the process can be considered to be operating steadily with no change in time. The change in entropy of the system is therefore zero. The irreversibility rate, which is the rate of entropy production caused by irreversibilities in the process, can be determined by rearranging Equation (10)

$$\dot{I} = \sum (\dot{m}s)_{out} - \sum (\dot{m}s)_{in} - \int \frac{\dot{Q}}{T_{surr}} \quad (11)$$

Equation (6) can be used to replace the heat transfer quantity. Note that the absolute temperature of the surroundings with which the system is exchanging heat is used in the last term. If the temperature of the surroundings is equal to the temperature of the system, the heat is transferred reversibly and Equation (11) becomes equal to zero.

Equation (11) is commonly applied to a system with one mass flow in, the same mass flow out, no work, and negligible kinetic or potential energy flows. Combining Equations (6) and (11) yields

$$\dot{I} = \dot{m} \left[ (s_{out} - s_{in}) - \frac{h_{out} - h_{in}}{T_{surr}} \right] \quad (12)$$

In a cycle, the reduction of work produced by a power cycle or the increase in work required by a refrigeration cycle is equal to the absolute ambient temperature multiplied by the sum of the irreversibilities in all the processes in the cycle. Thus the difference in the reversible work and the actual work for any refrigeration cycle, theoretical or real, operating under the same conditions becomes

$$\dot{W}_{actual} = \dot{W}_{reversible} + T_0 \sum \dot{I} \quad (13)$$

### THERMODYNAMIC ANALYSIS OF REFRIGERATION CYCLES

Refrigeration cycles transfer thermal energy from a region of low temperature  $T_R$  to one of higher temperature. Usually the higher temperature heat sink is the ambient air or cooling water. This temperature is designated as  $T_0$ , the temperature of the surroundings.

The first and second laws of thermodynamics can be applied to individual components to determine mass and energy balances and the irreversibility of the components. This procedure is illustrated in later sections in this chapter.

Performance of a refrigeration cycle is usually described by a **coefficient of performance**. COP is defined as the benefit of the cycle (amount of heat removed) divided by the required energy input to operate the cycle, or

$$\text{COP} \equiv \frac{\text{Useful refrigerating effect}}{\text{Net energy supplied from external sources}} \quad (14)$$

For a mechanical vapor compression system, the net energy supplied is usually in the form of work, mechanical or electrical, and may include work to the compressor and fans or pumps. Thus

$$\text{COP} = \frac{Q_{evap}}{W_{net}} \quad (15)$$

In an absorption refrigeration cycle, the net energy supplied is usually in the form of heat into the generator and work into the pumps and fans, or

$$\text{COP} = \frac{Q_{evap}}{Q_{gen} + W_{net}} \quad (16)$$

In many cases the work supplied to an absorption system is very small compared to the amount of heat supplied to the generator, so the work term is often neglected.

Application of the second law to an entire refrigeration cycle shows that a completely reversible cycle operating under the same conditions has the maximum possible Coefficient of Performance. A measure of the departure of the actual cycle from an ideal reversible cycle is given by the **refrigerating efficiency**:

$$\eta_R = \frac{\text{COP}}{(\text{COP})_{rev}} \quad (17)$$

The Carnot cycle usually serves as the ideal reversible refrigeration cycle. For multistage cycles, each stage is described by a reversible cycle.

### EQUATIONS OF STATE

The equation of state of a pure substance is a mathematical relation between pressure, specific volume, and temperature. When the system is in thermodynamic equilibrium,

$$f(p, v, T) = 0 \quad (18)$$

The principles of statistical mechanics are used to (1) explore the fundamental properties of matter, (2) predict an equation of state based on the statistical nature of a particular system, or (3) propose a functional form for an equation of state with unknown parameters that are determined by measuring thermodynamic properties of a substance. A fundamental equation with this basis is the **virial equation**. The virial equation is expressed as an expansion in pressure  $p$  or in reciprocal values of volume per unit mass  $v$  as

$$\frac{pv}{RT} = 1 + B'p + C'p^2 + D'p^3 + \dots \quad (19)$$

$$\frac{pv}{RT} = 1 + (B/v) + (C/v^2) + (D/v^3) + \dots \quad (20)$$

where coefficients  $B'$ ,  $C'$ ,  $D'$ , etc., and  $B$ ,  $C$ ,  $D$ , etc., are the virial coefficients.  $B'$  and  $B$  are second virial coefficients;  $C'$  and  $C$  are third virial coefficients, etc. The virial coefficients are functions of temperature only, and values of the respective coefficients in Equations (19) and (20) are related. For example,  $B' = B/RT$  and  $C' = (C - B^2)/(RT)^2$ .

The ideal gas constant  $R$  is defined as

$$R = \lim_{p \rightarrow 0} \frac{(pv)_T}{T_{tp}} \quad (21)$$

where  $(pv)_T$  is the product of the pressure and the volume along an isotherm, and  $T_{tp}$  is the defined temperature of the triple point of water, which is 273.16 K. The current best value of  $R$  is 8314.41 J/(kg mole · K).

The quantity  $pv/RT$  is also called the **compressibility factor**; i.e.,  $Z = pv/RT$  or

$$Z = 1 + (B/v) + (C/v^2) + (D/v^3) + \dots \quad (22)$$

An advantage of the virial form is that statistical mechanics can be used to predict the lower order coefficients and provide physical significance to the virial coefficients. For example, in Equation

(22), the term  $B/v$  is a function of interactions between two molecules,  $C/v^2$  between three molecules, etc. Since the lower order interactions are common, the contributions of the higher order terms are successively less. Thermodynamicists use the partition or distribution function to determine virial coefficients; however, experimental values of the second and third coefficients are preferred. For dense fluids, many higher order terms are necessary that can neither be satisfactorily predicted from theory nor determined from experimental measurements. In general, a truncated virial expansion of four terms is valid for densities of less than one-half the value at the critical point. For higher densities, additional terms can be used and determined empirically.

Digital computers allow the use of very complex equations of state in calculating  $p$ - $v$ - $T$  values, even to high densities. The Benedict-Webb-Rubin (B-W-R) equation of state (Benedict et al. 1940) and the Martin-Hou equation (1955) have had considerable use, but should generally be limited to densities less than the critical value. Strobridge (1962) suggested a modified Benedict-Webb-Rubin relation that gives excellent results at higher densities and can be used for a  $p$ - $v$ - $T$  surface that extends into the liquid phase.

The B-W-R equation has been used extensively for hydrocarbons (Cooper and Goldfrank 1967):

$$P = (RT/v) + (B_o RT - A_o - C_o/T^2)/v^2 + (bRT - a)/v^3 + (a\alpha)/v^6 + [c(1 + \gamma/v^2)e^{(-\gamma/v^2)}]/v^3 T^2 \quad (23)$$

where the constant coefficients are  $A_o, B_o, C_o, a, b, c, \alpha, \gamma$ .

The Martin-Hou equation, developed for fluorinated hydrocarbon properties, has been used to calculate the thermodynamic property tables in Chapter 20 and in ASHRAE *Thermodynamic Properties of Refrigerants* (Stewart et al. 1986). The Martin-Hou equation is as follows:

$$p = \frac{RT}{v-b} + \frac{A_2 + B_2 T + C_2 e^{(-kT/T_c)}}{(v-b)^2} + \frac{A_3 + B_3 T + C_3 e^{(-kT/T_c)}}{(v-b)^3} + \frac{A_4 + B_4 T}{(v-b)^4} + \frac{A_5 + B_5 T + C_5 e^{(-kT/T_c)}}{(v-b)^5} + (A_6 + B_6 T)e^{av} \quad (24)$$

where the constant coefficients are  $A_i, B_i, C_i, k, b$ , and  $\alpha$ .

Strobridge (1962) suggested an equation of state that was developed for nitrogen properties and used for most cryogenic fluids. This equation combines the B-W-R equation of state with an equation for high density nitrogen suggested by Benedict (1937). These equations have been used successfully for liquid and vapor phases, extending in the liquid phase to the triple-point temperature and the freezing line, and in the vapor phase from 10 to 1000 K, with pressures to 1 GPa. The equation suggested by Strobridge is accurate within the uncertainty of the measured  $p$ - $v$ - $T$  data. This equation, as originally reported by Strobridge, is

$$p = RT\rho + \left[ Rn_1 T + n_2 + \frac{n_3}{T} + \frac{n_4}{T^2} + \frac{n_5}{T^4} \right] \rho^2 + (Rn_6 T + n_7) \rho^3 + n_8 T \rho^4 + \rho^3 \left[ \frac{n_9}{T^2} + \frac{n_{10}}{T^3} + \frac{n_{11}}{T^4} \right] \exp(-n_{16} \rho^2) + \rho^5 \left[ \frac{n_{12}}{T^2} + \frac{n_{13}}{T^3} + \frac{n_{14}}{T^4} \right] \exp(-n_{16} \rho^2) + n_{15} \rho^6 \quad (25)$$

The 15 coefficients of this equation's linear terms are determined by a least-square fit to experimental data. Hust and Stewart (1966) and Hust and McCarty (1967) give further information on methods and techniques for determining equations of state.

In the absence of experimental data, Van der Waals' principle of corresponding states can predict fluid properties. This principle relates properties of similar substances by suitable reducing factors; i.e., the  $p$ - $v$ - $T$  surfaces of similar fluids in a given region are assumed to be of similar shape. The critical point can be used to define reducing parameters to scale the surface of one fluid to the dimensions of another. Modifications of this principle, as suggested by Kamerlingh Onnes, a Dutch cryogenic researcher, have been used to improve correspondence at low pressures. The principle of corresponding states provides useful approximations, and numerous modifications have been reported. More complex treatments for predicting property values, which recognize similarity of fluid properties, are by generalized equations of state. These equations ordinarily allow for adjustment of the  $p$ - $v$ - $T$  surface by introduction of parameters. One example (Hirschfelder et al. 1958) allows for departures from the principle of corresponding states by adding two correlating parameters.

## CALCULATING THERMODYNAMIC PROPERTIES

While equations of state provide  $p$ - $v$ - $T$  relations, a thermodynamic analysis usually requires values for internal energy, enthalpy, and entropy. These properties have been tabulated for many substances, including refrigerants (See Chapters 6, 20, and 38) and can be extracted from such tables by interpolating manually or with a suitable computer program. This approach is appropriate for hand calculations and for relatively simple computer models; however, for many computer simulations, the overhead in memory or input and output required to use tabulated data can make this approach unacceptable. For large thermal system simulations or complex analyses, it may be more efficient to determine internal energy, enthalpy, and entropy using fundamental thermodynamic relations or curves fit to experimental data. Some of these relations are discussed in the following sections. Also, the thermodynamic relations discussed in those sections are the basis for constructing tables of thermodynamic property data. Further information on the topic may be found in references covering system modeling and thermodynamics (Stoecker 1989, Howell and Buckius 1992).

At least two intensive properties must be known to determine the remaining properties. If two known properties are either  $p$ ,  $v$ , or  $T$  (these are relatively easy to measure and are commonly used in simulations), the third can be determined throughout the range of interest using an equation of state. Furthermore, if the specific heats at zero pressure are known, specific heat can be accurately determined from spectroscopic measurements using statistical mechanics (NASA 1971). Entropy may be considered a function of  $T$  and  $p$ , and from calculus an infinitesimal change in entropy can be written as follows:

$$ds = \left( \frac{\partial s}{\partial T} \right)_p dT + \left( \frac{\partial s}{\partial p} \right)_T dp \quad (26)$$

Likewise, a change in enthalpy can be written as

$$dh = \left( \frac{\partial h}{\partial T} \right)_p dT + \left( \frac{\partial h}{\partial p} \right)_T dp \quad (27)$$

Using the relation  $Tds = dh - vdp$  and the definition of specific heat at constant pressure,  $c_p \equiv (\partial h/\partial T)_p$ , Equation (27) can be rearranged to yield

$$ds = \frac{c_p}{T}dT + \left[ \left( \frac{\partial h}{\partial p} \right)_T - v \right] \frac{dp}{T} \quad (28)$$

Equations (26) and (28) combine to yield  $(\partial s/\partial T)_p = c_p/T$ . Then, using the Maxwell relation  $(\partial s/\partial p)_T = -(\partial v/\partial T)_p$ , Equation (26) may be rewritten as

$$ds = \frac{c_p}{T}dT - \left( \frac{\partial v}{\partial T} \right)_p dp \quad (29)$$

This is an expression for an exact derivative, so it follows that

$$\left( \frac{\partial c_p}{\partial p} \right)_T = -T \left( \frac{\partial^2 v}{\partial T^2} \right)_p \quad (30)$$

Integrating this expression at a fixed temperature yields

$$c_p = c_{p0} - \int_0^p T \left( \frac{\partial^2 v}{\partial T^2} \right)_p dp_T \quad (31)$$

where  $c_{p0}$  is the known zero pressure specific heat, and  $dp_T$  is used to indicate that the integration is performed at a fixed temperature. The second partial derivative of specific volume with respect to temperature can be determined from the equation of state. Thus, Equation (31) can be used to determine the specific heat at any pressure.

Using  $Tds = dh - vdp$ , Equation (29) can be written as

$$dh = c_p dT + \left[ v - T \left( \frac{\partial v}{\partial T} \right)_p \right] dp \quad (32)$$

Equations (28) and (32) may be integrated at constant pressure to obtain

$$s(T_1, p_0) = s(T_0, p_0) + \int_{T_0}^{T_1} \frac{c_p}{T} dT_p \quad (33)$$

$$\text{and } h(T_1, p_0) = h(T_0, p_0) + \int_{T_0}^{T_1} c_p dT \quad (34)$$

Integrating the Maxwell relation  $(\partial s/\partial p)_T = -(\partial v/\partial T)_p$  gives an equation for entropy changes at a constant temperature as

$$s(T_0, p_1) = s(T_0, p_0) - \int_{p_0}^{p_1} \left( \frac{\partial v}{\partial T} \right)_p dp_T \quad (35)$$

Likewise, integrating Equation (32) along an isotherm yields the following equation for enthalpy changes at a constant temperature

$$h(T_0, p_1) = h(T_0, p_0) + \int_{p_0}^{p_1} \left[ v - T \left( \frac{\partial v}{\partial T} \right)_p \right] dp \quad (36)$$

Internal energy can be calculated from  $u = h - pv$ .

Combinations (or variations) of Equations (33) through (36) can be incorporated directly into computer subroutines to calculate properties with improved accuracy and efficiency. However, these equations are restricted to situations where the equation of state is valid and the properties vary continuously. These restrictions are violated by a change of phase such as evaporation and condensation, which are essential processes in air-conditioning and refrigerating devices. Therefore, the Clapeyron equation is of particular value; for evaporation or condensation it gives

$$\left( \frac{dp}{dT} \right)_{sat} = \frac{s_{fg}}{v_{fg}} = \frac{h_{fg}}{Tv_{fg}} \quad (37)$$

where

$s_{fg}$  = entropy of vaporization

$h_{fg}$  = enthalpy of vaporization

$v_{fg}$  = specific volume difference between vapor and liquid phases

If vapor pressure and liquid and vapor density data are known at saturation, and these are relatively easy measurements to obtain, then changes in enthalpy and entropy can be calculated using Equation (37).

### Phase Equilibria for Multicomponent Systems

To understand phase equilibria, consider a container full of a liquid made of two components; the more volatile component is designated  $i$  and the less volatile component  $j$  (Figure 2A). This mixture is all liquid because the temperature is low—but not so low that a solid appears. Heat added at a constant pressure raises the temperature of the mixture, and a sufficient increase causes vapor to form, as shown in Figure 2B. If heat at constant pressure continues to be added, eventually the temperature will become so high that only vapor remains in the container (Figure 2C). A temperature-concentration ( $T$ - $x$ ) diagram is useful for exploring details of this situation.

Figure 3 is a typical  $T$ - $x$  diagram valid at a fixed pressure. The case shown in Figure 2A, a container full of liquid mixture with mole fraction  $x_{i,0}$  at temperature  $T_0$ , is point 0 on the  $T$ - $x$  diagram. When heat is added, the temperature of the mixture increases. The point at which vapor begins to form is the **bubble point**. Starting at point 0, the first bubble will form at temperature  $T_1$ , designated by point 1 on the diagram. The locus of bubble points is the **bubble point curve**, which provides bubble points for various liquid mole fractions  $x_i$ .

When the first bubble begins to form, the vapor in the bubble may not have the  $i$  mole fraction found in the liquid mixture. Rather, the mole fraction of the more volatile species is higher in the vapor than in the liquid. Boiling prefers the more volatile species, and the  $T$ - $x$  diagram shows this behavior. At  $T_1$ , the vapor-forming bubbles have an  $i$  mole fraction of  $y_{i,1}$ . If heat continues to be added, this preferential boiling will deplete the liquid of species

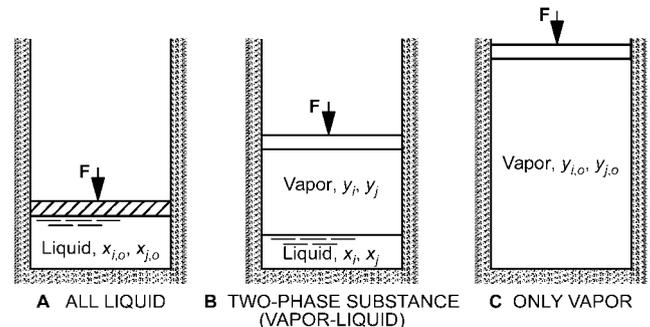

Fig. 2 Mixture of  $i$  and  $j$  Components in Constant Pressure Container

$i$  and the temperature required to continue the process will increase. Again, the  $T$ - $x$  diagram reflects this fact; at point 2 the  $i$  mole fraction in the liquid is reduced to  $x_{i,2}$  and the vapor has a mole fraction of  $y_{i,2}$ . The temperature required to boil the mixture is increased to  $T_2$ . Position 2 on the  $T$ - $x$  diagram could correspond to the physical situation shown in Figure 2B.

If the constant-pressure heating continues, all the liquid eventually becomes vapor at temperature  $T_3$ . At this point the  $i$  mole fraction in the vapor  $y_{i,3}$  equals the starting mole fraction in the all-liquid mixture  $x_{i,1}$ . This equality is required for mass and species conservation. Further addition of heat simply raises the vapor temperature. The final position 4 corresponds to the physical situation shown in Figure 2C.

Starting at position 4 in Figure 3, the removal of heat leads to 3, and further heat removal would cause droplets rich in the less volatile species to form. This point is called the **dew point**, and the locus of dew points is called the **dew-point curve**. The removal of heat will cause the mixture to reverse through points 3, 2, 1, and to starting point 0. Because the composition shifts, the temperature

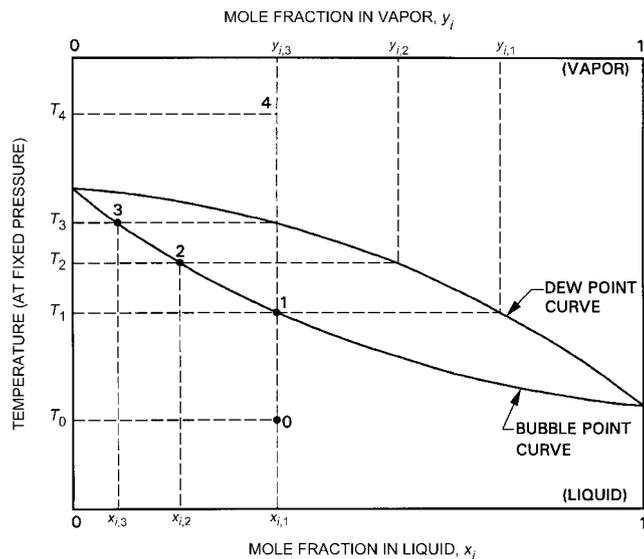

Fig. 3 Temperature-Concentration ( $T$ - $x$ ) Diagram for Zeotropic Mixture

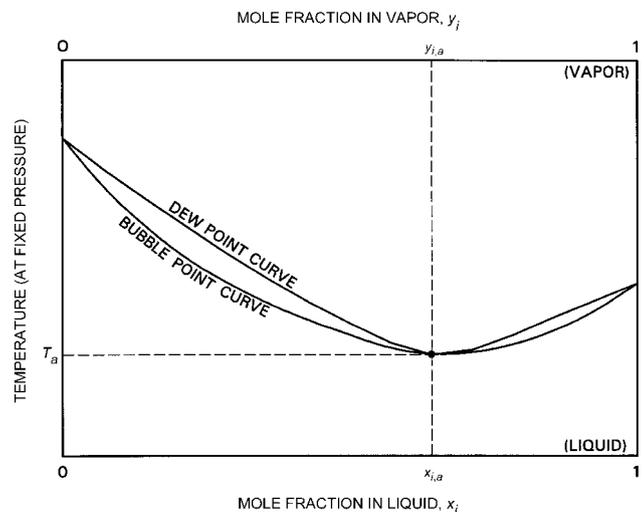

Fig. 4 Azeotropic Behavior Shown on  $T$ - $x$  Diagram

required to boil (or condense) this mixture changes as the process proceeds. This mixture is therefore called **zeotropic**.

Most mixtures have  $T$ - $x$  diagrams that behave as previously described, but some have a markedly different feature. If the dew point and bubble point curves intersect at any point other than at their ends, the mixture exhibits what is called **azeotropic** behavior at that composition. This case is shown as position a in the  $T$ - $x$  diagram of Figure 4. If a container of liquid with a mole fraction  $x_a$  were boiled, vapor would be formed with an identical mole fraction  $y_a$ . The addition of heat at constant pressure would continue with no shift in composition and no temperature glide.

Perfect azeotropic behavior is uncommon, while near azeotropic behavior is fairly common. The azeotropic composition is pressure dependent, so operating pressures should be considered for their impact on mixture behavior. Azeotropic and near-azeotropic refrigerant mixtures find wide application. The properties of an azeotropic mixture are such that they may be conveniently treated as pure substance properties. Zeotropic mixtures, however, require special treatment, using an equation-of-state approach with appropriate mixing rules or using the fugacities with the standard state method (Tassios 1993). Refrigerant and lubricant blends are a zeotropic mixture and can be treated by these methods (see Thome 1995 and Martz et al. 1996a, b).

## COMPRESSION REFRIGERATION CYCLES

### CARNOT CYCLE

The Carnot cycle, which is completely reversible, is a perfect model for a refrigeration cycle operating between two fixed temperatures, or between two fluids at different temperatures and each with infinite heat capacity. Reversible cycles have two important properties: (1) no refrigerating cycle may have a coefficient of performance higher than that for a reversible cycle operated between the same temperature limits, and (2) all reversible cycles, when operated between the same temperature limits, have the same coefficient of performance. Proof of both statements may be found in almost any textbook on elementary engineering thermodynamics.

Figure 5 shows the Carnot cycle on temperature-entropy coordinates. Heat is withdrawn at the constant temperature  $T_R$  from the region to be refrigerated. Heat is rejected at the constant ambient temperature  $T_0$ . The cycle is completed by an isentropic expansion and an isentropic compression. The energy transfers are given by

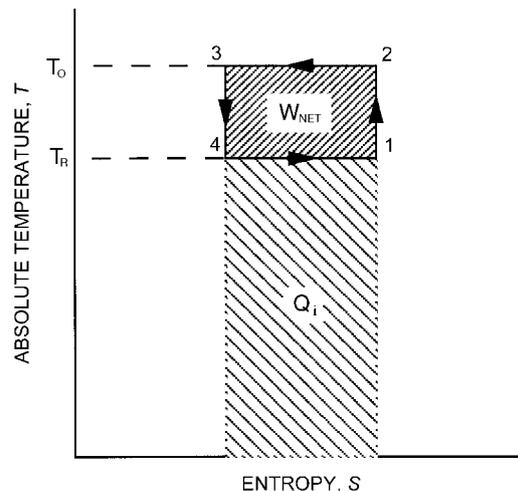

Fig. 5 Carnot Refrigeration Cycle

$$Q_o = T_o(S_2 - S_3)$$

$$Q_i = T_R(S_1 - S_4) = T_R(S_2 - S_3)$$

$$W_{net} = Q_o - Q_i$$

Thus, by Equation (15),

$$COP = \frac{T_R}{T_o - T_R} \quad (38)$$

**Example 1.** Determine entropy change, work, and coefficient of performance for the cycle shown in Figure 6. Temperature of the refrigerated space  $T_R$  is 250 K and that of the atmosphere  $T_o$  is 300 K. Refrigeration load is 125 kJ.

**Solution:**

$$\Delta S = S_1 - S_4 = Q_i/T_R = 125/250 = 0.5 \text{ kJ/K}$$

$$W = \Delta S(T_o - T_R) = 0.5(300 - 250) = 25 \text{ kJ}$$

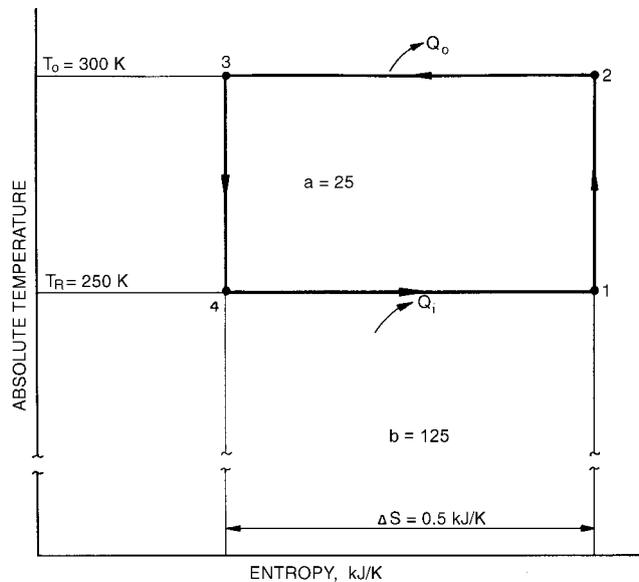

$$COP = Q_i/(Q_o - Q_i) = Q_i/W = 125/25 = 5$$

Flow of energy and its area representation in Figure 6 is:

Energy	kJ	Area
$Q_i$	125	$b$
$Q_o$	150	$a + b$
$W$	25	$a$

The net change of entropy of any refrigerant in any cycle is always zero. In Example 1 the change in entropy of the refrigerated space is  $\Delta S_R = -125/250 = -0.5 \text{ kJ/K}$  and that of the atmosphere is  $\Delta S_o = 125/250 = 0.5 \text{ kJ/K}$ . The net change in entropy of the isolated system is  $\Delta S_{total} = \Delta S_R + \Delta S_o = 0$ .

The Carnot cycle in Figure 7 shows a process in which heat is added and rejected at constant pressure in a two-phase region of a refrigerant. Saturated liquid at state 3 expands isentropically to the low temperature and pressure of the cycle at state d. Heat is added isothermally and isobarically by evaporating the liquid phase refrigerant from state d to state 1. The cold saturated vapor at state 1 is compressed isentropically to the high temperature in the cycle at state b. However the pressure at state b is below the saturation pressure corresponding to the high temperature in the cycle. The

**Fig. 6** Temperature-Entropy Diagram for Carnot Refrigeration Cycle of Example 1

compression process is completed by an isothermal compression process from state b to state c. The cycle is completed by an isothermal and isobaric heat rejection or condensing process from state c to state 3.

Applying the energy equation for a mass of refrigerant  $m$  yields (all work and heat transfer are positive)

$${}_3W_d = m(h_3 - h_d)$$

$${}_1W_b = m(h_b - h_1)$$

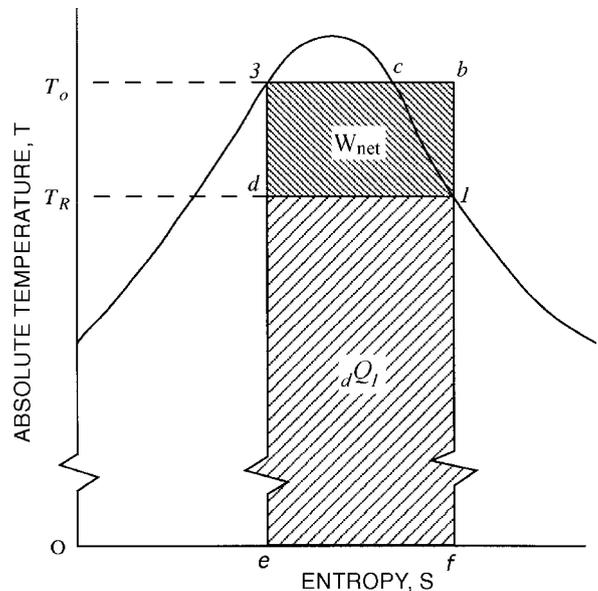

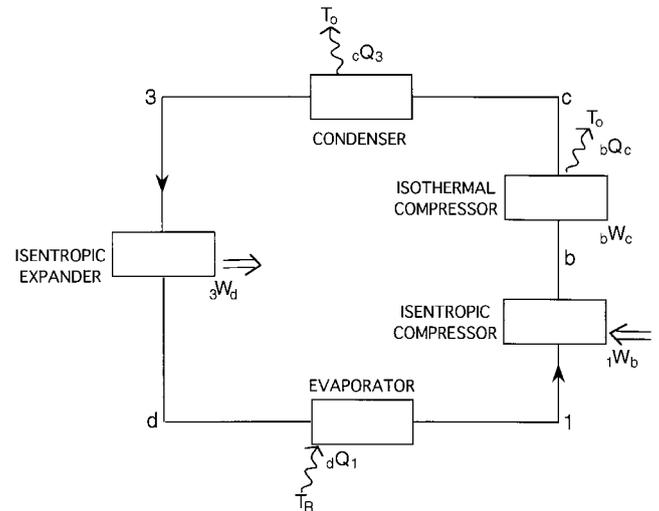

$${}_bW_c = T_o(S_b - S_c) - m(h_b - h_c)$$

$${}_dQ_1 = m(h_1 - h_d) = \text{Area def1d}$$

The net work for the cycle is

$$W_{net} = {}_1W_b + {}_bW_c - {}_3W_d = \text{Area d1bc3d}$$

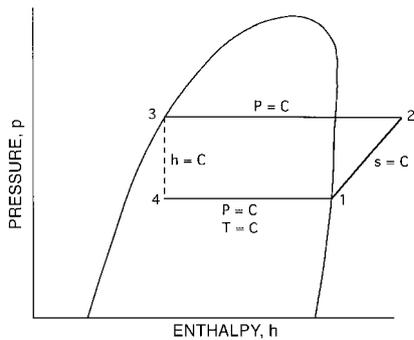

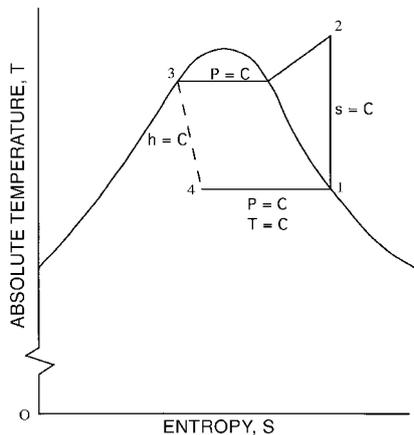

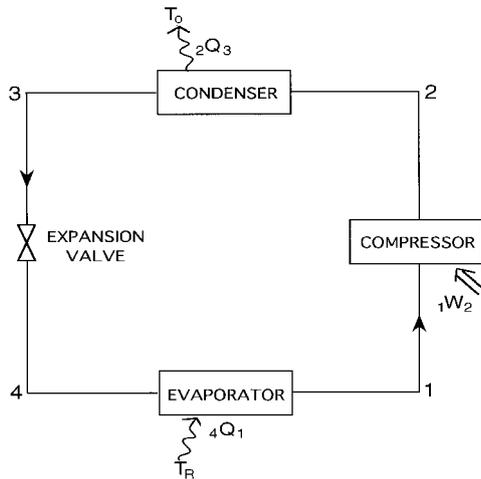

and 
$$COP = \frac{{}_dQ_1}{W_{net}} = \frac{T_R}{T_o - T_R}$$

**Fig. 7** Carnot Vapor Compression Cycle

**THEORETICAL SINGLE-STAGE CYCLE USING A PURE REFRIGERANT OR AZEOTROPIC MIXTURE**

A system designed to approach the ideal model shown in Figure 7 is desirable. A pure refrigerant or an azeotropic mixture can be used to maintain constant temperature during the phase changes by maintaining a constant pressure. Because of such concerns as high initial cost and increased maintenance requirements, a practical machine has one compressor instead of two and the expander (engine or turbine) is replaced by a simple expansion valve. The valve throttles the refrigerant from high pressure to low pressure.

**Fig. 8 Theoretical Single-Stage Vapor Compression Refrigeration Cycle**

Figure 8 shows the theoretical single-stage cycle used as a model for actual systems.

Applying the energy equation for a mass of refrigerant  $m$  yields

$$\begin{aligned} {}_4Q_1 &= m(h_1 - h_4) \\ {}_1W_2 &= m(h_2 - h_1) \\ {}_2Q_3 &= m(h_2 - h_3) \\ h_3 &= h_4 \end{aligned} \tag{39}$$

The constant enthalpy throttling process assumes no heat transfer or change in potential or kinetic energy through the expansion valve.

The coefficient of performance is

$$\text{COP} = \frac{{}_4Q_1}{{}_1W_2} = \frac{h_1 - h_4}{h_2 - h_1} \tag{40}$$

The theoretical compressor displacement CD (at 100% volumetric efficiency), is

$$\text{CD} = \dot{m}v_3 \tag{41}$$

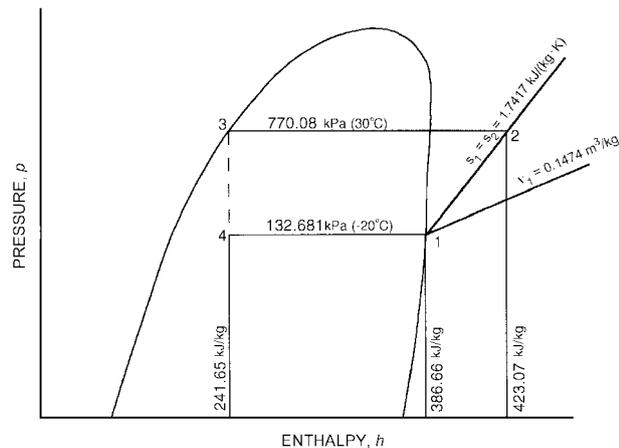

which is a measure of the physical size or speed of the compressor required to handle the prescribed refrigeration load.

**Example 2.** A theoretical single-stage cycle using R-134a as the refrigerant operates with a condensing temperature of 30°C and an evaporating temperature of -20°C. The system produces 50 kW of refrigeration. Determine (a) the thermodynamic property values at the four main state points of the cycle, (b) the coefficient of performance of the cycle, (c) the cycle refrigerating efficiency, and (d) rate of refrigerant flow.

**Solution:**

(a) Figure 9 shows a schematic  $p$ - $h$  diagram for the problem with numerical property data. Saturated vapor and saturated liquid properties for states 1 and 3 are obtained from the saturation table for R-134a in Chapter 20. Properties for superheated vapor at state 2 are obtained by linear interpolation of the superheat tables for R-134a in Chapter 20. Specific volume and specific entropy values for state 4 are obtained by determining the quality of the liquid-vapor mixture from the enthalpy.

$$\begin{aligned} x_4 &= \frac{h_4 - h_f}{h_g - h_f} = \frac{241.65 - 173.82}{386.66 - 173.82} = 0.3187 \\ v_4 &= v_f + x_4(v_g - v_f) = 0.0007374 + 0.3187(0.14744 - 0.0007374) \\ &= 0.04749 \text{ m}^3/\text{kg} \end{aligned}$$

**Fig. 9 Schematic  $p$ - $h$  Diagram for Example 2**

$$s_4 = s_f + x_4(s_g - s_f) = 0.9009 + 0.3187(1.7417 - 0.9009) = 1.16886 \text{ kJ/(kg}\cdot\text{K)}$$

The property data are tabulated in Table 1.

**Table 1 Thermodynamic Property Data for Example 2**

State	$t, ^\circ\text{C}$	$p, \text{kPa}$	$v, \text{m}^3/\text{kg}$	$h, \text{kJ/kg}$	$s, \text{kJ/(kg}\cdot\text{K)}$
1	-20.0	132.68	0.14744	386.66	1.7417
2	37.8	770.08	0.02798	423.07	1.7417
3	30.0	770.08	0.00084	241.65	1.1432
4	-20.0	132.68	0.04749	241.65	1.1689

(b) By Equation (40)

$$\text{COP} = \frac{386.66 - 241.65}{423.07 - 386.66} = 3.98$$

(c) By Equation (17)

$$\eta_R = \frac{\text{COP}(T_3 - T_1)}{T_1} = \frac{(3.98)(50)}{253.15} = 0.79 \text{ or } 79\%$$

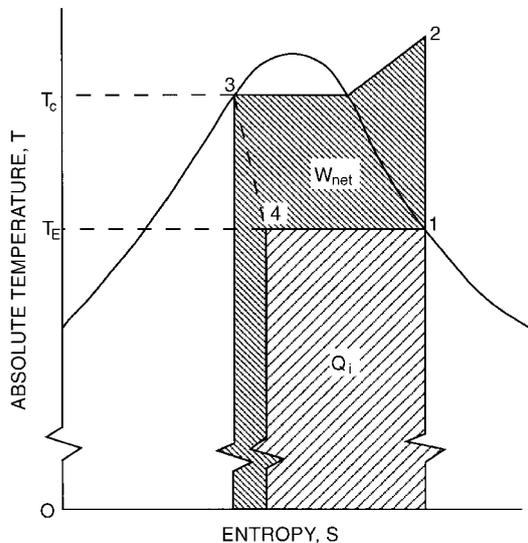

(d) The mass flow of refrigerant is obtained from an energy balance on the evaporator. Thus

$$\dot{m}(h_1 - h_4) = \dot{q}_i = 50 \text{ kW}$$

$$\text{and } \dot{m} = \frac{\dot{Q}_i}{(h_1 - h_4)} = \frac{50}{(386.66 - 241.65)} = 0.345 \text{ kg/s}$$

The saturation temperatures of the single-stage cycle have a strong influence on the magnitude of the coefficient of performance. This influence may be readily appreciated by an area analysis on a temperature-entropy ( $T$ - $s$ ) diagram. The area under a reversible process line on a  $T$ - $s$  diagram is directly proportional to the thermal energy added or removed from the working fluid. This observation follows directly from the definition of entropy [see Equation (8)].

In Figure 10 the area representing  $Q_o$  is the total area under the constant pressure curve between states 2 and 3. The area representing the refrigerating capacity  $Q_i$  is the area under the constant pressure line connecting states 4 and 1. The net work required  $W_{net}$  equals the difference ( $Q_o - Q_i$ ), which is represented by the shaded area shown on Figure 10.

**Fig. 10 Areas on  $T$ - $s$  Diagram Representing Refrigerating Effect and Work Supplied for Theoretical Single-Stage Cycle**

Because  $\text{COP} = Q_i/W_{net}$ , the effect on the COP of changes in evaporating temperature and condensing temperature may be observed. For example, a decrease in evaporating temperature  $T_E$  significantly increases  $W_{net}$  and slightly decreases  $Q_i$ . An increase in condensing temperature  $T_C$  produces the same results but with less effect on  $W_{net}$ . Therefore, for maximum coefficient of performance, the cycle should operate at the lowest possible condensing temperature and at the maximum possible evaporating temperature.

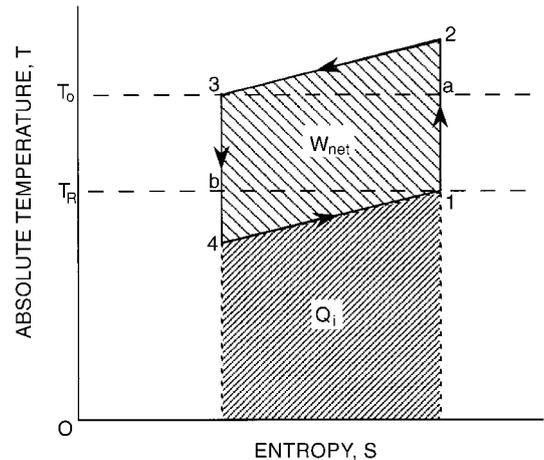

### LORENZ REFRIGERATION CYCLE

The Carnot refrigeration cycle includes two assumptions which make it impractical. The heat transfer capacity of the two external fluids are assumed to be infinitely large so the external fluid temperatures remain fixed at  $T_0$  and  $T_R$  (they become infinitely large thermal reservoirs). The Carnot cycle also has no thermal resistance between the working refrigerant and the external fluids in the two heat exchange processes. As a result, the refrigerant must remain fixed at  $T_0$  in the condenser and at  $T_R$  in the evaporator.

The Lorenz cycle eliminates the first restriction in the Carnot cycle and allows the temperature of the two external fluids to vary during the heat exchange. The second assumption of negligible thermal resistance between the working refrigerant and the two external fluids remains. Therefore the refrigerant temperature must change during the two heat exchange processes to equal the changing temperature of the external fluids. This cycle is completely reversible when operating between two fluids, each of which has a finite but constant heat capacity.

Figure 11 is a schematic of a Lorenz cycle. Note that this cycle does not operate between two fixed temperature limits. Heat is added to the refrigerant from state 4 to state 1. This process is assumed to be linear on  $T$ - $s$  coordinates, which represents a fluid with constant heat capacity. The temperature of the refrigerant is increased in an isentropic compression process from state 1 to state 2. Process 2-3 is a heat rejection process in which the refrigerant temperature decreases linearly with heat transfer. The cycle is concluded with an isentropic expansion process between states 3 and 4.

The heat addition and heat rejection processes are parallel so the entire cycle is drawn as a parallelogram on  $T$ - $s$  coordinates. A Carnot refrigeration cycle operating between  $T_0$  and  $T_R$  would lie between states 1, a, 3, and b. The Lorenz cycle has a smaller refrigerating effect than the Carnot cycle and more work is required. However this cycle is a more practical reference to use than the Carnot cycle when a refrigeration system operates between two single-phase fluids such as air or water.

**Fig. 11 Processes of Lorenz Refrigeration Cycle**

The energy transfers in a Lorenz refrigeration cycle are as follows, where  $\Delta T$  is the temperature change of the refrigerant during each of the two heat exchange processes.

$$Q_O = (T_O + \Delta T/2)(S_2 - S_3)$$

$$Q_i = (T_R - \Delta T/2)(S_1 - S_4) = (T_R - \Delta T/2)(S_2 - S_3)$$

$$W_{net} = Q_O - Q_R$$

Thus by Equation (15),

$$\text{COP} = \frac{T_R - (\Delta T/2)}{T_O - T_R + \Delta T} \quad (42)$$

**Example 3.** Determine the entropy change, the work required, and the coefficient of performance for the Lorenz cycle shown in Figure 11 when the temperature of the refrigerated space is  $T_R = 250$  K, the ambient temperature is  $T_O = 300$  K, the  $\Delta T$  of the refrigerant is 5 K and the refrigeration load is 125 kJ.

**Solution:**

$$\Delta S = \int_4^1 \frac{Q_i}{T} = \frac{Q_i}{T_R - (\Delta T/2)} = \frac{125}{247.5} = 0.5051 \text{ kJ/K}$$

$$Q_O = [T_O + (\Delta T/2)]\Delta S = (300 + 2.5)0.5051 = 152.78 \text{ kJ}$$

$$W_{net} = Q_O - Q_R = 152.78 - 125 = 27.78 \text{ kJ}$$

$$\text{COP} = \frac{T_R - (\Delta T/2)}{T_O - T_R + \Delta T} = \frac{250 - (5/2)}{300 - 250 + 5} = \frac{247.5}{55} = 4.50$$

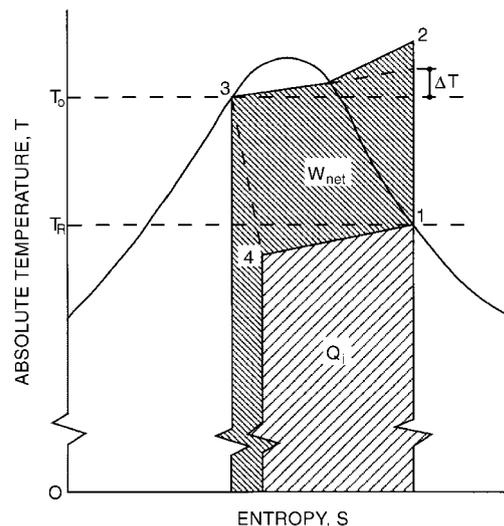

Note that the entropy change for the Lorenz cycle is larger than for the Carnot cycle at the same temperature levels and the same capacity (see Example 1). That is, the heat rejection is larger and the work requirement is also larger for the Lorenz cycle. This difference is caused by the finite temperature difference between the working fluid in the cycle compared to the bounding temperature reservoirs. However, as discussed previously, the assumption of constant temperature heat reservoirs is not necessarily a good representation of an actual refrigeration system because of the temperature changes that occur in the heat exchangers.

### THEORETICAL SINGLE-STAGE CYCLE USING ZEOTROPIC REFRIGERANT MIXTURE

A practical method to approximate the Lorenz refrigeration cycle is to use a fluid mixture as the refrigerant and the four system components shown in Figure 8. When the mixture is not azeotropic and the phase change processes occur at constant pressure, the temperatures change during the evaporation and condensation processes and the theoretical single-stage cycle can be shown on  $T$ - $s$  coordinates as in Figure 12. This can be compared with Figure 10 in which the system is shown operating with a pure simple substance or an azeotropic mixture as the refrigerant. Equations (14), (15), (39), (40), and (41) apply to this cycle and to conventional cycles with constant phase change temperatures. Equation (42) should be used as the reversible cycle COP in Equation (17).

For zeotropic mixtures, the concept of constant saturation temperatures does not exist. For example, in the evaporator, the refrigerant enters at  $T_4$  and exits at a higher temperature  $T_1$ . The temperature of saturated liquid at a given pressure is the **bubble point** and the temperature of saturated vapor at a given pressure is called the **dew point**. The temperature  $T_3$  on Figure 12 is at the bubble point at the condensing pressure and  $T_1$  is at the dew point at the evaporating pressure.

An analysis of areas on a  $T$ - $s$  diagram representing additional work and reduced refrigerating effect from a Lorenz cycle operating

**Fig. 12** Areas on  $T$ - $s$  Diagram Representing Refrigerating Effect and Work Supplied for Theoretical Single-Stage Cycle Using Zeotropic Mixture as Refrigerant

between the same two temperatures  $T_1$  and  $T_3$  with the same value for  $\Delta T$  can be performed. The cycle matches the Lorenz cycle most closely when counterflow heat exchangers are used for both the condenser and the evaporator.

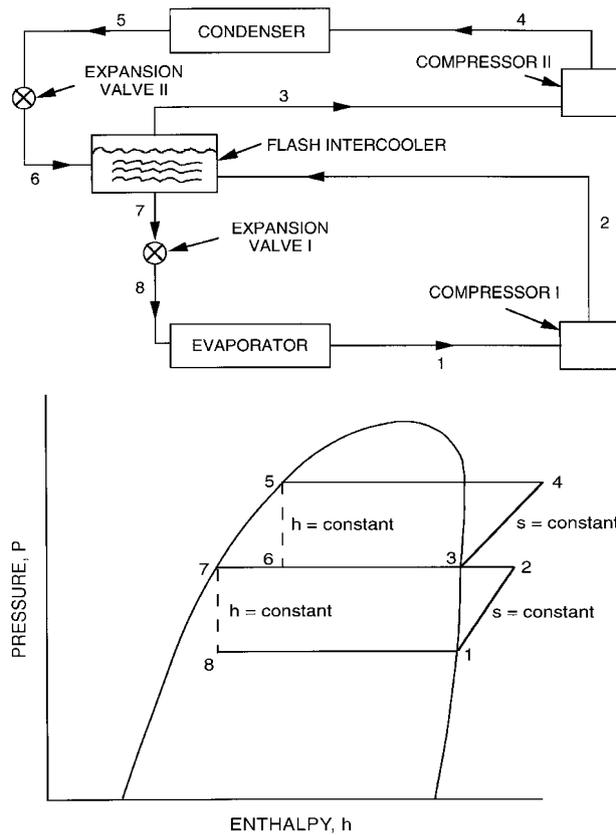

In a cycle that has heat exchangers with finite thermal resistances and finite external fluid capacity rates, Kuehn and Gronseth (1986) showed that a cycle which uses a refrigerant mixture has a higher coefficient of performance than a cycle that uses a simple pure substance as a refrigerant. However, the improvement in COP is usually small. The performance of the cycle that uses a mixture can be improved further by reducing the thermal resistance of the heat exchangers and passing the fluids through them in a counterflow arrangement.

### MULTISTAGE VAPOR COMPRESSION REFRIGERATION CYCLES

Multistage vapor compression refrigeration is used when several evaporators are needed at various temperatures such as in a supermarket or when the temperature of the evaporator becomes very low. Low evaporator temperature indicates low evaporator pressure and low refrigerant density into the compressor. Two small compressors in series have a smaller displacement and usually operate more efficiently than one large compressor that covers the entire pressure range from the evaporator to the condenser. This is especially true in refrigeration systems that use ammonia because of the large amount of superheating that occurs during the compression process.

The thermodynamic analysis of multistage cycles is similar to the analysis of single-stage cycles. The main difference is that the mass flow differs through various components of the system. A careful mass balance and energy balance performed on individual components or groups of components ensures the correct application of the first law of thermodynamics. Care must also be exercised when performing second law calculations. Often the refrigerating load is comprised of more than one evaporator, so the total system capacity is the sum of the loads from all evaporators. Likewise the total energy input is the sum of the work into all compressors. For multistage cycles, the expression for the coefficient of performance given in Equation 15 should be written as

$$\text{COP} = \frac{\sum Q_i}{W_{net}} \quad (43)$$

**Fig. 13 Schematic and Pressure-Enthalpy Diagram for Dual-Compression, Dual-Expansion Cycle of Example 4**

When compressors are connected in series, the vapor between stages should be cooled to bring the vapor to saturated conditions before proceeding to the next stage of compression. Intercooling usually minimizes the displacement of the compressors, reduces the work requirement, and increases the COP of the cycle. If the refrigerant temperature between stages is above ambient, a simple intercooler that removes heat from the refrigerant can be used. If the temperature is below ambient, which is the usual case, the refrigerant itself must be used to cool the vapor. This is accomplished with a flash intercooler. Figure 13 shows a cycle with a flash intercooler installed.

The superheated vapor from compressor I is bubbled through saturated liquid refrigerant at the intermediate pressure of the cycle. Some of this liquid is evaporated when heat is added from the superheated refrigerant. The result is that only saturated vapor at the intermediate pressure is fed to compressor II. A common assumption is to operate the intercooler at about the geometric mean of the evaporating and condensing pressures. This operating point provides the same pressure ratio and nearly equal volumetric efficiencies for the two compressors. Example 4 illustrates the thermodynamic analysis of this cycle

**Example 4.** Determine the thermodynamic properties of the eight state points shown in Figure 13, the mass flows, and the COP of this theoretical multistage refrigeration cycle when R-134a is the refrigerant. The saturated evaporator temperature is  $-20^{\circ}\text{C}$ , the saturated condensing temperature is  $30^{\circ}\text{C}$ , and the refrigeration load is 50 kW. The saturation temperature of the refrigerant in the intercooler is  $0^{\circ}\text{C}$ , which is nearly at the geometric mean pressure of the cycle.

**Solution:**

Thermodynamic property data are obtained from the saturation and superheat tables for R-134a in Chapter 20. States 1, 3, 5, and 7 are obtained directly from the saturation table. State 6 is a mixture of liquid and vapor. The quality is calculated by

**Table 2 Thermodynamic Property Values for Example 4**

State	Temperature, $^{\circ}\text{C}$	Pressure, kPa	Specific Volume, $\text{m}^3/\text{kg}$	Specific Enthalpy, kJ/kg	Specific Entropy, kJ/(kg·K)
1	-20.0	132.68	0.14744	386.66	1.7417
2	2.8	292.69	0.07097	401.51	1.7417
3	0.0	292.69	0.06935	398.68	1.7274
4	33.6	770.08	0.02726	418.68	1.7274
5	30.0	770.08	0.00084	241.65	1.1432
6	0.0	292.69	0.01515	241.65	1.1525
7	0.0	292.69	0.00077	200.00	1.0000
8	-20.0	132.68	0.01878	200.00	1.0043

$$x_6 = \frac{h_6 - h_7}{h_3 - h_7} = \frac{241.65 - 200}{398.68 - 200} = 0.20963$$

Then,

$$\begin{aligned} v_6 &= v_7 + x_6(v_3 - v_7) = 0.000773 + 0.20963(0.06935 - 0.000773) \\ &= 0.01515 \text{ m}^3/\text{kg} \\ s_6 &= s_7 + x_6(s_3 - s_7) = 1.0 + 0.20963(0.7274 - 1.0) \\ &= 1.15248 \text{ kJ}/(\text{kg}\cdot\text{K}) \end{aligned}$$

Similarly for state 8,

$$x_8 = 0.12300, v_8 = 0.01878 \text{ m}^3/\text{kg}, s_8 = 1.0043 \text{ kJ}/(\text{kg}\cdot\text{K})$$

States 2 and 4 are obtained from the superheat tables by linear interpolation. The thermodynamic property data are summarized in Table 2.

The mass flow through the lower circuit of the cycle is determined from an energy balance on the evaporator.

$$\begin{aligned} \dot{m}_1 &= \frac{\dot{Q}_i}{h_1 - h_8} = \frac{50}{386.66 - 200} = 0.2679 \text{ kg/s} \\ \dot{m}_1 &= \dot{m}_2 = \dot{m}_7 = \dot{m}_8 \end{aligned}$$

For the upper circuit of the cycle,

$$\dot{m}_3 = \dot{m}_4 = \dot{m}_5 = \dot{m}_6$$

Assuming the intercooler has perfect external insulation, an energy balance on it is used to compute  $\dot{m}_3$ .

$$\dot{m}_6 h_6 + \dot{m}_2 h_2 = \dot{m}_7 h_7 + \dot{m}_3 h_3$$

Rearranging and solving for  $\dot{m}_3$ ,

$$\dot{m}_3 = \dot{m}_2 \frac{h_7 - h_2}{h_6 - h_3} = 0.2679 \frac{200 - 401.51}{241.65 - 398.68} = 0.3438 \text{ kg/s}$$

$$\begin{aligned} \dot{W}_I &= \dot{m}_1 (h_2 - h_1) = 0.2679(401.51 - 386.66) \\ &= 3.978 \text{ kW} \end{aligned}$$

$$\begin{aligned} \dot{W}_{II} &= \dot{m}_3 (h_4 - h_3) = 0.3438(418.68 - 398.68) \\ &= 6.876 \text{ kW} \end{aligned}$$

$$\text{COP} = \frac{\dot{Q}_i}{\dot{W}_I + \dot{W}_{II}} = \frac{50}{3.978 + 6.876} = 4.61$$

Examples 2 and 4 have the same refrigeration load and operate with the same evaporating and condensing temperatures. The two-stage cycle in Example 4 has a higher COP and less work input than the single-stage cycle. Also the highest refrigerant temperature leaving the compressor is about  $34^{\circ}\text{C}$  for the two-stage cycle versus about  $38^{\circ}\text{C}$  for the single-stage cycle. These differences are more pronounced for cycles operating at larger pressure ratios.

**ACTUAL REFRIGERATION SYSTEMS**

Actual systems operating steadily differ from the ideal cycles considered in the previous sections in many respects. Pressure drops occur everywhere in the system except in the compression process. Heat transfers occur between the refrigerant and its environment in all components. The actual compression process differs substantially from the isentropic compression assumed above. The working fluid is not a pure substance but a mixture of refrigerant and oil. All of these deviations from a theoretical cycle cause irreversibilities within the system. Each irreversibility requires additional power into the compressor. It is useful to understand how these irreversibilities are distributed throughout a real system. Insight is gained that can be useful when design changes are contemplated or operating conditions are modified. Example 5 illustrates how the irreversibilities can be computed in a real system and how they require additional compressor power to overcome. The input data have been rounded off for ease of computation.

**Example 5.** An air-cooled, direct-expansion, single-stage mechanical vapor-compression refrigerator uses R-22 and operates under steady conditions. A schematic drawing of this system is shown in Figure 14. Pressure drops occur in all piping and heat gains or losses occur as indicated. Power input includes compressor power and the power required to operate both fans. The following performance data are obtained:

- Ambient air temperature,  $t_O = 30^\circ\text{C}$
- Refrigerated space temperature,  $t_R = -10^\circ\text{C}$
- Refrigeration load,  $\dot{Q}_{evap} = 7.0 \text{ kW}$
- Compressor power input,  $\dot{W}_{comp} = 2.5 \text{ kW}$
- Condenser fan input,  $\dot{W}_{CF} = 0.15 \text{ kW}$
- Evaporator fan input,  $\dot{W}_{EF} = 0.11 \text{ kW}$

Refrigerant pressures and temperatures are measured at the seven locations shown on Figure 14. Table 3 lists the measured and computed thermodynamic properties of the refrigerant neglecting the dissolved oil. A pressure-enthalpy diagram of this cycle is shown in Figure 15 and is compared with a theoretical single-stage cycle operating between the air temperatures  $t_R$  and  $t_O$ .

Compute the energy transfers to the refrigerant in each component of the system and determine the second law irreversibility rate in each component. Show that the total irreversibility rate multiplied by the absolute ambient temperature is equal to the difference between the actual power input and the power required by a Carnot cycle operating between  $t_R$  and  $t_O$  with the same refrigerating load.

**Solution:** The mass flow of refrigerant is the same through all components, so it is only computed once through the evaporator. Each component in the system is analyzed sequentially beginning with the evaporator. Equation (6) is used to perform a first law energy balance on each component and Equation (13) is used for the second law analysis. Note that the temperature used in the second law analysis is the absolute temperature.

*Evaporator:*

Energy balance

$$7\dot{Q}_1 = \dot{m}(h_1 - h_7) = 7.0 \text{ kW}$$

$$\dot{m} = \frac{7.0}{(402.08 - 240.13)} = 0.04322 \text{ kg/s}$$

Second law

$$\begin{aligned} 7\dot{i}_1 &= \dot{m}(s_1 - s_7) - \frac{7\dot{Q}_1}{T_R} \\ &= 0.04322(1.7810 - 1.1561) - \frac{7.0}{263.15} \\ &= 0.4074 \text{ W/K} \end{aligned}$$

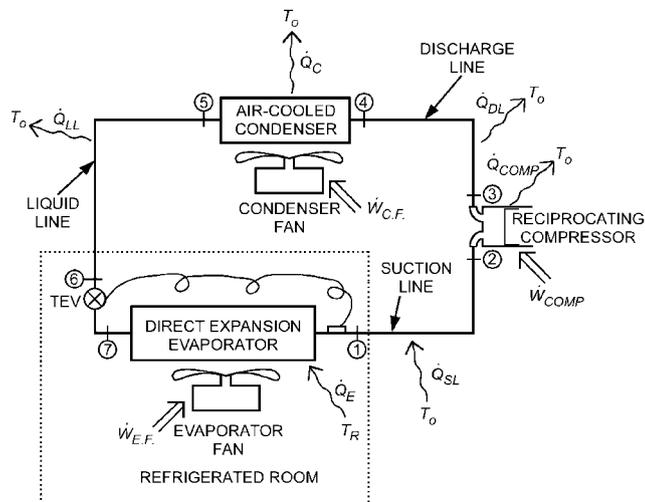

*Suction Line:*

Energy balance

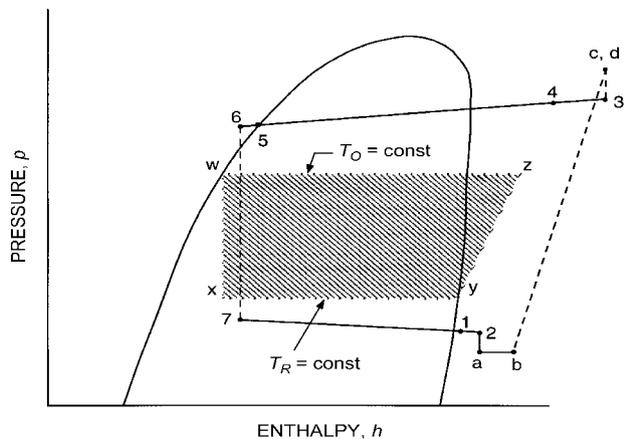

$$\begin{aligned} 1\dot{Q}_2 &= \dot{m}(h_2 - h_1) \\ &= 0.04322(406.25 - 402.08) = 0.1802 \text{ kW} \end{aligned}$$

Compressor	-0.4276	2.5	2.1928	46
Discharge line	-0.4274	0	0.2258	5
Condenser	-8.7698	0	0.8747	18
Liquid line	-0.0549	0	0.0039	≈0
Expansion device	0	0	0.8730	18
Totals	-2.4995	2.5	4.7351	

$$\text{COP}_{Carnot} = \frac{T_R}{T_o - T_R} = \frac{263.15}{40} = 6.579$$

The Carnot power requirement for the 7 kW load is

$$\dot{W}_{Carnot} = \frac{\dot{Q}_e}{\text{COP}_{Carnot}} = \frac{7.0}{6.579} = 1.064 \text{ kW}$$

The actual power requirement for the compressor is

$$\begin{aligned}\dot{W}_{comp} &= \dot{W}_{Carnot} + \dot{I}_{total}T_o \\ &= 1.064 + 4.7351(303.15) = 2.4994 \text{ kW}\end{aligned}$$

This result is within computational error of the measured power input to the compressor of 2.5 kW.

The analysis demonstrated in Example 5 can be applied to any actual vapor compression refrigeration system. The only required information for the second law analysis is the refrigerant thermodynamic state points and mass flow rates and the temperatures in which the system is exchanging heat. In this example, the extra compressor power required to overcome the irreversibility in each component is determined. The component with the largest loss is the compressor. This loss is due to motor inefficiency, friction losses, and irreversibilities due to pressure drops, mixing, and heat transfer between the compressor and the surroundings. The unrestrained expansion in the expansion device is also a large loss. This loss could be reduced by using an expander rather than a throttling process. An expander may be economical on large machines.

All heat transfer irreversibilities on both the refrigerant side and the air side of the condenser and evaporator are included in the analysis. The refrigerant pressure drop is also included. The only items not included are the air-side pressure drop irreversibilities of the two heat exchangers. However these are equal to the fan power requirements as all the fan power is dissipated as heat.

An overall second law analysis, such as in Example 5, shows the designer those components with the most losses, and it helps determine which components should be replaced or redesigned to improve performance. However, this type of analysis does not identify the nature of the losses. A more detailed second law analysis in which the actual processes are analyzed in terms of fluid flow and heat transfer is required to identify the nature of the losses (Liang and Kuehn 1991). A detailed analysis will show that most irreversibilities associated with heat exchangers are due to heat transfer, while pressure drop on the air side causes a very small loss and the refrigerant pressure drop causes a negligible loss. This finding indicates that promoting refrigerant heat transfer at the expense of increasing the pressure drop usually improves performance. This analysis does not provide the cost/benefits associated with reducing component irreversibilities. The use of a thermo-economic technique is required.

## ABSORPTION REFRIGERATION CYCLES

An absorption cycle is a heat-activated thermal cycle. It exchanges only thermal energy with its surroundings—no appreciable mechanical energy is exchanged. Furthermore, no appreciable conversion of heat to work or work to heat occurs in the cycle.

Absorption cycles find use in applications where one or more of the heat exchanges with the surroundings is the useful product. This includes refrigeration, air conditioning, and heat pumping. The two great advantages of this type of cycle in comparison to other cycles with similar product are

- No large rotating mechanical equipment is required
- Any source of heat can be used, including low-temperature sources (e.g., waste heat)

### IDEAL THERMAL CYCLE

All absorption cycles include at least three thermal energy exchanges with their surroundings; that is, energy exchange at three different temperatures. The highest temperature and lowest temperature heat flows are in one direction, and the mid-temperature one (or two) is in the opposite direction. In the **forward cycle**, the extreme temperature (hottest and coldest) heat flows are into the cycle. This cycle is also called the heat amplifier, heat pump, conventional cycle, or Type I cycle. When the extreme temperature heat flows are out of the cycle, it is called a **reverse cycle**, heat transformer, temperature amplifier, temperature booster, or Type II cycle. Figure 16 illustrates both types of thermal cycles.

This fundamental constraint of heat flow into or out of the cycle at three or more different temperatures establishes the first limitation on cycle performance. By the first law of thermodynamics (at steady state),

$$Q_{hot} + Q_{cold} = -Q_{mid} \quad (44)$$

(positive heat quantities are into the cycle)

The second law requires that

$$\frac{Q_{hot}}{T_{hot}} + \frac{Q_{cold}}{T_{cold}} + \frac{Q_{mid}}{T_{mid}} \geq 0 \quad (45)$$

with equality holding in the ideal case.

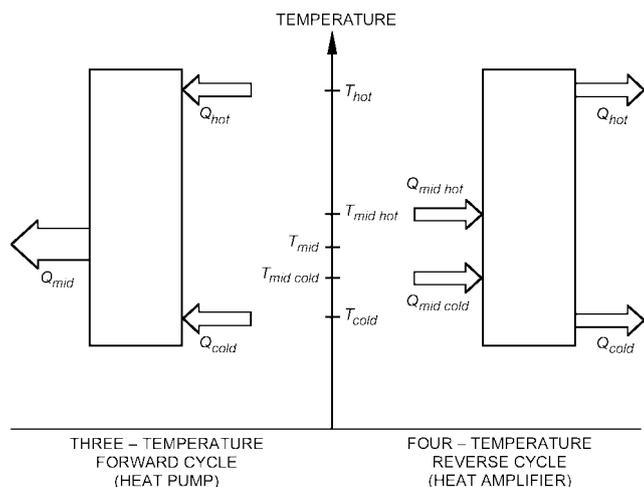

Fig. 16 Thermal Cycles

From these two laws alone (i.e., without invoking any further assumptions) it follows that, for the ideal forward cycle,

$$COP_{ideal} = \frac{Q_{cold}}{Q_{hot}} = \frac{T_{hot} - T_{mid}}{T_{hot}} \frac{T_{cold}}{T_{mid} - T_{cold}} \quad (46)$$

The heat ratio  $Q_{cold}/Q_{hot}$  is commonly called the **coefficient of performance (COP)**, which is the cooling realized divided by the driving heat supplied.

Heat that is rejected to ambient may be at two different temperatures, creating a **four-temperature cycle**. The ideal COP of the four-temperature cycle is also expressed by Equation (46), with  $T_{mid}$  signifying the entropic mean heat rejection temperature. In that case,  $T_{mid}$  is calculated as follows:

$$T_{mid} = \frac{Q_{mid hot} + Q_{mid cold}}{\frac{Q_{mid hot}}{T_{mid hot}} + \frac{Q_{mid cold}}{T_{mid cold}}} \quad (47)$$

This expression results from assigning all the entropy flow to the single temperature  $T_{mid}$ .

The ideal COP for the four-temperature cycle requires additional assumptions, such as the relationship between the various heat quantities. Under the assumptions that  $Q_{cold} = Q_{mid cold}$  and  $Q_{hot} = Q_{mid hot}$ , the following expression results:

$$COP_{ideal} = \frac{T_{hot} - T_{mid hot}}{T_{hot}} \frac{T_{cold}}{T_{mid cold}} \frac{T_{cold}}{T_{mid hot}} \quad (48)$$

### WORKING FLUID PHASE CHANGE CONSTRAINTS

Absorption cycles require at least two working substances—a sorbent and a fluid refrigerant; and each substance achieves its cycle function with a phase change. Given this constraint, many combinations are not achievable. The first result of invoking the phase change constraints is that the various heat flows assume known identities. As illustrated in Figure 17, the refrigerant phase changes occur in an evaporator and a condenser, and those of the sorbent in an absorber and a desorber (generator). For the **forward absorption cycle**, the highest temperature heat is always supplied to the generator,

$$Q_{hot} \equiv Q_{gen} \quad (49)$$

and the coldest heat is supplied to the evaporator:

$$Q_{cold} \equiv Q_{evap} \quad (50)$$

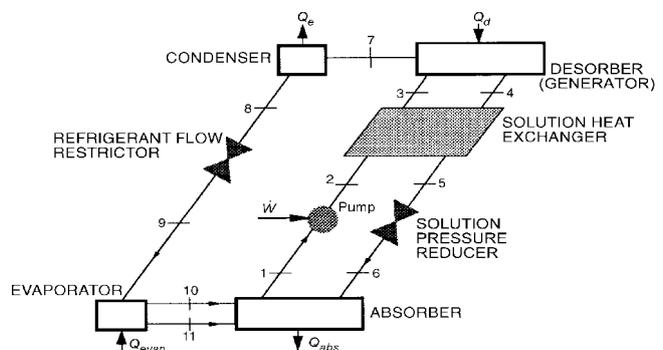

Fig. 17 Single-Effect Absorption Cycle

For the **reverse absorption cycle**, the highest temperature heat is rejected from the absorber, and the lowest temperature heat is rejected from the condenser.

The second result of the phase change constraint is that for all known refrigerants and sorbents over pressure ranges of interest,

$$Q_{evap} \approx Q_{cond} \quad (51)$$

and 
$$Q_{gen} \approx Q_{abs} \quad (52)$$

These two relations are true because the latent heat of phase change (vapor  $\leftrightarrow$  condensed phase) is relatively constant when far removed from the critical point. Thus, each heat input can not be independently adjusted.

The ideal single-effect forward cycle COP expression is

$$COP_{ideal} \leq \frac{T_{gen} - T_{abs}}{T_{gen}} \frac{T_{evap}}{T_{cond} - T_{evap}} \frac{T_{cond}}{T_{abs}} \quad (53)$$

Equality holds only if the heat quantities at each temperature may be adjusted to specific values, which as shown below is not possible.

The third result of invoking the phase change constraint is that only three of the four temperatures  $T_{evap}$ ,  $T_{cond}$ ,  $T_{gen}$ , and  $T_{abs}$  may be independently selected.

Practical liquid absorbents for absorption cycles have a significant negative deviation from behavior predicted by Raoult's law. This has the beneficial effect of reducing the required amount of absorbent recirculation, at the expense of reduced lift and increased sorption duty. The practical effect of the negative deviation is that for most absorbents,

$$\frac{Q_{abs}}{Q_{cond}} \approx 1.2 \text{ to } 1.3 \quad (54)$$

and

$$T_{gen} - T_{abs} \approx 1.2(T_{cond} - T_{evap}) \quad (55)$$

The net result of applying the above approximations and constraints to the ideal cycle COP for the single-effect forward cycle is

$$COP_{ideal} \approx 1.2 \frac{T_{evap} T_{cond}}{T_{gen} T_{abs}} \approx \frac{Q_{cond}}{Q_{abs}} \approx 0.8 \quad (56)$$

In practical terms, the temperature constraint reduces the ideal COP to about 0.9, and the heat quantity constraint further reduces it to about 0.8.

Another useful result is

$$T_{gen \min} = T_{cond} + T_{abs} - T_{evap} \quad (57)$$

where  $T_{gen \min}$  is the minimum generator temperature necessary to achieve a given evaporator temperature.

Alternative approaches are available that lead to nearly the same upper limit on ideal cycle COP. For example, one approach equates the exergy production from a "driving" portion of the cycle to the exergy consumption in a "cooling" portion of the cycle (Tozer et al. 1997). This leads to the expression

$$COP_{ideal} \leq \frac{T_{evap}}{T_{abs}} = \frac{T_{cond}}{T_{gen}} \quad (58)$$

Another approach derives the idealized relationship between the cycle **lift** ( $T_{cond} - T_{evap}$ ) and **drop** ( $T_{gen} - T_{abs}$ ), i.e., between the two temperature differences that define the cycle.

## WORKING FLUIDS

The working fluids for absorption cycles naturally fall into four categories, each requiring a different approach to cycle modeling and thermodynamic analysis. For the liquid absorbents, the important distinction is whether the absorbent is volatile or nonvolatile. In the latter case, the vapor phase is always pure refrigerant (neglecting noncondensables), and analysis is relatively straightforward. For volatile absorbents, wherein vapor concentration is variable, the cycle and component modeling techniques must keep track of vapor concentration as well as liquid concentration.

The sorbent may be either liquid phase or solid phase. For the solid sorbents, the important distinction is whether the solid is a physisorbent (also known as adsorbent) or a chemisorbent. With the physisorbent, the sorbent temperature depends on both pressure and refrigerant loading (bivariance), the same as for the liquid absorbents. In contrast, the chemisorbent temperature does not vary with loading, at least over small ranges, and hence a different modeling approach is required.

Beyond these distinctions, various other characteristics are either necessary or desirable for suitable liquid absorbent-refrigerant pairs, as follows:

**Absence of Solid Phase (Solubility Field).** The refrigerant-absorbent pair should not form a solid over the expected range of composition and temperature. If a solid forms, it will stop flow and cause equipment to shut down. Controls must prevent operation beyond the acceptable solubility range for the pair.

**Relative Volatility.** The refrigerant should be much more volatile than the absorbent so the two can be separated easily. Otherwise, cost and heat requirements may be excessive. Many of the absorbents are effectively nonvolatile.

**Affinity.** The absorbent should have a strong affinity for the refrigerant under conditions in which absorption takes place. Affinity means a negative deviation from Raoult's law and results in an activity coefficient of less than unity for the refrigerant. Strong affinity allows less absorbent to be circulated for the same refrigeration effect, reducing sensible heat losses. A smaller liquid heat exchanger to transfer heat from the absorbent to the pressurized refrigerant-absorption solution is also a benefit of affinity. On the other hand, as affinity increases, extra heat is required in the generators to separate refrigerant from the absorbent, and the COP suffers.

**Pressure.** Operating pressures, established by the thermodynamic properties of the refrigerant, should be moderate. High pressure requires the use of heavy-walled equipment, and significant electrical power may be required to pump the fluids from the low-pressure side to the high-pressure side. Vacuum requires the use of large-volume equipment and special means of reducing pressure drop in the refrigerant vapor paths.

**Stability.** High chemical stability is required because fluids are subjected to severe conditions over many years of service. Instability can cause undesirable formation of gases, solids, or corrosive substances. The purity of all components charged into the system is critical for high performance and corrosion prevention.

**Corrosion.** Most absorption fluids corrode materials used in construction. Therefore, corrosion inhibitors are used.

**Safety.** Precautions as dictated by code are followed in the cases where fluids are toxic, inflammable, or at high pressure. Codes vary according to country and region.

**Transport Properties.** Viscosity, surface tension, thermal diffusivity, and mass diffusivity are important characteristics of the refrigerant-absorbent pair. For example, low viscosity promotes heat and mass transfer and reduces pumping power.

**Latent Heat.** The refrigerant latent heat should be high, so the circulation rate of the refrigerant and absorbent can be minimized.

**Environmental Soundness.** The two parameters of greatest concern are the global warming potential and the ozone depletion potential.

No refrigerant-absorbent pair meets all requirements. Unfortunately, many requirements work at cross-purposes. For example, a greater solubility field goes hand-in-hand with reduced relative volatility. Thus, selection of a working pair is inherently a compromise.

Water-lithium bromide and ammonia-water offer the best compromises of thermodynamic performance and have no known detrimental environmental effect (zero ozone depletion potential and zero global warming potential).

The ammonia-water pair meets most requirements, but its volatility ratio is low and it requires high operating pressures. Ammonia is also a Safety Code Group 2 fluid (ASHRAE *Standard 15*), which restricts its use indoors.

Advantages of the water-lithium bromide pair include high safety, high volatility ratio, high affinity, high stability, and high latent heat. However, this pair tends to form solids and operates at deep vacuum. Because the refrigerant turns to ice at 0°C, the pair cannot be used for low-temperature refrigeration. Lithium bromide (LiBr) crystallizes at moderate concentrations, as would be encountered in air-cooled chillers, which ordinarily limits the pair to applications where the absorber is water-cooled and the concentrations are lower. However, using a combination of salts as the absorbent can reduce this crystallization tendency enough to permit air cooling (Macriss 1968). Other disadvantages of the water-lithium bromide pair include the low operating pressures and high viscosity. This is particularly detrimental to the absorption step; however, alcohols with a high relative molecular mass enhance LiBr absorption. Proper equipment design and additives can overcome these disadvantages.

Other refrigerant-absorbent pairs are listed in Table 5 (Macriss and Zawacki 1989, ISHPC 1999). Several refrigerant-absorbent pairs appear suitable for certain cycles and may solve some problems associated with traditional pairs. However, stability, corrosion, and property information on several is limited. Also, some of the fluids are somewhat hazardous.

**Table 5 Refrigerant-Absorbent Pairs**

Refrigerant	Absorbents
H <sub>2</sub> O	Salts
	Alkali halides
	LiBr
	LiClO <sub>3</sub>
	CaCl <sub>2</sub>
	ZnCl <sub>2</sub>
	ZnBr
	Alkali nitrates
	Alkali thiocyanates
	Bases
	Alkali hydroxides
	Acids
	H <sub>2</sub> SO <sub>4</sub>
	H <sub>3</sub> PO <sub>4</sub>
NH <sub>3</sub>	H <sub>2</sub> O
	Alkali thiocyanates
TFE (Organic)	NMP
	E181
	DMF
	Pyrrolidone
SO <sub>2</sub>	Organic solvents

## ABSORPTION CYCLE REPRESENTATIONS

The quantities of interest to absorption cycle designers are temperature, concentration, pressure, and enthalpy. The most useful plots are those with linear scales and in which the key properties plot as straight lines. Some of the following plots are used:

- **Absorption plots** embody the vapor-liquid equilibrium of both the refrigerant and the sorbent. Plots of vapor-liquid equilibrium on linear pressure-temperature coordinates have a logarithmic shape and hence are little used.
- In the **van't Hoff plot** ( $\ln P$  versus  $-1/T$ ), the constant concentration contours plot as nearly straight lines. Thus, it is more readily constructed (e.g., from sparse data) in spite of the awkward coordinates.
- The **Dühring diagram** (solution temperature versus reference temperature) retains the linearity of the van't Hoff plot, while eliminating the complexity of nonlinear coordinates. Thus, it has found extensive use (see Figure 20). The primary drawback is the need for a reference substance.
- The **Gibbs plot** (solution temperature versus  $T \ln P$ ) retains most of the advantages of the Dühring plot (linear temperature coordinates, concentration contours are straight lines) while eliminating the recourse to a reference substance.
- The **Merkel plot** (enthalpy versus concentration) is used to assist thermodynamic calculations and to solve the distillation problems that arise with volatile absorbents. It has also been used for basic cycle analysis.
- **Temperature-entropy coordinates** are occasionally used to relate absorption cycles to their mechanical vapor compression counterparts.

## CONCEPTUALIZING THE CYCLE

The basic absorption cycle shown in Figure 17 must be altered in many cases to take advantage of the available energy. Examples include the following: (1) the driving heat is much hotter than the minimum required  $T_{gen\ min}$ : a multistage cycle boosts the COP; and (2) the driving heat temperature is below  $T_{gen\ min}$ : a different multistage cycle (half-effect cycle) can reduce the  $T_{gen\ min}$ .

**Multistage** means that one or more of the four basic exchangers (generator, absorber, condenser, evaporator) are present at two or more places in the cycle at different pressures or concentrations. **Multieffect** is a special case of multistaging, signifying the number of times the driving heat is used as it transits the cycle. Thus there are several types of two-stage cycles: the double-effect cycle, the half-effect cycle, and the two-stage, triple-effect cycle.

Two or more single-effect absorption cycles, such as shown in Figure 17, can be combined to form a multistage cycle by coupling any of the components. **Coupling** implies either (1) sharing of component(s) between the cycles to form an integrated single hermetic cycle or (2) alternatively exchanging heat between components belonging to two hermetically separate cycles that operate at (nearly) the same temperature level.

Figure 18 shows a **double-effect absorption cycle** formed by coupling the absorbers and evaporators of two single-effect cycles into an integrated, single hermetic cycle. Heat is transferred between the high-pressure condenser and intermediate-pressure generator. The heat of condensation of the refrigerant (generated in the high-temperature generator) generates additional refrigerant in the lower temperature generator. Thus, the prime energy provided to the high-temperature generator is **cascaded** (used) twice in the cycle, making it a double-effect cycle. With the generation of additional refrigerant from a given heat input, the cycle COP increases. Commercial water-lithium bromide chillers normally use this cycle.

The cycle COP can be further increased by coupling additional components and by increasing the number of cycles that are combined. This way, several different multiple-effect cycles can be

combined by pressure-staging and/or concentration-staging. The double-effect cycle, for example, is formed by pressure-staging two single-effect cycles.

Figure 19 shows twelve generic triple-effect cycles identified by Alefeld and Radermacher (1994). Cycle 5 is a pressure-staged cycle, and Cycle 10 is a concentration-staged cycle. All other cycles are pressure- and concentration-staged. Cycle 1, which is called a dual loop cycle, is the only cycle consisting of two loops that doesn't circulate absorbent in the low-temperature portion of the cycle.

Each of the cycles shown in Figure 19 can be made with one, two, or sometimes three separate **hermetic loops**. Dividing a cycle into separate hermetic loops allows the use of a different working fluid in each loop. Thus, a corrosive and/or high-lift absorbent can be restricted to the loop where it is required, and a conventional additive-enhanced absorbent can be used in other loops to reduce the system cost significantly. As many as 78 hermetic loop configurations can be synthesized from the twelve triple-effect cycles shown in Figure 19. For each hermetic loop configuration, further variations are possible according to the absorbent flow pattern (e.g., series or parallel), the absorption working pairs selected, and various other hardware details. Thus, literally thousands of distinct variations of the triple-effect cycle are possible.

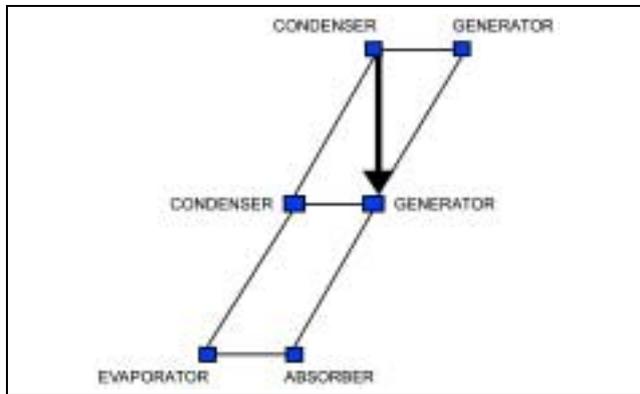

Fig. 18 Double-Effect Absorption Cycle

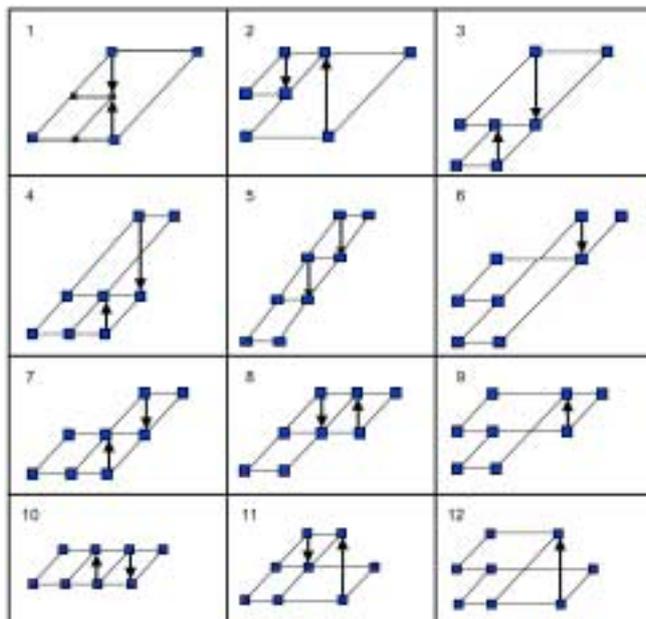

Fig. 19 Generic Triple-Effect Cycles

The ideal analysis can be extended to these multistage cycles (Alefeld and Radermacher 1994). A similar range of cycle variants is possible for situations calling for the half-effect cycle, in which the available heat source temperature is below  $t_{gen\ min}$ .

**ABSORPTION CYCLE MODELING**

**Analysis and Performance Simulation**

A physical-mathematical model of an absorption cycle consists of four types of thermodynamic equations: mass balances, energy balances, relations describing the heat and mass transfer, and equations for the thermophysical properties of the working fluids.

As an example of simulation, Figure 20 shows a Dühring plot of a single-effect water-lithium bromide absorption chiller. The chiller is hot water driven, rejects waste heat from the absorber and the condenser to a stream of cooling water, and produces chilled water. A simulation of this chiller starts by specifying the assumptions (Table 6) and the design parameters and the operating conditions at the design point (Table 7). Design parameters are the specified  $UA$  values and the flow regime (co/counter/crosscurrent, pool, or film) of all heat exchangers (evaporator, condenser, generator, absorber, solution heat exchanger) and the flow rate of weak solution through the solution pump.

One complete set of input operating parameters could be the design point values of the chilled water and cooling water temperatures  $t_{chill\ in}$ ,  $t_{chill\ out}$ ,  $t_{cool\ in}$ ,  $t_{cool\ out}$ , the hot water flow rate  $\dot{m}_{hot}$ , and the total cooling capacity  $Q_e$ . With this information, a cycle simulation calculates the required hot water temperatures; the cooling water flow rate; and the temperatures, pressures, and concentrations at all internal state points. Some additional assumptions are made that reduce the number of unknown parameters.

**Table 6 Assumptions for Single-Effect Water-Lithium Bromide Model (Figure 17)**

Assumptions
• Generator and condenser as well as evaporator and absorber are under same pressure
• Refrigerant vapor leaving the evaporator is saturated pure water
• Liquid refrigerant leaving the condenser is saturated
• Strong solution leaving the generator is boiling
• Refrigerant vapor leaving the generator has the equilibrium temperature of the weak solution at generator pressure
• Weak solution leaving the absorber is saturated
• No liquid carryover from evaporator
• Flow restrictors are adiabatic
• Pump is isentropic
• No jacket heat losses
• The $l_{mtd}$ (log mean temperature difference) expression adequately estimates the latent changes

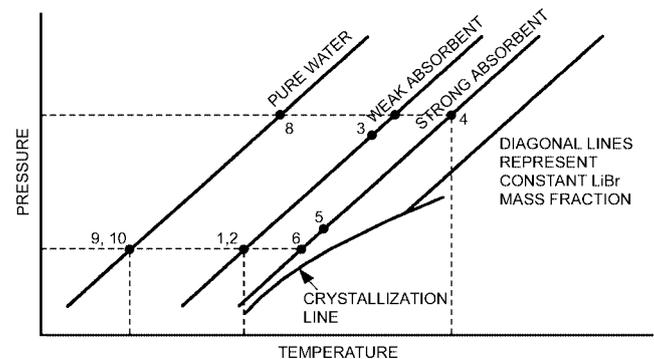

Fig. 20 Single-Effect Water-Lithium Bromide Absorption Cycle Dühring Plot

With these assumptions and the design parameters and operating conditions as specified in Table 7, the cycle simulation can be conducted by solving the following set of equations:

**Mass Balances**

$$\dot{m}_{refr} + \dot{m}_{strong} = \dot{m}_{weak} \quad (59)$$

$$\dot{m}_{strong}\xi_{strong} = \dot{m}_{weak}\xi_{weak} \quad (60)$$

**Energy Balances**

$$\begin{aligned} \dot{Q}_{evap} &= \dot{m}_{refr}(h_{vapor, evap} - h_{liq, cond}) \\ &= \dot{m}_{chill}(h_{chill in} - h_{chill out}) \end{aligned} \quad (61)$$

$$\begin{aligned} \dot{Q}_{evap} &= \dot{m}_{refr}(h_{vapor, gen} - h_{liq, cond}) \\ &= \dot{m}_{cool}(h_{cool out} - h_{cool mean}) \end{aligned} \quad (62)$$

$$\begin{aligned} \dot{Q}_{abs} &= \dot{m}_{refr}h_{vapor, evap} + \dot{m}_{strong}h_{strong, gen} \\ - \dot{m}_{weak}h_{weak, abs} - \dot{Q}_{sol} &= \dot{m}_{cool}(h_{cool mean} - h_{cool in}) \end{aligned} \quad (63)$$

$$\begin{aligned} \dot{Q}_{gen} &= \dot{m}_{refr}h_{vapor, gen} + \dot{m}_{strong}h_{strong, gen} \\ - \dot{m}_{weak}h_{weak, abs} - \dot{Q}_{sol} &= \dot{m}_{hot}(h_{hot in} - h_{hot out}) \end{aligned} \quad (64)$$

**Table 7 Design Parameters and Operating Conditions for Single-Effect Water-Lithium Bromide Absorption Chiller**

	Design Parameters	Operating Conditions
Evaporator	$UA_{evap} = 319.2$ kW/K, countercurrent film	$t_{chill in} = 12^\circ\text{C}$ $t_{chill out} = 6^\circ\text{C}$
Condenser	$UA_{cond} = 180.6$ kW/K, countercurrent film	$t_{cool out} = 35^\circ\text{C}$
Absorber	$UA_{abs} = 186.9$ kW/K, countercurrent film-absorber	$t_{cool in} = 27^\circ\text{C}$
Generator	$UA_{gen} = 143.4$ kW/K, pool-generator	$\dot{m}_{hot} = 74.4$ kg/s
Solution	$UA_{sol} = 33.8$ kW/K, countercurrent	
General	$\dot{m}_{weak} = 12$ kg/s	$\dot{Q}_{evap} = 2148$ kW

**Table 8 Simulation Results for Single-Effect Water-Lithium Bromide Absorption Chiller**

	Internal Parameters	Performance Parameters
Evaporator	$t_{vapor, evap} = 1.8^\circ\text{C}$ $p_{sat, evap} = 0.697$ kPa	$\dot{Q}_{evap} = 2148$ kW $\dot{m}_{chill} = 85.3$ kg/s
Condenser	$T_{liq, cond} = 46.2^\circ\text{C}$ $p_{sat, cond} = 10.2$ kPa	$\dot{Q}_{cond} = 2322$ kW $\dot{m}_{cool} = 158.7$ kg/s
Absorber	$\xi_{weak} = 59.6\%$ $t_{weak} = 40.7^\circ\text{C}$ $t_{strong, abs} = 49.9^\circ\text{C}$	$\dot{Q}_{abs} = 2984$ kW $t_{cool, mean} = 31.5^\circ\text{C}$
Generator	$\xi_{strong} = 64.6\%$ $t_{strong, gen} = 103.5^\circ\text{C}$ $t_{weak, gen} = 92.4^\circ\text{C}$ $t_{weak, sol} = 76.1^\circ\text{C}$	$\dot{Q}_{gen} = 3158$ kW $t_{hot in} = 125^\circ\text{C}$ $t_{hot out} = 115^\circ\text{C}$
Solution	$t_{strong, sol} = 62.4^\circ\text{C}$ $t_{weak, sol} = 76.1^\circ\text{C}$	$\dot{Q}_{sol} = 825$ kW $\epsilon = 65.4\%$
General	$\dot{m}_{vapor} = 0.93$ kg/s $\dot{m}_{strong} = 11.06$ kg/s	COP = 0.68

$$\begin{aligned} \dot{Q}_{sol} &= \dot{m}_{strong}(h_{strong, gen} - h_{strong, sol}) \\ &= \dot{m}_{weak}(h_{weak, sol} - h_{weak, abs}) \end{aligned} \quad (65)$$

**Heat Transfer Equations**

$$\dot{Q}_{evap} = UA_{evap} \frac{t_{chill in} - t_{chill out}}{\ln\left(\frac{t_{chill in} - t_{vapor, evap}}{t_{chill out} - t_{vapor, evap}}\right)} \quad (66)$$

$$\dot{Q}_{cond} = UA_{cond} \frac{t_{cool out} - t_{cool mean}}{\ln\left(\frac{t_{liq, cond} - t_{cool mean}}{t_{liq, cond} - t_{cool out}}\right)} \quad (67)$$

$$\dot{Q}_{abs} = UA_{abs} \frac{(t_{strong, abs} - t_{cool mean}) - (t_{weak, abs} - t_{cool in})}{\ln\left(\frac{t_{strong, abs} - t_{cool mean}}{t_{weak, abs} - t_{cool in}}\right)} \quad (68)$$

$$\dot{Q}_{gen} = UA_{gen} \frac{(t_{hot in} - t_{strong, gen}) - (t_{hot out} - t_{weak, gen})}{\ln\left(\frac{t_{hot in} - t_{strong, gen}}{t_{hot out} - t_{weak, gen}}\right)} \quad (69)$$

$$\dot{Q}_{sol} = UA_{sol} \frac{(t_{strong, gen} - t_{weak, sol}) - (t_{strong, sol} - t_{weak, abs})}{\ln\left(\frac{t_{strong, gen} - t_{weak, sol}}{t_{strong, sol} - t_{weak, abs}}\right)} \quad (70)$$

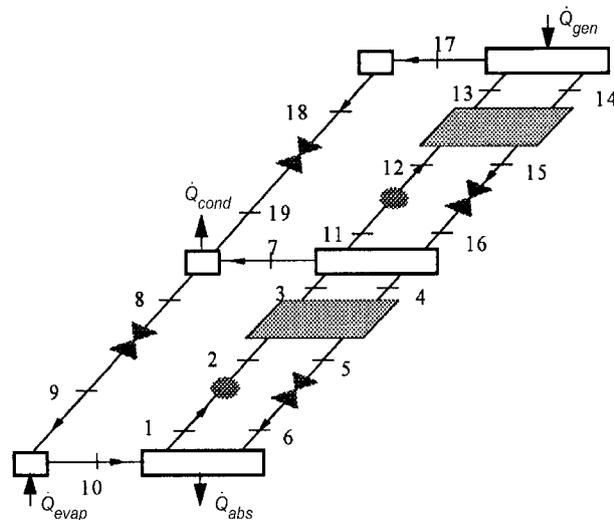

**Fluid Property Equations at each state point**

Thermal Equations of State:  $h_{water}(t, p), h_{sol}(t, p, \xi)$   
Two-Phase Equilibrium:  $t_{water, sat}(p), t_{sol, sat}(p, \xi)$

The results are listed in Table 8.

**Double-Effect Cycle**

Double-effect cycle calculations can be performed in a manner similar to that illustrated for the single-effect cycle. Mass and energy balances of the model shown in Figure 21 were calculated using the inputs and assumptions listed in Table 9. The results are shown in Table 10. The COP is quite sensitive to several inputs and

**Fig. 21 Double-Effect Water-Lithium Bromide Absorption Cycle with State Points**

assumptions. In particular, the effectiveness of the solution heat exchangers and the driving temperature difference between the high-temperature condenser and the low-temperature generator influence the COP strongly.

**Table 9 Inputs and Assumptions for Double-Effect Water-Lithium Bromide Model**

Inputs		
Capacity	$Q_{evap}$	1760 kW
Evaporator temperature	$t_{10}$	5.1°C
Desorber solution exit temperature	$t_{14}$	170.7°C
Condenser/absorber low temperature	$t_1, t_8$	42.4°C
Solution heat exchanger effectiveness	$\epsilon$	0.6
Assumptions

**AMMONIA-WATER ABSORPTION CYCLES**

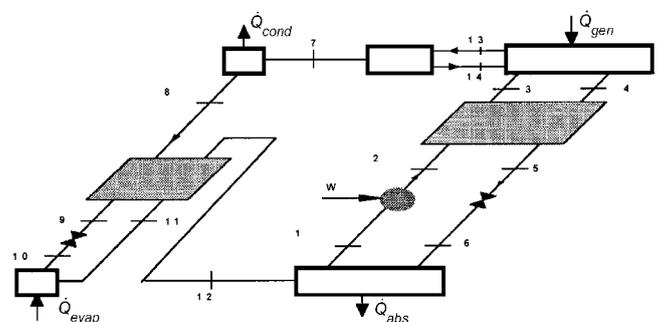

Ammonia-water absorption cycles are similar to the water-lithium bromide cycles, but with some important differences. The differences arise due to the lower latent heat of ammonia compared to water, the volatility of the absorbent, and the different pressure and solubility ranges. The latent heat of ammonia is only about half that of water, so, for the same duty, the refrigerant and absorbent mass circulation rates are roughly double that of water-lithium bromide. As a result, the sensible heat loss associated with heat exchanger approaches is greater. Accordingly, ammonia-water cycles incorporate more techniques to reclaim sensible heat described in Hanna et al. (1995). The refrigerant heat exchanger (RHX), also known as refrigerant subcooler, which improves COP by about 8%, is the most important (Holldorff 1979). Next is the absorber heat exchanger (AHX), accompanied by a generator heat exchanger (GHX) (Phillips 1976). These either replace or supplement the traditional solution heat exchanger (SHX). These components would also benefit the water-lithium bromide cycle, except that the deep vacuum in that cycle makes them impractical there.

The volatility of the water absorbent is also key. It makes the distinction between crosscurrent, cocurrent, and countercurrent mass exchange more important in all of the latent heat exchangers (Briggs 1971). It also requires a distillation column on the high-pressure side. When improperly implemented, this column can impose both cost and COP penalties. Those penalties are avoided by refluxing the column from an internal diabatic section (e.g., solution cooled rectifier [SCR]) rather than with an external reflux pump.

The high-pressure operating regime makes it impractical to achieve multieffect performance via pressure-staging. On the other hand, the exceptionally wide solubility field facilitates concentration-staging. The generator-absorber heat exchange (GAX) cycle is an especially advantageous embodiment of concentration-staging (Modahl and Hayes 1988).

Ammonia-water cycles can equal the performance of water-lithium bromide cycles. The single-effect or basic GAX cycle yields the same performance as a single-effect water-lithium bromide cycle; the branched GAX cycle (Herold et al. 1991) yields the same performance as a water-lithium bromide double-effect cycle; and the VX GAX cycle (Erickson and Rane 1994) yields the same performance as a water-lithium bromide triple-effect cycle. Additional advantages of the ammonia-water cycle include refrigeration capability, air-cooling capability, all mild steel construction, extreme compactness, and capability of direct integration into industrial processes. Between heat-activated refrigerators, gas-fired residential air conditioners, and large industrial refrigeration plants, this technology has accounted for the vast majority of absorption activity over the past century.

Figure 22 shows the diagram of a typical single-effect ammonia-water absorption cycle. The inputs and assumptions in Table 11 are used to calculate a single-cycle solution, which is summarized in Table 12.

**Fig. 22 Single-Effect Ammonia-Water Absorption Cycle**

**Table 11 Inputs and Assumptions for Single-Effect Ammonia/Water Cycle of Figure 22**

Inputs		
Capacity	$\dot{Q}_{evap}$	1760 kW
High-side pressure	$p_{high}$	1461 kPa
Low-side pressure	$p_{low}$	515 kPa
Absorber exit temperature	$t_1$	40.6°C
Generator exit temperature	$t_4$	95°C
Rectifier vapor exit temperature	$t_7$	55°C
Solution heat exchanger eff.	$\epsilon_{shx}$	0.692
Refrigerant heat exchanger eff.	$\epsilon_{rhx}$	0.629

**Assumptions**

- Steady state
- No pressure changes except through flow restrictors and pump
- States at points 1, 4, 8, 11, and 14 are saturated liquid
- States at point 12 and 13 are saturated vapor
- Flow restrictors are adiabatic
- Pump is isentropic
- No jacket heat losses
- No liquid carryover from evaporator to absorber
- Vapor leaving generator is at equilibrium temperature of entering solution stream

**NOMENCLATURE FOR EXAMPLES**

$c_p$	= specific heat at constant pressure
COP	= coefficient of performance
$g$	= local acceleration of gravity
$h$	= enthalpy, kJ/kg
$I$	= irreversibility
$\dot{I}$	= irreversibility rate
$m$	= mass
$\dot{m}$	= mass flow, kg/s
$p$	= pressure
$Q$	= heat energy, kJ
$\dot{Q}$	= rate of heat flow, kJ/s
$R$	= ideal gas constant

$s$	= entropy, kJ/(kg·K)
$S$	= total entropy
$t$	= temperature, °C
$T$	= absolute temperature, K
$u$	= internal energy
$W$	= mechanical or shaft work
$\dot{W}$	= rate of work, power
$v$	= specific volume, m <sup>3</sup> /kg
$V$	= velocity of fluid
$x$	= mass fraction (of either lithium bromide or ammonia)
$z$	= vapor quality (fraction)
$z$	= elevation above horizontal reference plane
$Z$	= compressibility factor
$\epsilon$	= heat exchanger effectiveness
$\eta$	= efficiency
$\rho$	= density, kg/m <sup>3</sup>

**Subscripts**

<i>abs</i>	= absorber
<i>cond</i>	= condenser or cooling mode
<i>cg</i>	= condenser to generator
<i>evap</i>	= evaporator
<i>fg</i>	= fluid to vapor
<i>gen</i>	= generator
<i>gh</i>	= high-temperature generator
<i>o, 0</i>	= reference conditions, usually ambient
<i>p</i>	= pump
<i>R</i>	= refrigerating or evaporator conditions
<i>sol</i>	= solution
<i>rhx</i>	= refrigerant heat exchanger
<i>shx</i>	= solution heat exchanger

## CHAPTER 2

# FLUID FLOW

<i>Fluid Properties</i> .....	2.1
<i>Basic Relations of Fluid Dynamics</i> .....	2.1
<i>Basic Flow Processes</i> .....	2.3
<i>Flow Analysis</i> .....	2.7
<i>Noise from Fluid Flow</i> .....	2.13

**F**LOWING fluids in heating, ventilating, air-conditioning, and refrigeration systems transfer heat and mass. This chapter introduces the basics of fluid mechanics that are related to HVAC processes, reviews pertinent flow processes, and presents a general discussion of single-phase fluid flow analysis.

### FLUID PROPERTIES

Fluids differ from solids in their reaction to shearing. When placed under shear stress, a solid deforms only a finite amount, whereas a fluid deforms continuously for as long as the shear is applied. Both liquids and gases are fluids. Although liquids and gases differ strongly in the nature of molecular actions, their primary mechanical differences are in the degree of compressibility and liquid formation of a free surface (interface).

Fluid motion can usually be described by one of several simplified modes of action or models. The simplest is the ideal-fluid model, which assumes no resistance to shearing. Ideal flow analysis is well developed (Baker 1983, Schlichting 1979, Streeter and Wylie 1979), and when properly interpreted is valid for a wide range of applications. Nevertheless, the effects of viscous action may need to be considered. Most fluids in HVAC applications can be treated as Newtonian, where the rate of deformation is directly proportional to the shearing stress. Turbulence complicates fluid behavior, and viscosity influences the nature of the turbulent flow.

#### Density

The density  $\rho$  of a fluid is its mass per unit volume. The densities of air and water at standard indoor conditions of 20°C and 101.325 kPa (sea level atmospheric pressure) are

$$\begin{aligned}\rho_{water} &= 998 \text{ kg/m}^3 \\ \rho_{air} &= 1.20 \text{ kg/m}^3\end{aligned}$$

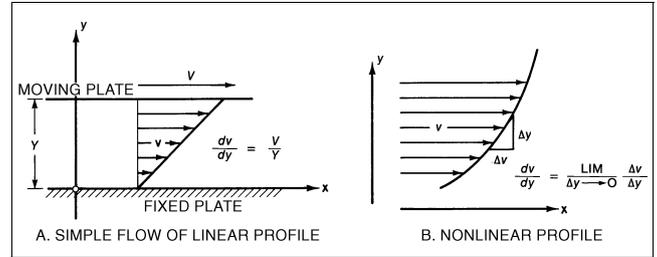

#### Viscosity

Viscosity is the resistance of adjacent fluid layers to shear. For shearing between two parallel plates, each of area  $A$  and separated by distance  $Y$ , the tangential force  $F$  per unit area required to slide one plate with velocity  $V$  parallel to the other is proportional to  $V/Y$ :

$$F/A = \mu(V/Y)$$

where the proportionality factor  $\mu$  is the **absolute viscosity** or **dynamic viscosity** of the fluid. The ratio of the tangential force  $F$  to area  $A$  is the **shearing stress**  $\tau$ , and  $V/Y$  is the **lateral velocity gradient** (Figure 1A). In complex flows, velocity and shear stress may vary across the flow field; this is expressed by the following differential equation:

The preparation of this chapter is assigned to TC 1.3, Heat Transfer and Fluid Flow.

**Fig. 1 Velocity Profiles and Gradients in Shear Flows**

$$\tau = \mu \frac{dv}{dy} \quad (1)$$

The velocity gradient associated with viscous shear for a simple case involving flow velocity in the  $x$  direction but of varying magnitude in the  $y$  direction is illustrated in Figure 1B.

Absolute viscosity  $\mu$  depends primarily on temperature. For gases (except near the critical point), viscosity increases with the square root of the absolute temperature, as predicted by the kinetic theory. Liquid viscosity decreases with increasing temperature. Viscosities of various fluids are given in Chapter 38.

Absolute viscosity has dimensions of force  $\cdot$  time/length<sup>2</sup>. At standard indoor conditions, the absolute viscosities of water and dry air are

$$\begin{aligned}\mu_{water} &= 1.0 \text{ mN}\cdot\text{s/m}^2 \\ \mu_{air} &= 18 \text{ }\mu\text{N}\cdot\text{s/m}^2\end{aligned}$$

In fluid dynamics, **kinematic viscosity**  $\nu$  is the ratio of absolute viscosity to density:

$$\nu = \mu/\rho$$

At standard indoor conditions, the kinematic viscosities of water and dry air are

$$\begin{aligned}\nu_{water} &= 1.00 \times 10^{-6} \text{ m}^2/\text{s} \\ \nu_{air} &= 16 \times 10^{-4} \text{ m}^2/\text{s}\end{aligned}$$

### BASIC RELATIONS OF FLUID DYNAMICS

This section considers homogeneous, constant-property, incompressible fluids and introduces fluid dynamic considerations used in most analyses.

### Continuity

Conservation of matter applied to fluid flow in a conduit requires that

$$\int \rho v \, dA = \text{constant}$$

where

$v$  = velocity normal to the differential area  $dA$

$\rho$  = fluid density

Both  $\rho$  and  $v$  may vary over the cross section  $A$  of the conduit. If both  $\rho$  and  $v$  are constant over the cross-sectional area normal to the flow, then

$$\dot{m} = \rho VA = \text{constant} \quad (2a)$$

where  $\dot{m}$  is the mass flow rate across the area normal to the flow. When flow is effectively incompressible,  $\rho = \text{constant}$ ; in pipeline and duct flow analyses, the average velocity is then  $V = (1/A) \int v \, dA$ . The continuity relation is

$$Q = AV = \text{constant} \quad (2b)$$

where  $Q$  is the volumetric flow rate. Except when branches occur,  $Q$  is the same at all sections along the conduit.

For the ideal-fluid model, flow patterns around bodies (or in conduit section changes) result from displacement effects. An obstruction in a fluid stream, such as a strut in a flow or a bump on the conduit wall, pushes the flow smoothly out of the way, so that behind the obstruction, the flow becomes uniform again. The effect of fluid inertia (density) appears only in pressure changes.

### Pressure Variation Across Flow

Pressure variation in fluid flow is important and can be easily measured. Variation across streamlines involves fluid rotation (vorticity). Lateral pressure variation across streamlines is given by the following relation (Bober and Kenyon 1980, Olson 1980, Robertson 1965):

$$\frac{\partial}{\partial r} \left( \frac{p}{\rho} + gz \right) = \frac{v^2}{r} \quad (3)$$

where

$r$  = radius of curvature of the streamline

$z$  = elevation

This relation explains the pressure difference found between the inside and outside walls of a bend and near other regions of conduit section change. It also states that pressure variation is hydrostatic ( $p + \rho gz = \text{constant}$ ) across any conduit where streamlines are parallel.

### Bernoulli Equation and Pressure Variation along Flow

A basic tool of fluid flow analysis is the Bernoulli relation, which involves the principle of energy conservation along a streamline. Generally, the Bernoulli equation is not applicable across streamlines. The first law of thermodynamics can be applied to mechanical flow energies (kinetic and potential) and thermal energies: heat is a form of energy and energy is conserved.

The change in energy content  $\Delta E$  per unit mass of flowing material is a result from the work  $W$  done on the system plus the heat  $Q$  absorbed:

$$\Delta E = W + Q$$

Fluid energy is composed of kinetic, potential (due to elevation  $z$ ), and internal ( $u$ ) energies. Per unit mass of fluid, the above energy change relation between two sections of the system is

$$\Delta \left( \frac{v^2}{2} + gz + u \right) = E_M - \Delta \left( \frac{p}{\rho} \right) + Q$$

where the work terms are (1) the external work  $E_M$  from a fluid machine ( $E_M$  is positive for a pump or blower) and (2) the pressure or flow work  $p/\rho$ . Rearranging, the energy equation can be written as the **generalized Bernoulli equation**:

$$\Delta \left( \frac{v^2}{2} + gz + \frac{p}{\rho} \right) + \Delta u = E_M + Q \quad (4)$$

The term in parentheses in Equation (4) is the **Bernoulli constant**:

$$\frac{p}{\rho} + \frac{v^2}{2} + gz = B \quad (5a)$$

In cases with no viscous action and no work interaction,  $B$  is constant; more generally its change (or lack thereof) is considered in applying the Bernoulli equation. The terms making up  $B$  are fluid energies (pressure, kinetic, and potential) per mass rate of fluid flow. Alternative forms of this relation are obtained through multiplication by  $\rho$  or division by  $g$ :

$$p + \frac{\rho v^2}{2} + \rho gz = \rho B \quad (5b)$$

$$\frac{p}{\rho g} + \frac{v^2}{2g} + z = \frac{B}{g} \quad (5c)$$

The first form involves energies per volume flow rate, or pressures; the second involves energies per mass flow rate, or heads. In gas flow analysis, Equation (5b) is often used with the  $\rho gz$  term dropped as negligible. Equation (5a) should be used when density variations occur. For liquid flows, Equation (5c) is commonly used. Identical results are obtained with the three forms if the units are consistent and the fluids are homogeneous.

Many systems of pipes or ducts and pumps or blowers can be considered as one-dimensional flow. The Bernoulli equation is then considered as velocity and pressure vary along the conduit. Analysis is adequate in terms of the section-average velocity  $V$  of Equation (2a) or (2b). In the Bernoulli relation [Equations (4) and (5)],  $v$  is replaced by  $V$ , and variation across streamlines can be ignored; the whole conduit is now taken as one streamline. Two- and three-dimensional details of local flow occurrences are still significant, but their effect is combined and accounted for in factors.

The kinetic energy term of the Bernoulli constant  $B$  is expressed as  $\alpha V^2/2$ , where the **kinetic energy factor** ( $\alpha > 1$ ) expresses the ratio of the true kinetic energy of the velocity profile to that of the mean flow velocity.

For laminar flow in a wide rectangular channel,  $\alpha = 1.54$ , and for laminar flow in a pipe,  $\alpha = 2.0$ . For turbulent flow in a duct  $\alpha \approx 1$ .

Heat transfer  $Q$  may often be ignored. The change of mechanical energy into internal energy  $\Delta u$  may be expressed as  $E_L$ . Flow analysis involves the change in the Bernoulli constant ( $\Delta B = B_2 - B_1$ ) between stations 1 and 2 along the conduit, and the Bernoulli equation can be expressed as

$$\left(\frac{p}{\rho} + \alpha \frac{V^2}{2} + gz\right)_1 + E_M = \left(\frac{p}{\rho} + \alpha \frac{V^2}{2} + gz\right)_2 + E_L \quad (6a)$$

or, dividing by  $g$ , in the form as

$$\left(\frac{p}{\rho g} + \alpha \frac{V^2}{2g} + z\right)_1 + H_M = \left(\frac{p}{\rho g} + \alpha \frac{V^2}{2g} + z\right)_2 + H_L \quad (6b)$$

The factors  $E_M$  and  $E_L$  are defined as positive, where  $gH_M = E_M$  represents energy added to the conduit flow by pumps or blowers, and  $gH_L = E_L$  represents energy dissipated, that is, converted into heat as mechanically nonrecoverable energy. A turbine or fluid motor thus has a negative  $H_M$  or  $E_M$ . For conduit systems with branches involving inflow or outflow, the total energies must be treated, and analysis is in terms of  $\dot{m}B$  and not  $B$ .

When real-fluid effects of viscosity or turbulence are included, the continuity relation in Equation (2b) is not changed, but  $V$  must be evaluated from the integral of the velocity profile, using time-averaged local velocities.

In fluid flow past fixed boundaries, the velocity at the boundary is zero and shear stresses are produced. The equations of motion then become complex and exact solutions are difficult to find, except in simple cases.

### Laminar Flow

For steady, fully developed laminar flow in a parallel-walled conduit, the shear stress  $\tau$  varies linearly with distance  $y$  from the centerline. For a wide rectangular channel,

$$\tau = \left(\frac{y}{b}\right)\tau_w = \mu \frac{dv}{dy}$$

where

- $\tau_w$  = wall shear stress =  $b(dp/ds)$
- $2b$  = wall spacing
- $s$  = flow direction

Because the velocity is zero at the wall ( $y = b$ ), the integrated result is

$$v = \left(\frac{b^2 - y^2}{2\mu}\right)\frac{dp}{ds}$$

This is the **Poiseuille-flow parabolic velocity profile** for a wide rectangular channel. The average velocity  $V$  is two-thirds the maximum velocity (at  $y = 0$ ), and the longitudinal pressure drop in terms of conduit flow velocity is

$$\frac{dp}{ds} = -\left(\frac{3\mu V}{b^2}\right) \quad (7)$$

The parabolic velocity profile can also be derived for the axisymmetric conduit (pipe) of radius  $R$  but with a different constant. The average velocity is then half the maximum, and the pressure drop relation is

$$\frac{dp}{ds} = -\left(\frac{8\mu V}{R^2}\right) \quad (8)$$

### Turbulence

Fluid flows are generally turbulent, involving random perturbations or fluctuations of the flow (velocity and pressure), characterized by an extensive hierarchy of scales or frequencies (Robertson 1963). Flow disturbances that are not random, but have some degree of periodicity, such as the oscillating vortex trail behind bodies,

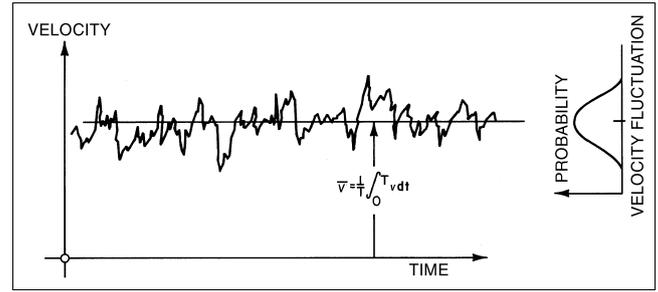

Fig. 2 Velocity Fluctuation at Point in Turbulent Flow

have been erroneously identified as turbulence. Only flows involving random perturbations without any order or periodicity are turbulent; the velocity in such a flow varies with time or locale of measurement (Figure 2).

Turbulence can be quantified by statistical factors. Thus, the velocity most often used in velocity profiles is the temporal average velocity  $\bar{v}$ , and the strength of the turbulence is characterized by the root-mean-square of the instantaneous variation in velocity about this mean. The effects of turbulence cause the fluid to diffuse momentum, heat, and mass very rapidly across the flow.

The **Reynolds number**  $Re$ , a dimensionless quantity, gives the relative ratio of inertial to viscous forces:

$$Re = VL/\nu$$

where

- $L$  = characteristic length
- $\nu$  = kinematic viscosity

In flow through round pipes and tubes, the characteristic length is the diameter  $D$ . Generally, laminar flow in pipes can be expected if the Reynolds number, which is based on the pipe diameter, is less than about 2300. Fully turbulent flow exists when  $Re_D > 10000$ . Between 2300 and 10000, the flow is in a transition state and predictions are unreliable. In other geometries, different criteria for the Reynolds number exist.

## BASIC FLOW PROCESSES

### Wall Friction

At the boundary of real-fluid flow, the relative tangential velocity at the fluid surface is zero. Sometimes in turbulent flow studies, velocity at the wall may appear finite, implying a fluid slip at the wall. However, this is not the case; the difficulty is in velocity measurement (Goldstein 1938). Zero wall velocity leads to a high shear stress near the wall boundary and a slowing down of adjacent fluid layers. A velocity profile develops near a wall, with the velocity increasing from zero at the wall to an exterior value within a finite lateral distance.

Laminar and turbulent flow differ significantly in their velocity profiles. Turbulent flow profiles are flat compared to the more pointed profiles of laminar flow (Figure 3). Near the wall, velocities of the turbulent profile must drop to zero more rapidly than those of the laminar profile, so the shear stress and friction are much greater in the turbulent flow case. Fully developed conduit flow may be characterized by the **pipe factor**, which is the ratio of average to maximum (centerline) velocity. Viscous velocity profiles result in pipe factors of 0.667 and 0.50 for wide rectangular and axisymmetric conduits. Figure 4 indicates much higher values for rectangular and circular conduits for turbulent flow. Due to the flat velocity profiles, the kinetic energy factor  $\alpha$  in Equation (6) ranges from 1.01 to 1.10 for fully developed turbulent pipe flow.

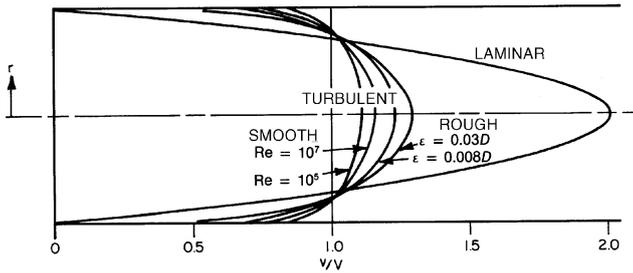

Fig. 3 Velocity Profiles of Flow in Pipes

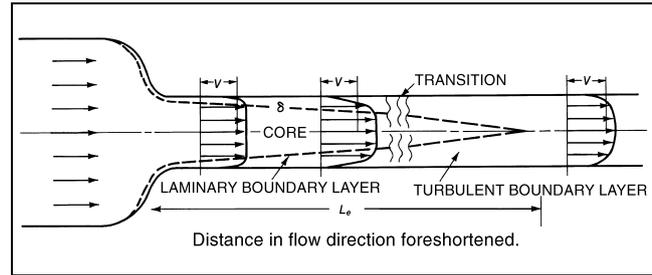

Fig. 5 Flow in Conduit Entrance Region

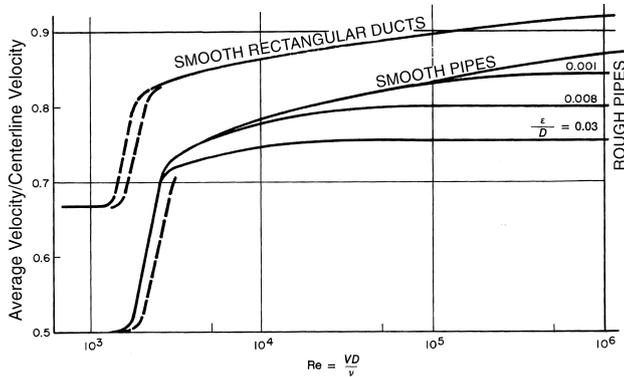

Fig. 4 Pipe Factor for Flow in Conduits

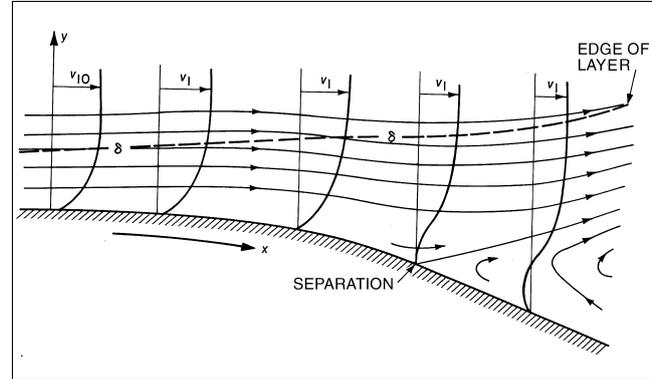

Fig. 6 Boundary Layer Flow to Separation

**Boundary Layer**

In most flows, the friction of a bounding wall on the fluid flow is evidenced by a boundary layer. For flow around bodies, this layer (which is quite thin relative to distances in the flow direction) encompasses all viscous or turbulent actions, causing the velocity in it to vary rapidly from zero at the wall to that of the outer flow at its edge. Boundary layers are generally laminar near the start of their formation but may become turbulent downstream of the transition point (Figure 5). For conduit flows, spacing between adjacent walls is generally small compared with distances in the flow direction. As a result, layers from the walls meet at the centerline to fill the conduit.

A significant boundary-layer occurrence exists in a pipeline or conduit following a well-rounded entrance (Figure 5). Layers grow from the walls until they meet at the center of the pipe. Near the start of the straight conduit, the layer is very thin (and laminar in all probability), so the uniform velocity core outside has a velocity only slightly greater than the average velocity. As the layer grows in thickness, the slower velocity near the wall requires a velocity increase in the uniform core to satisfy continuity. As the flow proceeds, the wall layers grow (and the centerline velocity increases) until they join, after an entrance length  $L_e$ . Application of the Bernoulli relation of Equation (5) to the core flow indicates a decrease in pressure along the layer. Ross (1956) shows that although the entrance length  $L_e$  is many diameters, the length in which the pressure drop significantly exceeds those for fully developed flow is on the order of 10 diameters for turbulent flow in smooth pipes.

In more general boundary-layer flows, as with wall layer development in a diffuser or for the layer developing along the surface of a strut or turning vane, pressure gradient effects can be severe and may even lead to separation. The development of a layer in an adverse-pressure gradient situation (velocity  $v_1$  at edge  $y = \delta$  of layer decreasing in flow direction) with separation is shown in Figure 6. Downstream from the separation point, fluid backflows near the wall. Separation is due to frictional velocity (thus local kinetic

energy) reduction near the wall. Flow near the wall no longer has energy to move into the higher pressure imposed by the decrease in  $v_1$  at the edge of the layer. The locale of this separation is difficult to predict, especially for the turbulent boundary layer. Analyses verify the experimental observation that a turbulent boundary layer is less subject to separation than a laminar one because of its greater kinetic energy.

**Flow Patterns with Separation**

In technical applications, flow with separation is common and often accepted if it is too expensive to avoid. Flow separation may be geometric or dynamic. Dynamic separation is shown in Figure 6. Geometric separation (Figures 7 and 8) results when a fluid stream passes over a very sharp corner, as with an orifice; the fluid generally leaves the corner irrespective of how much its velocity has been reduced by friction.

For geometric separation in orifice flow (Figure 7), the outer streamlines separate from the sharp corners and, because of fluid inertia, contract to a section smaller than the orifice opening, the **vena contracta**, with a limiting area of about six-tenths of the orifice opening. After the vena contracta, the fluid stream expands rather slowly through turbulent or laminar interaction with the fluid along its sides. Outside the jet, fluid velocity is small compared to that in the jet. Turbulence helps spread out the jet, increases the losses, and brings the velocity distribution back to a more uniform profile. Finally, at a considerable distance downstream, the velocity profile returns to the fully developed flow of Figure 3.

Other geometric separations (Figure 8) occur at a sharp entrance to a conduit, at an inclined plate or damper in a conduit, and at a sudden expansion. For these, a vena contracta can be identified; for sudden expansion, its area is that of the upstream contraction. Ideal-fluid theory, using free streamlines, provides insight and predicts contraction coefficients for valves, orifices, and vanes (Robertson 1965). These geometric flow separations are large loss-producing devices. To expand a flow efficiently or to have an entrance with

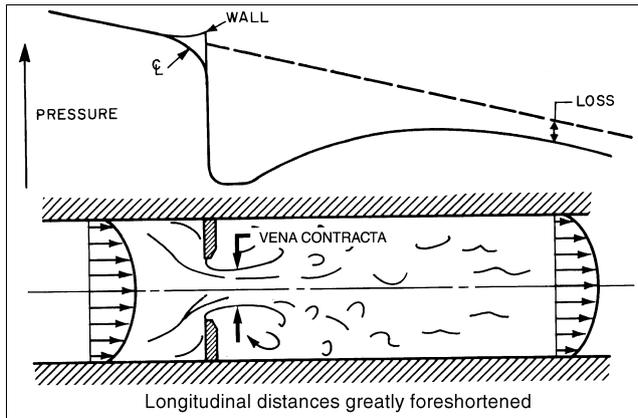

Fig. 7 Geometric Separation, Flow Development, and Loss in Flow Through Orifice

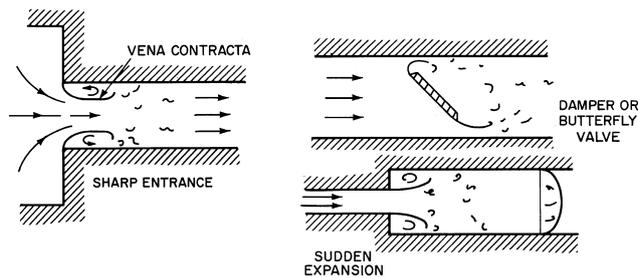

Fig. 8 Examples of Geometric Separation Encountered in Flows in Conduits

minimum losses, the device should be designed with gradual contours, a diffuser, or a rounded entrance.

Flow devices with gradual contours are subject to separation that is more difficult to predict, because it involves the dynamics of boundary layer growth under an adverse pressure gradient rather than flow over a sharp corner. In a diffuser, which is used to reduce the loss in expansion, it is possible to expand the fluid some distance at a gentle angle without difficulty (particularly if the boundary layer is turbulent). Eventually, separation may occur (Figure 9), which is frequently asymmetrical because of irregularities. Downstream flow involves flow reversal (backflow) and excess losses exist. Such separation is termed **stall** (Kline 1959). Larger area expansions may use splitters that divide the diffuser into smaller divisions less likely to have separations (Moore and Kline 1958). Another technique for controlling separation is to bleed some low-velocity fluid near the wall (Furuya et al. 1976). Alternatively, Heskested (1965, 1970) shows that suction at the corner of a sudden expansion has a strong positive effect on geometric separation.

**Drag Forces on Bodies or Struts**

Bodies in moving fluid streams are subjected to appreciable fluid forces or drag. Conventionally expressed in coefficient form, drag forces on bodies can be expressed as

$$D = C_D \rho A V^2 / 2 \tag{9}$$

where  $A$  is the projected (normal to flow) area of the body. The **drag coefficient**  $C_D$  depends on the body's shape and angularity and on the Reynolds number of the relative flow in terms of the body's characteristic dimension.

For Reynolds numbers of  $10^3$  to above  $10^5$ , the  $C_D$  of most bodies is constant due to flow separation, but above  $10^5$ , the  $C_D$  of

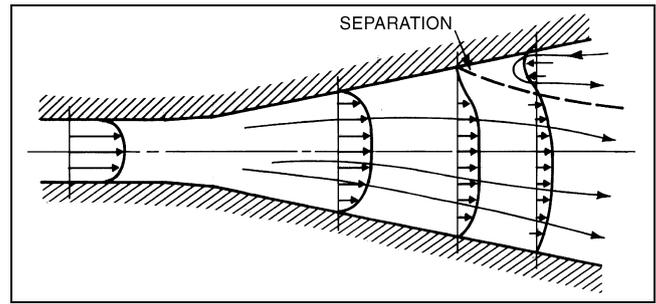

Fig. 9 Separation in Flow in Diffuser

Table 1 Drag Coefficients

Body Shape	$10^3 < Re < 2 \times 10^5$	$Re > 3 \times 10^5$
Sphere	0.36 to 0.47	~0.1
Disk	1.12	1.12
Streamlined strut	0.1 to 0.3	< 0.1
Circular cylinder	1.0 to 1.1	0.35
Elongated rectangular strut	1.0 to 1.2	1.0 to 1.2
Square strut	~2.0	~2.0

rounded bodies drops suddenly as the surface boundary layer undergoes transition to turbulence. Typical  $C_D$  values are given in Table 1; Hoerner (1965) gives expanded values.

For a strut crossing a conduit, the contribution to the loss of Equation (6b) is

$$H_L = C_D \left( \frac{A}{A_c} \right) \left( \frac{V^2}{2g} \right) \tag{10}$$

where

- $A_c$  = conduit cross-sectional area
- $A$  = area of the strut facing the flow

**Cavitation**

Liquid flow with gas- or vapor-filled pockets can occur if the absolute pressure is reduced to vapor pressure or less. In this case, a cavity or series of cavities forms, because liquids are rarely pure enough to withstand any tensile stressing or pressures less than vapor pressure for any length of time (John and Haberman 1980, Knapp et al. 1970, Robertson and Wislicenus 1969). Robertson and Wislicenus (1969) indicate significant occurrences in various technical fields, chiefly in hydraulic equipment and turbomachines.

Initial evidence of cavitation is the collapse noise of many small bubbles that appear initially as they are carried by the flow into regions of higher pressure. The noise is not deleterious and serves as a warning of the occurrence. As flow velocity further increases or pressure decreases, the severity of cavitation increases. More bubbles appear and may join to form large fixed cavities. The space they occupy becomes large enough to modify the flow pattern and alter performance of the flow device. Collapse of the cavities on or near solid boundaries becomes so frequent that the cumulative impact in time results in damage in the form of cavitation erosion of the surface or excessive vibration. As a result, pumps can lose efficiency or their parts may erode locally. Control valves may be noisy or seriously damaged by cavitation.

Cavitation in orifice and valve flow is indicated in Figure 10. With high upstream pressure and a low flow rate, no cavitation occurs. As pressure is reduced or flow rate increased, the minimum pressure in the flow (in the shear layer leaving the edge of the orifice) eventually approaches vapor pressure. Turbulence in this layer causes fluctuating pressures below the mean (as in vortex cores) and small bubble-like cavities. These are carried downstream into the

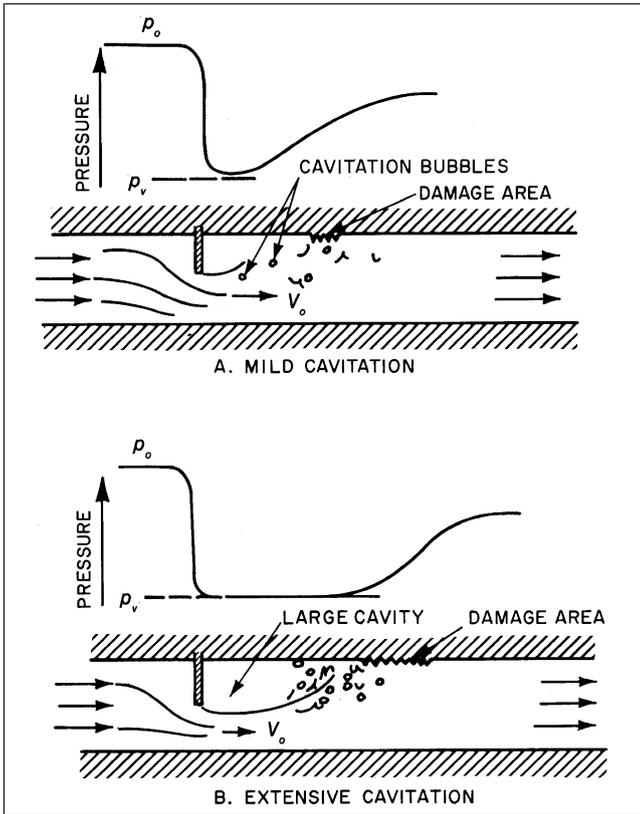

Fig. 10 Cavitation in Flows in Orifice or Valve

region of pressure regain where they collapse, either in the fluid or on the wall (Figure 10A). As the pressure is reduced, more vapor- or gas-filled bubbles result and coalesce into larger ones. Eventually, a single large cavity results that collapses further downstream (Figure 10B). The region of wall damage is then as many as 20 diameters downstream from the valve or orifice plate.

Sensitivity of a device to cavitation occurrence is measured by the **cavitation index** or **cavitation number**, which is the ratio of the available pressure above vapor pressure to the dynamic pressure of the reference flow:

$$\sigma = \frac{2(p_o - p_v)}{\rho V_o^2} \tag{11}$$

where  $p_v$  is the vapor pressure, and the subscript  $o$  refers to appropriate reference conditions. Valve analyses use such an index in order to determine when cavitation will affect the discharge coefficient (Ball 1957). With flow-metering devices such as orifices, venturis, and flow nozzles, there is little cavitation, because it occurs mostly downstream of the flow regions involved in establishing the metering action.

The detrimental effects of cavitation can be avoided by operating the liquid-flow device at high enough pressures. When this is not possible, the flow must be changed or the device must be built to withstand cavitation effects. Some materials or surface coatings are more resistant to cavitation erosion than others, but none is immune. Surface contours can be designed to delay the onset of cavitation.

**Nonisothermal Effects**

When appreciable temperature variations exist, the primary fluid properties (density and viscosity) are no longer constant, as usually

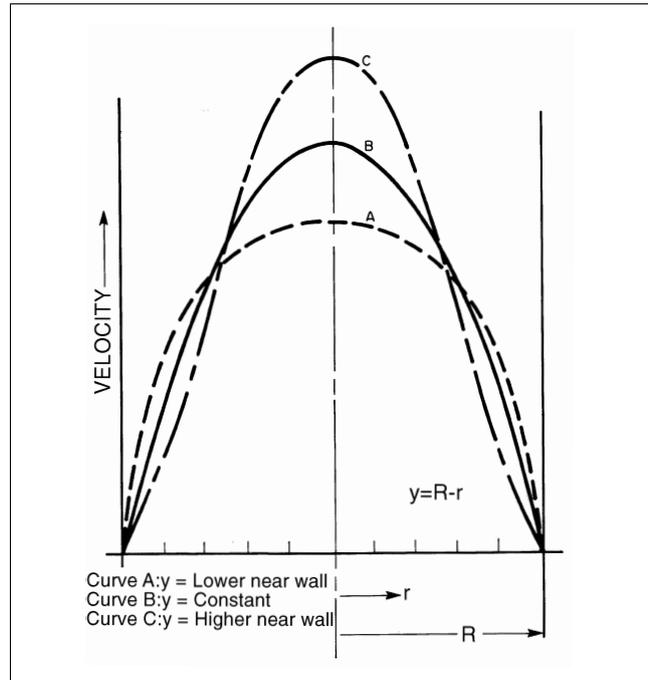

Fig. 11 Effect of Viscosity Variation on Velocity Profile of Laminar Flow in Pipe

assumed, but vary across or along the flow. The Bernoulli equation in the form of Equations (5a) through (5c) must be used, because volumetric flow is not constant. With gas flows, the thermodynamic process involved must be considered. In general, this is assessed in applying Equation (5a), written in the following form:

$$\int \frac{dp}{\rho} + \frac{V^2}{2} + gz = B \tag{12}$$

Effects of viscosity variations also appear. With nonisothermal laminar flow, the parabolic velocity profile (Figure 3) is no longer valid. For gases, viscosity increases as the square root of absolute temperature, and for liquids, it decreases with increasing temperature. This results in opposite effects.

For fully developed pipe flow, the linear variation in shear stress from the wall value  $\tau_w$  to zero at the centerline is independent of the temperature gradient. In the section on Laminar Flow,  $\tau$  is defined as  $\tau = (y/b)\tau_w$ , where  $y$  is the distance from the centerline and  $2b$  is the wall spacing. For pipe radius  $R = D/2$  and distance from the wall  $y = R - r$  (see Figure 11), then  $\tau = \tau_w (R - y)/R$ . Then, solving Equation (1) for the change in velocity gives

$$dv = \left[ \frac{\tau_w(R - y)}{R\mu} \right] dy = - \left( \frac{\tau_w}{R\mu} \right) r dr \tag{13}$$

When the fluid has a lower viscosity near the wall than at the center (due to external heating of liquid or cooling of gas via heat transfer through the pipe wall), the velocity gradient is steeper near the wall and flatter near the center, so the profile is generally flattened. When liquid is cooled or gas is heated, the velocity profile becomes more pointed for laminar flow (Figure 11). Calculations were made for such flows of gases and liquid metals in pipes (Deissler 1951). Occurrences in turbulent flow are less apparent. If enough heating is applied to gaseous flows, the viscosity increase can cause reversion to laminar flow.

Buoyancy effects and gradual approach of the fluid temperature to equilibrium with that outside the pipe can cause considerable variation in the velocity profile along the conduit. Thus, Colborne and Drobitch (1966) found the pipe factor for upward vertical flow of hot air at a Reynolds number less than 2000 reduced to about 0.6 at 40 diameters from the entrance, then increased to about 0.8 at 210 diameters, and finally decreased to the isothermal value of 0.5 at the end of 320 diameters.

### Compressibility

All fluids are compressible to some degree; their density depends on the pressure. Steady liquid flow may ordinarily be treated as incompressible, and incompressible flow analysis is satisfactory for gases and vapors at velocities below about 20 to 40 m/s, except in long conduits.

For liquids in pipelines, if flow is suddenly stopped, a severe pressure surge or water hammer is produced that travels along the pipe at the speed of sound in the liquid. This pressure surge alternately compresses and decompresses the liquid. For steady gas flows in long conduits, a decrease in pressure along the conduit can reduce the density of the gas significantly enough to cause the velocity to increase. If the conduit is long enough, velocities approaching the speed of sound are possible at the discharge end, and the Mach number (the ratio of the flow velocity to the speed of sound) must be considered.

Some compressible flows occur without heat gain or loss (adiabatically). If there is no friction (conversion of flow mechanical energy into internal energy), the process is reversible as well. Such a reversible adiabatic process is called isentropic, and follows the relationship

$$p/\rho^k = \text{constant}$$

$$k = c_p/c_v$$

where  $k$ , the ratio of specific heats at constant pressure and volume, has a value of 1.4 for air and diatomic gases.

The Bernoulli equation of steady flow, Equation (12), as an integral of the ideal-fluid equation of motion along a streamline, then becomes

$$\int \frac{dp}{\rho} + \frac{V^2}{2} = \text{constant} \quad (14)$$

where, as in most compressible flow analyses, the elevation terms involving  $z$  are insignificant and are dropped.

For a frictionless adiabatic process, the pressure term has the form

$$\int_1^2 \frac{dp}{\rho} = \frac{k}{k-1} \left( \frac{p_2}{\rho_2} - \frac{p_1}{\rho_1} \right) \quad (15)$$

Then, between stations 1 and 2 for the isentropic process,

$$\frac{p_1}{\rho_1} \left( \frac{k}{k-1} \right) \left[ \left( \frac{p_2}{p_1} \right)^{(k-1)/k} - 1 \right] + \frac{V_2^2 - V_1^2}{2} = 0 \quad (16)$$

Equation (16) replaces the Bernoulli equation for compressible flows and may be applied to the stagnation point at the front of a body. With this point as station 2 and the upstream reference flow ahead of the influence of the body as station 1,  $V_2 = 0$ . Solving Equation (16) for  $p_2$  gives

$$p_s = p_2 = p_1 \left[ 1 + \left( \frac{k-1}{2} \right) \frac{\rho_1 V_1^2}{k p_1} \right]^{k/(k-1)} \quad (17)$$

where  $p_s$  is the stagnation pressure.

Because  $k\rho/p$  is the square of the acoustic velocity  $a$  and the Mach number  $M = V/a$ , the stagnation pressure relation becomes

$$p_s = p_1 \left[ 1 + \left( \frac{k-1}{2} \right) M_1^2 \right]^{k/(k-1)} \quad (18)$$

For Mach numbers less than one,

$$p_s = p_1 + \frac{\rho_1 V_1^2}{2} \left[ 1 + \frac{M_1}{4} + \left( \frac{2-k}{24} \right) M_1^4 + \dots \right] \quad (19)$$

When  $M = 0$ , Equation (19) reduces to the incompressible flow result obtained from Equation (5a). Appreciable differences appear when the Mach number of the approaching flow exceeds 0.2. Thus a pitot tube in air is influenced by compressibility at velocities over about 66 m/s.

Flows through a converging conduit, as in a flow nozzle, venturi, or orifice meter, also may be considered isentropic. Velocity at the upstream station 1 is negligible. From Equation (16), velocity at the downstream station is

$$V_2 = \sqrt{\frac{2k}{k-1} \left( \frac{p_1}{\rho_1} \right) \left[ 1 - \left( \frac{p_2}{p_1} \right)^{(k-1)/k} \right]} \quad (20)$$

The mass flow rate is

$$\dot{m} = V_2 A_2 \rho_2 = A_2 \sqrt{\frac{2k}{k-1} (p_1 \rho_1) \left[ \left( \frac{p_2}{p_1} \right)^{2/k} - \left( \frac{p_2}{p_1} \right)^{(k+1)/k} \right]} \quad (21)$$

The corresponding incompressible flow relation is

$$\dot{m}_{in} = A_2 \rho \sqrt{2\Delta p/\rho} = A_2 \sqrt{2\rho(p_1 - p_2)} \quad (22)$$

The compressibility effect is often accounted for in the **expansion factor**  $Y$ :

$$\dot{m} = Y \dot{m}_{in} = A_2 Y \sqrt{2\rho(p_1 - p_2)} \quad (23)$$

$Y$  is 1.00 for the incompressible case. For air ( $k = 1.4$ ), a  $Y$  value of 0.95 is reached with orifices at  $p_2/p_1 = 0.83$  and with venturis at about 0.90, when these devices are of relatively small diameter ( $D_2/D_1$  less than 0.5).

As  $p_2/p_1$  decreases, the flow rate increases, but more slowly than for the incompressible case because of the nearly linear decrease in  $Y$ . However, the downstream velocity reaches the local acoustic value and the discharge levels off at a value fixed by upstream pressure and density at the critical ratio:

$$\left. \frac{p_2}{p_1} \right|_c = \left( \frac{2}{k+1} \right)^{k/(k-1)} = 0.53 \text{ for air} \quad (24)$$

At higher pressure ratios than critical, **choking** (no increase in flow with decrease in downstream pressure) occurs and is used in some

flow control devices to avoid flow dependence on downstream conditions.

**FLOW ANALYSIS**

Fluid flow analysis is used to correlate pressure changes with flow rates and the nature of the conduit. For a given pipeline, either the pressure drop for a certain flow rate, or the flow rate for a certain pressure difference between the ends of the conduit, is needed. Flow analysis ultimately involves comparing a pump or blower to a conduit piping system for evaluating the expected flow rate.

**Generalized Bernoulli Equation**

Internal energy differences are generally small and usually the only significant effect of heat transfer is to change the density  $\rho$ . For gas or vapor flows, use the generalized Bernoulli equation in the pressure-over-density form of Equation (6a), allowing for the thermodynamic process in the pressure-density relation:

$$\int_1^2 \frac{dp}{\rho} + \alpha_1 \frac{V_1^2}{2} + E_M = \alpha_2 \frac{V_2^2}{2} + E_L \tag{25a}$$

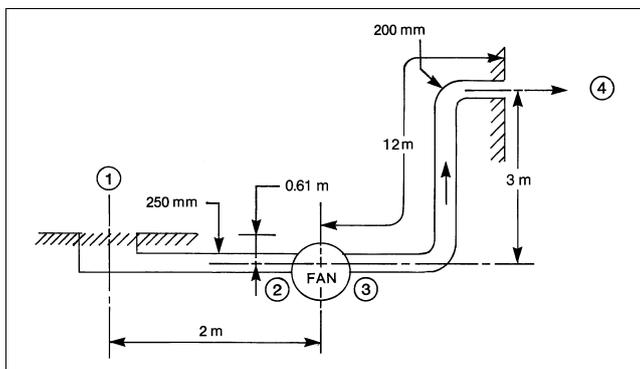

The elevation changes involving  $z$  are often negligible and are dropped. The pressure form of Equation (5b) is generally unacceptable when appreciable density variations occur, because the volumetric flow rate differs at the two stations. This is particularly serious in friction-loss evaluations where the density usually varies over considerable lengths of conduit (Benedict and Carlucci 1966). When the flow is essentially incompressible, Equation (25a) is satisfactory.

**Example 1.** Specify the blower to produce an isothermal airflow of 200 L/s through a ducting system (Figure 12). Accounting for intake and fitting losses, the equivalent conduit lengths are 18 and 50 m and the flow is isothermal. The pressure at the inlet (station 1) and following the discharge (station 4), where the velocity is zero, is the same. The frictional losses  $H_L$  are evaluated as 7.5 m of air between stations 1 and 2, and 72.3 m between stations 3 and 4.

**Solution:** The following form of the generalized Bernoulli relation is used in place of Equation (25a), which also could be used:

$$\begin{aligned} (p_1/\rho_1 g) + \alpha_1(V_1^2/2g) + z_1 + H_M \\ = (p_2/\rho_2 g) + \alpha_2(V_2^2/2g) + z_2 + H_L \end{aligned} \tag{25b}$$

The term  $V_1^2/2g$  can be calculated as follows:

**Fig. 12 Blower and Duct System for Example 1**

$$A_1 = \pi \left(\frac{D}{2}\right)^2 = \pi \left(\frac{0.250}{2}\right)^2 = 0.0491 \text{ m}^2$$

$$V_1 = Q/A_1 = \frac{0.200}{0.0491} = 4.07 \text{ m/s}$$

$$V_1^2/2g = (4.07)^2/2(9.8) = 0.846 \text{ m}$$

The term  $V_2^2/2g$  can be calculated in a similar manner.

In Equation (25b),  $H_M$  is evaluated by applying the relation between any two points on opposite sides of the blower. Because conditions at stations 1 and 4 are known, they are used, and the location-specifying subscripts on the right side of Equation (25b) are changed to 4. Note that  $p_1 = p_4 = p$ ,  $\rho_1 = \rho_4 = \rho$ , and  $V_1 = V_4 = 0$ . Thus,

$$(p/\rho g) + 0 + 0.61 + H_M = (p/\rho g) + 0 + 3 + (7.5 + 72.3)$$

so  $H_M = 82.2$  m of air. For standard air ( $\rho = 1.20 \text{ kg/m}^3$ ), this corresponds to 970 Pa.

The pressure difference measured across the blower (between stations 2 and 3), is often taken as the  $H_M$ . It can be obtained by calculating the static pressure at stations 2 and 3. Applying Equation (25b) successively between stations 1 and 2 and between 3 and 4 gives

$$(p_1/\rho g) + 0 + 0.61 + 0 = (p_2/\rho g) + (1.06 \times 0.846) + 0 + 7.5$$

$$(p_3/\rho g) + (1.03 \times 2.07) + 0 + 0 = (p_4/\rho g) + 0 + 3 + 72.3$$

where  $\alpha$  just ahead of the blower is taken as 1.06, and just after the blower as 1.03; the latter value is uncertain because of possible uneven discharge from the blower. Static pressures  $p_1$  and  $p_4$  may be taken as zero gage. Thus,

$$p_2/\rho g = -7.8 \text{ m of air}$$

$$p_3/\rho g = 73.2 \text{ m of air}$$

The difference between these two numbers is 81 m, which is *not* the  $H_M$  calculated after Equation (25b) as 82.2 m. The apparent discrepancy results from ignoring the velocity at stations 2 and 3. Actually,  $H_M$  is the following:

$$\begin{aligned} H_M &= (p_3/\rho g) + \alpha_3(V_3^2/2g) - [(p_2/\rho g) + \alpha_2(V_2^2/2g)] \\ &= 73.2 + (1.03 \times 2.07) - [-7.8 + (1.06 \times 0.846)] \\ &= 75.3 - (-6.9) = 82.2 \text{ m} \end{aligned}$$

The required blower energy is the same, no matter how it is evaluated. It is the specific energy added to the system by the machine. Only when the conduit size and velocity profiles on both sides of the machine are the same is  $E_M$  or  $H_M$  simply found from  $\Delta p = p_3 - p_2$ .

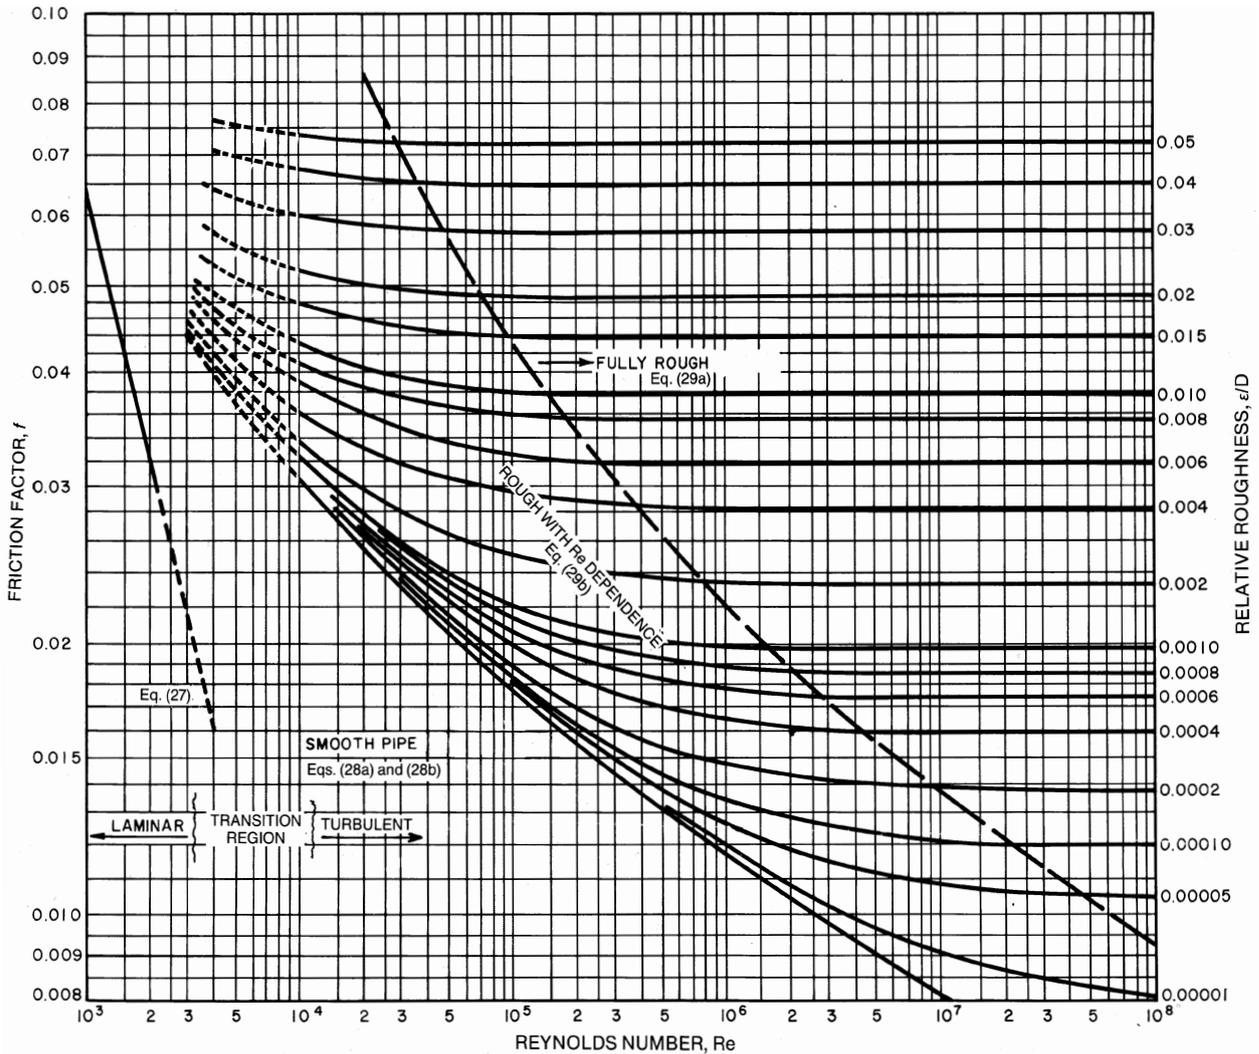

**Conduit Friction**

The loss term  $E_L$  or  $H_L$  of Equation (6a) or (6b) accounts for friction caused by conduit-wall shearing stresses and losses from conduit-section changes.  $H_L$  is the loss of energy per unit weight (J/N) of flowing fluid.

In real-fluid flow, a frictional shear occurs at bounding walls, gradually influencing the flow further away from the boundary. A lateral velocity profile is produced and flow energy is converted into heat (fluid internal energy), which is generally unrecoverable (a loss). This loss in fully developed conduit flow is evaluated through the **Darcy-Weisbach equation**:

$$(H_L)_f = f \left(\frac{L}{D}\right) \left(\frac{V^2}{2g}\right) \tag{26}$$

where  $L$  is the length of conduit of diameter  $D$  and  $f$  is the **friction factor**. Sometimes a numerically different relation is used with the **Fanning friction factor** (one-quarter of  $f$ ). The value of  $f$  is nearly constant for turbulent flow, varying only from about 0.01 to 0.05.

**Fig. 13 Relation Between Friction Factor and Reynolds Number**  
(Moody 1944)

For fully developed laminar-viscous flow in a pipe, the loss is evaluated from Equation (8) as follows:

$$(H_L)_f = \frac{L}{\rho g} \left( \frac{8\mu V}{R^2} \right) = \frac{32LvV}{D^2g} = \frac{64}{VD/v} \left( \frac{L}{D} \right) \left( \frac{V^2}{2g} \right) \quad (27)$$

where  $Re = VD/v$  and  $f = 64/Re$ . Thus, for laminar flow, the friction factor varies inversely with the Reynolds number.

With turbulent flow, friction loss depends not only on flow conditions, as characterized by the Reynolds number, but also on the nature of the conduit wall surface. For smooth conduit walls, empirical correlations give

$$f = \frac{0.3164}{Re^{0.25}} \quad \text{for } Re < 10^5 \quad (28a)$$

$$f = 0.0032 + \frac{0.221}{Re^{0.237}} \quad \text{for } 10^5 < Re < 3 \times 10^6 \quad (28b)$$

Generally,  $f$  also depends on the wall roughness  $\epsilon$ . The variation is complex and best expressed in chart form (Moody 1944) as

shown in Figure 13. Inspection indicates that, for high Reynolds numbers and relative roughness, the friction factor becomes independent of the Reynolds number in a fully-rough flow regime. Then

$$\frac{1}{\sqrt{f}} = 1.14 + 2 \log (D/\epsilon) \quad (29a)$$

Values of  $f$  between the values for smooth tubes and those for the fully-rough regime are represented by **Colebrook's natural roughness function**:

$$\frac{1}{\sqrt{f}} = 1.14 + 2 \log (D/\epsilon) - 2 \log \left[ 1 + \frac{9.3}{Re(\epsilon/D)\sqrt{f}} \right] \quad (29b)$$

A transition region appears in Figure 13 for Reynolds numbers between 2000 and 10 000. Below this critical condition, for smooth walls, Equation (27) is used to determine  $f$ ; above the critical condition, Equation (28b) is used. For rough walls, Figure 13 or Equation (29b) must be used to assess the friction factor in turbulent flow. To do this, the roughness height  $\epsilon$ , which may increase with conduit use or aging, must be evaluated from the conduit surface (Table 2).

**Table 2 Effective Roughness of Conduit Surfaces**

Material	$\epsilon$ , ft
Commercially smooth brass, lead, copper, or plastic pipe	0.000005
Steel and wrought iron	0.00015
Galvanized iron or steel	0.0005
Cast iron	0.00085

Although the preceding discussion has focused on circular pipes and ducts, air ducts are often rectangular in cross section. The equivalent circular conduit corresponding to the noncircular conduit must be found before Figure 13 or Equations (28) or (29) can be used. Based on turbulent flow concepts, the **equivalent diameter** is determined by

$$D_{eq} = 4A/P_w \quad (30)$$

where

$A$  = flow area

$P_w$  = wetted perimeter of the cross section

For turbulent flow,  $D_{eq}$  is substituted for  $D$  in Equation (26) and the Reynolds number definition in Equation (27). Noncircular duct friction can be evaluated to within 5% for all except very extreme cross sections. A more refined method for finding the equivalent circular duct diameter is given in Chapter 34. With laminar flow, the loss predictions may be off by a factor as large as two.

### Section Change Effects and Losses

Valve and section changes (contractions, expansions and diffusers, elbows or bends, tees), as well as entrances, distort the fully developed velocity profiles (Figure 3) and introduce extra flow losses (dissipated as heat) into pipelines or duct systems. Valves produce such extra losses to control flow rate. In contractions and expansions, flow separation as shown in Figures 8 and 9 causes the extra loss. The loss at rounded entrances develops as the flow accelerates to higher velocities. The resulting higher velocity near the wall leads to wall shear stresses greater than those of fully developed flow (Figure 5). In flow around bends, the velocity increases along the inner wall near the start of the bend. This increased velocity creates a secondary motion, which is a double helical vortex pattern of flow downstream from the bend. In all these devices, the disturbance produced locally is converted into turbulence and appears as a loss in the downstream region.

The return of disturbed flow to a fully developed velocity profile is quite slow. Ito (1962) showed that the secondary motion following a bend takes up to 100 diameters of conduit to die out but the pressure gradient settles out after 50 diameters.

With laminar flow following a rounded entrance, the entrance length depends on the Reynolds number:

$$L_e/D \approx 0.06 \text{ Re} \quad (31)$$

At  $\text{Re} = 2000$ , a length of 120 diameters is needed to establish the parabolic profile. The pressure gradient reaches the developed value of Equation (26) much sooner. The extra drop is  $1.2V^2/2g$ ; the change in profile from uniform to parabolic results in a drop of  $1.0V^2/2g$  (since  $\alpha = 2.0$ ), and the rest is due to excess friction. With turbulent flow, 80 to 100 diameters following the rounded entrance are needed for the velocity profile to become fully developed, but the friction loss per unit length reaches a value close to that of the fully developed flow value more quickly. After six diameters, the loss rate at a Reynolds number of  $10^5$  is only 14% above that of fully developed flow in the same length, while at  $10^7$ , it is only 10% higher (Robertson 1963). For a sharp entrance, the flow separation (Figure 8) causes a greater disturbance, but fully developed flow is achieved in about half the length required for a rounded entrance. With

sudden expansion, the pressure change settles out in about eight times the diameter change ( $D_2 = D_1$ ), while the velocity profile takes at least a 50% greater distance to return to fully developed pipe flow (Lipstein 1962).

These disturbance effects are assumed compressed (in the flow direction) into a point, and the losses are treated as locally occurring. Such a loss is related to the velocity by the **fitting loss coefficient**  $K$ :

$$\text{Loss of section} = K \left( \frac{V^2}{2g} \right) \quad (32)$$

Chapter 35 and the *Pipe Friction Manual* (Hydraulic Institute 1961) have information for pipe applications. Chapter 34 gives information for airflow. The same type of fitting in pipes and ducts may give a different loss, because flow disturbances are controlled by the detailed geometry of the fitting. The elbow of a small pipe may be a threaded fitting that differs from a bend in a circular duct. For 90 screw-fitting elbows,  $K$  is about 0.8 (Ito 1962), whereas smooth flanged elbows have a  $K$  as low as 0.2 at the optimum curvature.

Table 3 gives a list of fitting loss coefficients. These values indicate the losses, but there is considerable variance. Expansion flows, such as from one conduit size to another or at the exit into a room or reservoir, are not included. For such occurrences, the **Borda loss prediction** (from impulse-momentum considerations) is appropriate:

$$\text{Loss at expansion} = \frac{(V_1 - V_2)^2}{2g} = \frac{V_1^2}{2g} \left( 1 - \frac{A_1}{A_2} \right)^2 \quad (33)$$

Such expansion loss is reduced by avoiding or delaying separation using a gradual diffuser (Figure 9). For a diffuser of about  $7^\circ$  total angle, the loss is minimal, about one-sixth that given by Equation (33). The diffuser loss for total angles above  $45$  to  $60^\circ$  exceeds that of the sudden expansion, depending somewhat on the diameter ratio of the expansion. Optimum design of diffusers involves many factors; excellent performance can be achieved in short diffusers with splitter vanes or suction. Turning vanes in miter bends produce the least disturbance and loss for elbows; with careful design, the loss coefficient can be reduced to as low as 0.1.

For losses in smooth elbows, Ito (1962) found a Reynolds number effect ( $K$  slowly decreasing with increasing  $\text{Re}$ ) and a minimum loss at a bend curvature (bend radius to diameter ratio) of 2.5. At this optimum curvature, a  $45^\circ$  turn had 63%, and a  $180^\circ$  turn approximately 120%, of the loss of a  $90^\circ$  bend. The loss does not vary linearly with the turning angle because secondary motion occurs.

Use of coefficient  $K$  presumes its independence of the Reynolds number. Crane Co. (1976) found a variation with the Reynolds number similar to that of the friction factor; Kittridge and Rowley (1957) observed it only with laminar flow. Assuming that  $K$  varies with  $\text{Re}$  similarly to  $f$ , it is convenient to represent fitting losses as adding to the effective length of uniform conduit. The **effective length** of a fitting is then

$$L_{eff}/D = K/f_{ref} \quad (34)$$

where  $f_{ref}$  is an appropriate reference value of the friction factor. Deissler (1951) uses 0.028, and the air duct values in Chapter 34 are based on an  $f_{ref}$  of about 0.02. For rough conduits, appreciable errors can occur if the relative roughness does not correspond to that used when  $f_{ref}$  was fixed. It is unlikely that the fitting losses involving separation are affected by pipe roughness. The effective length method for fitting loss evaluation is still useful.

When a conduit contains a number of section changes or fittings, the values of  $K$  are added to the  $fL/D$  friction loss, or the  $L_{eff}/D$  of the fittings are added to the conduit length  $L/D$  for evaluating the total loss  $H_L$ . This assumes that each fitting loss is fully developed and its disturbance fully smoothed out before the next section

change. Such an assumption is frequently wrong, and the total loss can be overestimated. For elbow flows, the total loss of adjacent bends may be over or underestimated. The secondary flow pattern following an elbow is such that when one follows another, perhaps in a different plane, the secondary flow of the second elbow may reinforce or partially cancel that of the first. Moving the second elbow a few diameters can reduce the total loss (from more than twice the amount) to less than the loss from one elbow. Screens or perforated plates can be used for smoothing velocity profiles (Wile 1947) and flow spreading. Their effectiveness and loss coefficients depend on their amount of open area (Baines and Peterson 1951).

**Compressible Conduit Flow**

When friction loss is included, as it must be except for a very short conduit, the incompressible flow analysis previously considered applies until the pressure drop exceeds about 10% of the initial pressure. The possibility of sonic velocities at the end of relatively long conduits limits the amount of pressure reduction achieved. For an inlet Mach number of 0.2, the discharge pressure can be reduced to about 0.2 of the initial pressure; for an inflow at  $M = 0.5$ , the discharge pressure cannot be less than about  $0.45p_1$  in the adiabatic case and about  $0.6p_1$  in isothermal flow.

Analysis of such conduit flow must treat density change, as evaluated from the continuity relation in Equation (2), with the frictional occurrences evaluated from wall roughness and Reynolds number correlations of incompressible flow (Binder 1944). In evaluating valve and fitting losses, consider the reduction in  $K$  caused by compressibility (Benedict and Carlucci 1966). Although the analysis differs significantly, isothermal and adiabatic flows involve essentially the same pressure variation along the conduit, up to the limiting conditions.

**Control Valve Characterization**

Control valves are characterized by a discharge coefficient  $C_d$ . As long as the Reynolds number is greater than 250, the orifice equation holds for liquids:

$$Q = C_d A_o \sqrt{2\Delta P / \rho} \tag{35}$$

where

- $A_o$  = area of orifice opening
- $P$  = absolute pressure

The discharge coefficient is about 0.63 for sharp-edged configurations and 0.8 to 0.9 for chamfered or rounded configurations. For gas flows at pressure ratios below the choking critical [Equation (24)], the mass rate of flow is

$$\dot{m} = C_d A_o C_1 \left( \frac{P_u}{\sqrt{T_u}} \right) \sqrt{\frac{P_d}{P_u}} \sqrt{1 - \left( \frac{P_d}{P_u} \right)^{(k-1)/k}} \tag{36}$$

where

- $C_1 = \sqrt{2k/R(k-1)}$
- $k$  = ratio of specific heats at constant pressure and volume
- $R$  = gas constant
- $T$  = absolute temperature
- $u, d$  = subscripts referring to upstream and downstream positions

**Incompressible Flow in Systems**

Flow devices must be evaluated in terms of their interaction with other elements of the system, for example, the action of valves in modifying flow rate and in matching the flow-producing device (pump or blower) with the system loss. Analysis is via the general Bernoulli equation and the loss evaluations noted previously.

A valve regulates or stops the flow of fluid by throttling. The change in flow is not proportional to the change in area of the valve opening. Figures 14 and 15 indicate the nonlinear action of valves in controlling flow. Figure 14 shows a flow in a pipe discharging water from a tank that is controlled by a gate valve. The fitting loss coefficient  $K$  values are those of Table 3; the friction factor  $f$  is 0.027. The degree of control also depends on the conduit  $L/D$  ratio. For a relatively long conduit, the valve must be nearly closed before its high  $K$  value becomes a significant portion of the loss. Figure 15 shows a control damper (essentially a butterfly valve) in a duct discharging air from a plenum held at constant pressure. With a long duct, the damper does not affect the flow rate until it is about one-quarter closed. Duct length has little effect when the damper is more than half closed. The damper closes the duct totally at the  $90^\circ$  position ( $K = \infty$ ).

Flow in a system (pump or blower and conduit with fittings) involves interaction between the characteristics of the flow-producing device (pump or blower) and the loss characteristics of the pipeline or duct system. Often the devices are centrifugal, in which case the pressure produced decreases as the flow increases, except for the lowest flow rates. System pressure required to overcome losses increases roughly as the square of the flow rate. The flow rate of a given system is that where the two curves of pressure versus flow rate intersect (point 1 in Figure 16). When a control valve (or

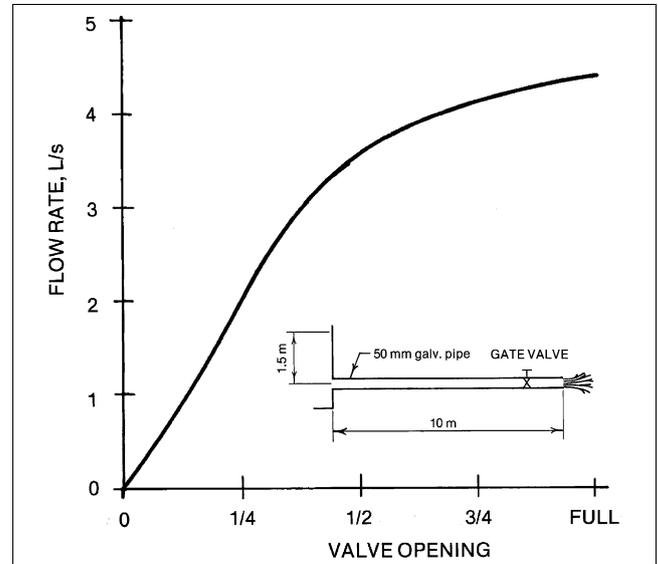

Fig. 14 Valve Action in Pipeline

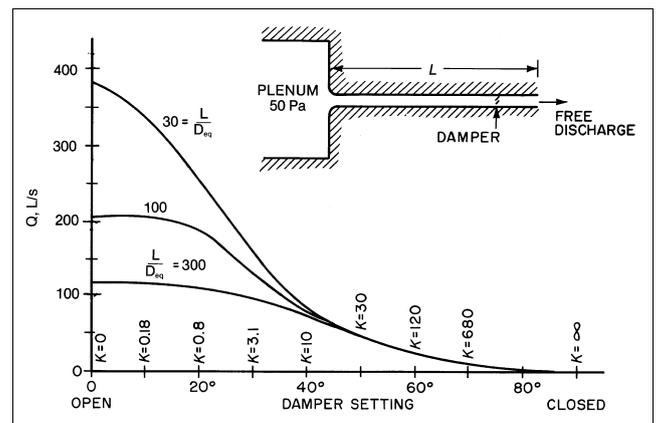

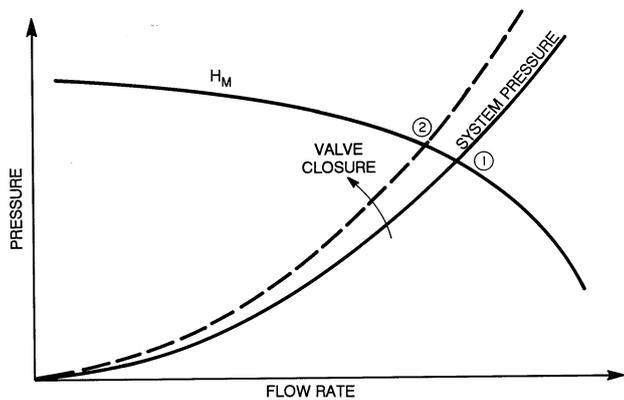

Fig. 15 Effect of Duct Length on Damper Action

**Table 3 Fitting Loss Coefficients of Turbulent Flow**

Fitting	Geometry	$K = \frac{\Delta p / \rho g}{V^2 / 2g}$
Entrance	Sharp	0.50
	Well-rounded	0.05
Contraction	Sharp ( $D_2/D_1 = 0.5$ )	0.38
90° Elbow	Miter	1.3
	Short radius	0.90
	Long radius	0.60
	Miter with turning vanes	0.2
Globe valve	Open	10
Angle valve	Open	5
Gate valve	Open	0.19 to 0.22
	75% open	1.10
	50% open	3.6
	25% open	28.8
Any valve	Closed	$\infty$
Tee	Straight through flow	0.5
	Flow through branch	1.8

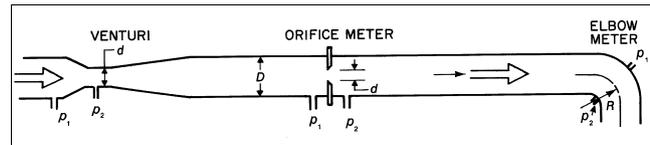

**Fig. 16 Matching of Pump or Blower to System Characteristics**

dampener) is partially closed, it increases the losses and reduces the flow (point 2 in Figure 16). For cases of constant pressure, the flow decrease due to valving is not as great as that indicated in Figures 14 and 15.

**Flow Measurement**

The general principles noted (the continuity and Bernoulli equations) are basic to most fluid-metering devices. Chapter 14 has further details.

The pressure difference between the stagnation point (total pressure) and that in the ambient fluid stream (static pressure) is used to give a point velocity measurement. The flow rate in a conduit is measured by placing a pitot device at various locations in the cross section and spatially integrating the velocity profile found. A single point measurement may be used for approximate flow rate evaluation. When the flow is fully developed, the pipe-factor information of Figure 4 can be used to estimate the flow rate from a centerline measurement. Measurements can be made in one of two modes. With the pitot-static tube, the ambient (static) pressure is found from pressure taps along the side of the forward-facing portion of the tube. When this portion is not long and slender, static pressure indication will be low and velocity indication high; as a result, a tube coefficient less than unity must be used. For parallel conduit flow, wall piezometers (taps) may take the ambient pressure, and the pitot tube indicates the impact (total pressure).

**Fig. 17 Differential Pressure Flowmeters**

The venturi meter, flow nozzle, and orifice meter are flow rate metering devices based on the pressure change associated with relatively sudden changes in conduit section area (Figure 17). The elbow meter (also shown in Figure 17) is another differential pressure flowmeter. The flow nozzle is similar to the venturi in action, but does not have the downstream diffuser. For all these, the flow rate is proportional to the square root of the pressure difference resulting from fluid flow. With the area change devices (venturi, flow nozzle, and orifice meter), a theoretical flow rate relation is found by applying the Bernoulli and continuity equations in Equations (6) and (2) between stations 1 and 2:

$$Q_{theor} = \frac{\pi d^2}{4} \sqrt{\frac{2\Delta p}{\rho(1-\beta^4)}} \tag{37}$$

where  $\beta = d/D =$  ratio of throat (or orifice) diameter to conduit diameter.

The actual flow rate through the device can differ because the approach flow kinetic energy factor  $\alpha$  deviates from unity and because of small losses. More significantly, the jet contraction of orifice flow is neglected in deriving Equation (37), to the extent that it can reduce the effective flow area by a factor of 0.6. The effect of all these factors can be combined into the discharge coefficient  $C_d$ :

$$Q = C_d Q_{theor} = C_d \left( \frac{\pi d^2}{4} \right) \sqrt{\frac{2\Delta p}{\rho(1-\beta^4)}} \tag{38}$$

Sometimes an alternate coefficient is used of the form

$$\frac{C_d}{\sqrt{1-\beta^4}}$$

For compressible fluid metering, the expansion factor  $Y$  as described by Equation (23) must be included, and the mass flow rate is

$$\dot{m} = C_d Y \rho Q_{theor} = C_d Y \left( \frac{\pi d^2}{4} \right) \sqrt{\frac{2\rho\Delta p}{1-\beta^4}} \tag{39}$$

Values of  $Y$  depend primarily on the pressure ratio  $p_2/p_1$ , and also on the metering device and  $k$  value of the particular gas.

The general mode of variation in  $C_d$  for orifices and venturis is indicated in Figure 18 as a function of Reynolds number and, to a lesser extent, diameter ratio  $\beta$ . For Reynolds numbers less than 10, the coefficient varies as  $\sqrt{Re}$ .

The elbow meter employs the pressure difference between inside and outside the bend as the metering signal (Murdock et al. 1964). A momentum analysis gives the flow rate as

$$Q_{theor} = \frac{\pi D^2}{4} \sqrt{\frac{R}{2D} \left( \frac{2\Delta p}{\rho} \right)} \tag{40}$$

where  $R$  is the radius of curvature of the bend. Again, a discharge coefficient  $C_d$  is needed; as in Figure 18, this drops off for the lower Reynolds numbers (below  $10^5$ ). These devices are calibrated in pipes

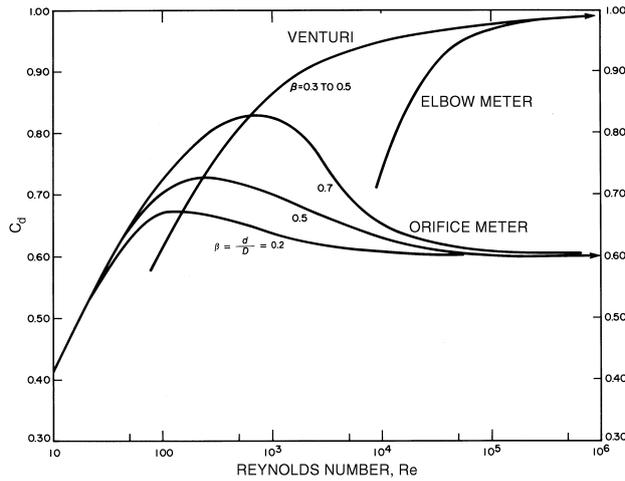

Fig. 18 Flowmeter Coefficients

with fully developed velocity profiles, so they must be located far enough downstream of sections that modify the approach velocity.

**Unsteady Flow**

Conduit flows are not always steady. In a compressible fluid, the acoustic velocity is usually high and the conduit length is rather short, so the time of signal travel is negligibly small. Even in the incompressible approximation, system response is not instantaneous. If a pressure difference  $\Delta p$  is applied between the conduit ends, the fluid mass must be accelerated and wall friction overcome, so a finite time passes before the steady flow rate corresponding to the pressure drop is achieved.

The time it takes for an incompressible fluid in a horizontal constant-area conduit of length  $L$  to achieve steady flow may be estimated by using the unsteady flow equation of motion with wall friction effects included. On the quasi-steady assumption, friction is given by Equation (26); also by continuity,  $V$  is constant along the conduit. The occurrences are characterized by the relation

$$\frac{dV}{d\theta} + \left(\frac{1}{\rho}\right) \frac{dp}{ds} + \frac{fV^2}{2D} = 0 \tag{41}$$

where

- $\theta$  = time
- $s$  = distance in the flow direction

Since a certain  $\Delta p$  is applied over the conduit length  $L$ ,

$$\frac{dV}{d\theta} = \frac{\Delta p}{\rho L} - \frac{fV^2}{2D} \tag{42}$$

For laminar flow,  $f$  is given by Equation (27), and

$$\frac{dV}{d\theta} = \frac{\Delta p}{\rho L} - \frac{32\mu V}{\rho D^2} = A - BV \tag{43}$$

Equation (43) can be rearranged and integrated to yield the time to reach a certain velocity:

$$\theta = \int d\theta = \int \frac{dV}{A - BV} = -\frac{1}{B} \ln(A - BV) \tag{44}$$

and

$$V = \frac{\Delta p}{L} \left(\frac{D^2}{32\mu}\right) \left[1 - \frac{\rho L}{\Delta p} \exp\left(\frac{-32\nu\theta}{D^2}\right)\right] \tag{45a}$$

For long times ( $\theta \rightarrow \infty$ ), this indicates steady velocity as

$$V_\infty = \frac{\Delta p}{L} \left(\frac{D^2}{32\mu}\right) = \frac{\Delta p}{L} \left(\frac{R^2}{8\mu}\right) \tag{45b}$$

as by Equation (8). Then, Equation (45a) becomes

$$V = V_\infty \left[1 - \frac{\rho L}{\Delta p} \exp\left(\frac{-f_\infty V_\infty \theta}{2D}\right)\right] \tag{46}$$

where

$$f_\infty = \frac{64\nu}{V_\infty D}$$

The general nature of velocity development for starting-up flow is derived by more complex techniques; however, the temporal variation is as given above. For shutdown flow (steady flow with  $\Delta p = 0$  at  $\theta > 0$ ), the flow decays exponentially as  $e^{-\theta}$ .

Turbulent flow analysis of Equation (41) also must be based on the quasi-steady approximation, with less justification. Daily et al. (1956) indicate that the frictional resistance is slightly greater than the steady-state result for accelerating flows, but appreciably less for decelerating flows. If the friction factor is approximated as constant,

$$\frac{dV}{d\theta} = \frac{\Delta p}{\rho L} - \frac{fV^2}{2D} = A - BV^2$$

and, for the accelerating flow,

$$\theta = \frac{1}{\sqrt{AB}} \tanh^{-1}\left(V\sqrt{\frac{B}{A}}\right)$$

or

$$V = \sqrt{\frac{A}{B}} \tanh(\theta\sqrt{AB})$$

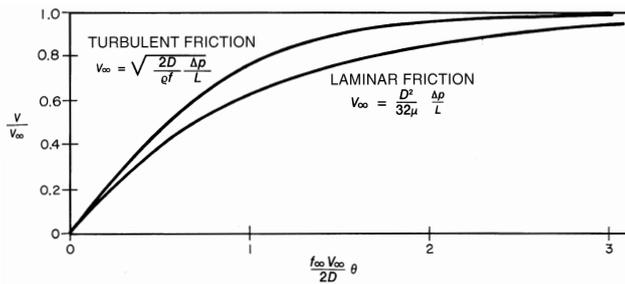

Because the hyperbolic tangent is zero when the independent variable is zero and unity when the variable is infinity, the initial ( $V = 0$  at  $\theta = 0$ ) and final conditions are verified. Thus, for long times ( $\theta \rightarrow \infty$ ),

$$V_\infty = \sqrt{\frac{A}{B}} = \sqrt{\frac{\Delta p / \rho L}{f_\infty / 2D}} = \sqrt{\frac{\Delta p (2D)}{\rho L (f_\infty)}}$$

which is in accord with Equation (26) when  $f$  is constant (the flow regime is the fully rough one of Figure 13). The temporal velocity variation is then

$$V = V_\infty \tanh(f_\infty V_\infty \theta / 2D) \tag{47}$$

In Figure 19, the turbulent velocity start-up result is compared with the laminar one in Figure 19, where initially the turbulent is steeper but of the same general form, increasing rapidly at the start but reaching  $V_\infty$  asymptotically.

**Fig. 19 Temporal Increase in Velocity Following Sudden Application of Pressure**

## NOISE FROM FLUID FLOW

Noise in flowing fluids results from unsteady flow fields and can be at discrete frequencies or broadly distributed over the audible range. With liquid flow, cavitation results in noise through the collapse of vapor bubbles. The noise in pumps or fittings (such as valves) can be a rattling or sharp hissing sound. It is easily eliminated by raising the system pressure. With severe cavitation, the resulting unsteady flow can produce indirect noise from induced vibration of adjacent parts. See Chapter 46 of the 1999 *ASHRAE Handbook—Applications* for more information on sound control.

The disturbed laminar flow behind cylinders can be an oscillating motion. The shedding frequency  $f$  of these vortices is characterized by a Strouhal number  $St = fd/V$  of about 0.21 for a circular cylinder of diameter  $d$ , over a considerable range of Reynolds numbers. This oscillating flow can be a powerful noise source, particularly when  $f$  is close to the natural frequency of the cylinder or some nearby structural member so that resonance occurs. With cylinders of another shape, such as impeller blades of a pump or blower, the characterizing Strouhal number involves the trailing edge thickness of the member. The strength of the vortex wake, with its resulting vibrations and noise potential, can be reduced by breaking up the flow with downstream splitter plates or boundary-layer trip devices (wires) on the cylinder surface.

Noise produced in pipes and ducts, especially from valves and fittings, is associated with the loss through such elements. The sound pressure of noise in water pipe flow increases linearly with the pressure loss; the broad-band noise increases, but only in the lower frequency range. Fitting-produced noise levels also increase with fitting loss (even without cavitation) and significantly exceed noise levels of the pipe flow. The relation between noise and loss is not surprising because both involve excessive flow perturbations. A valve's pressure-flow characteristics and structural elasticity may be such that for some operating point it oscillates, perhaps in resonance with part of the piping system, to produce excessive noise. A change in the operating point conditions or details of the valve geometry can result in significant noise reduction.

Pumps and blowers are strong potential noise sources. Turbo-machinery noise is associated with blade-flow occurrences. Broad-band noise appears from vortex and turbulence interaction with walls and is primarily a function of the operating point of the machine. For blowers, it has a minimum at the peak efficiency point (Groff et al. 1967). Narrow-band noise also appears at the blade-crossing frequency and its harmonics. Such noise can be very annoying because it stands out from the background. To reduce this noise, increase clearances between impeller and housing, and space impeller blades unevenly around the circumference.

**H**HEAT is energy in transit due to a temperature difference. The thermal energy is transferred from one region to another by three modes of **heat transfer**: conduction, convection, and radiation. Heat transfer is among a group of energy transport phenomena that includes mass transfer (see Chapter 5), momentum transfer or fluid friction (see Chapter 2), and electrical conduction. Transport phenomena have similar rate equations, in which flux is proportional to a potential difference. In heat transfer by conduction and convection, the potential difference is the temperature difference. Heat, mass, and momentum transfer are often considered together because of their similarities and interrelationship in many common physical processes.

This chapter presents the elementary principles of single-phase heat transfer with emphasis on heating, refrigerating, and air conditioning. Boiling and condensation are discussed in Chapter 4. More specific information on heat transfer to or from buildings or refrigerated spaces can be found in Chapters 25 through 31 of this volume and in Chapter 12 of the 1998 *ASHRAE Handbook—Refrigeration*. Physical properties of substances can be found in Chapters 18, 22, 24, and 36 of this volume and in Chapter 8 of the 1998 *ASHRAE Handbook—Refrigeration*. Heat transfer equipment, including evaporators, condensers, heating and cooling coils, furnaces, and radiators, is covered in the 2000 *ASHRAE Handbook—Systems and Equipment*. For further information on heat transfer, see the section on Bibliography.

### HEAT TRANSFER PROCESSES

**Thermal Conduction.** This is the mechanism of heat transfer whereby energy is transported between parts of a continuum by the transfer of kinetic energy between particles or groups of particles at the atomic level. In gases, conduction is caused by elastic collision of molecules; in liquids and electrically nonconducting solids, it is believed to be caused by longitudinal oscillations of the lattice structure. Thermal conduction in metals occurs, like electrical conduction, through the motion of free electrons. Thermal energy transfer occurs in the direction of decreasing temperature, a consequence of the second law of thermodynamics. In solid opaque bodies, thermal conduction is the significant heat transfer mechanism because no net material flows in the process and radiation is not a factor. With flowing fluids, thermal conduction dominates in the region very close to a solid boundary, where the flow is **laminar** and parallel to the surface and where there is no eddy motion.

**Thermal Convection.** This form of heat transfer involves energy transfer by fluid movement and molecular conduction (Burmeister 1983, Kays and Crawford 1980). Consider heat transfer to a fluid flowing inside a pipe. If the Reynolds number is large enough, three different flow regions exist. Immediately

adjacent to the wall is a **laminar sublayer** where heat transfer occurs by thermal conduction; outside the laminar sublayer is a transition region called the **buffer layer**, where both eddy mixing and conduction effects are significant; beyond the buffer layer and extending to the center of the pipe is the **turbulent region**, where the dominant mechanism of transfer is eddy mixing.

In most equipment, the main body of fluid is in turbulent flow, and the laminar layer exists at the solid walls only. In cases of low-velocity flow in small tubes, or with viscous liquids such as glycol (i.e., at low Reynolds numbers), the entire flow may be laminar with no transition or turbulent region.

When fluid currents are produced by external sources (for example, a blower or pump), the solid-to-fluid heat transfer is termed **forced convection**. If the fluid flow is generated internally by non-homogeneous densities caused by temperature variation, the heat transfer is termed **free convection** or **natural convection**.

**Thermal Radiation.** In conduction and convection, heat transfer takes place through matter. In thermal radiation, there is a change in energy form from internal energy at the source to electromagnetic energy for transmission, then back to internal energy at the receiver. Whereas conduction and convection heat transfer rates are driven primarily by temperature difference and somewhat by temperature level, radiative heat transfer rates increase rapidly with temperature levels (for the same temperature difference).

Although some generalized heat transfer equations have been mathematically derived from fundamentals, they are usually obtained from correlations of experimental data. Normally, the correlations employ certain dimensionless numbers, shown in Table 1, that are derived from dimensional analysis or analogy.

### STEADY-STATE CONDUCTION

For steady-state heat conduction in one dimension, the Fourier law is

$$q = -(kA) \frac{dt}{dx} \quad (1)$$

where

$q$  = heat flow rate, W

$k$  = thermal conductivity, W/(m·K)

$A$  = cross-sectional area normal to flow, m<sup>2</sup>

$dt/dx$  = temperature gradient, K/m

Equation (1) states that the heat flow rate  $q$  in the  $x$  direction is directly proportional to the temperature gradient  $dt/dx$  and the cross-sectional area  $A$  normal to the heat flow. The proportionality factor is the thermal conductivity  $k$ . The minus sign indicates that the heat flow is positive in the direction of decreasing temperature. Conductivity values are sometimes given in other units, but consistent units must be used in Equation (1).

The preparation of this chapter is assigned to TC 1.3, Heat Transfer and Fluid Flow.

**Table 1 Dimensionless Numbers Commonly Used in Heat Transfer**

Name	Symbol	Value <sup>a</sup>	Application
Nusselt number	Nu	$hD/k, hL/k, q'' D/\Delta tk, \text{ or } q'' L/\Delta tk$	Natural or forced convection, boiling or condensing
Reynolds number	Re	$GD/\mu \text{ or } \rho VL/\mu$	Forced convection, boiling or condensing
Prandtl number	Pr	$\mu c_p/k$	Natural or forced convection, boiling or condensing
Stanton number	St	$h/Gc_p$	Forced convection
Grashof number	Gr	$L^3 \rho^2 \beta g \Delta t / \mu^2 \text{ or } L^3 \rho^2 g \Delta t / T \mu^2$	Natural convection (for ideal gases)
Fourier number	Fo	$\alpha t / L^2$	Unsteady-state conduction
Peclet number	Pe	$GDc_p/k \text{ or } Re Pr$	Forced convection (small Pr)
Graetz number	Gz	$GD^2 c_p / kL \text{ or } Re Pr D/L$	Laminar forced convection

<sup>a</sup>A list of the other symbols used in this chapter appears in the section on Symbols.

Equation (1) may be integrated along a path of constant heat flow rate to obtain

$$q = k \left( \frac{A_m}{L_m} \right) \Delta t = \frac{\Delta t}{R} \tag{2}$$

where

- $A_m$  = mean cross-sectional area normal to flow, m<sup>2</sup>
- $L_m$  = mean length of heat flow path, m
- $\Delta t$  = overall temperature difference, K
- $R$  = thermal resistance, K/W

**Thermal resistance  $R$**  is directly proportional to the mean length  $L_m$  of the heat flow path and inversely proportional to the conductivity  $k$  and the mean cross-sectional area  $A_m$  normal to the flow. Equations for thermal resistances of a few common shapes are given in Table 2. Mathematical solutions to many heat conduction problems are addressed by Carslaw and Jaeger (1959). Complicated problems can be solved by graphical or numerical methods such as described by Croft and Lilley (1977), Adams and Rogers (1973), and Patankar (1980).

**Analogy to Electrical Conduction.** Equation (2) is analogous to Ohm's law for electrical circuits: thermal current (heat flow) in a **thermal circuit** is directly proportional to the thermal potential (temperature difference) and inversely proportional to the thermal resistance. This electrical-thermal analogy can be used for heat conduction in complex shapes that resist solution by exact analytical means. The thermal circuit concept is also useful for problems involving combined conduction, convection, and radiation.

**OVERALL HEAT TRANSFER**

In most steady-state heat transfer problems, more than one heat transfer mode is involved. The various heat transfer coefficients may be combined into an overall coefficient so that the total heat transfer can be calculated from the terminal temperatures. The solution to this problem is much simpler if the concept of a thermal circuit is employed.

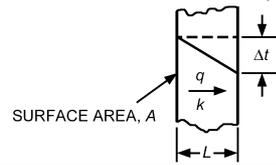

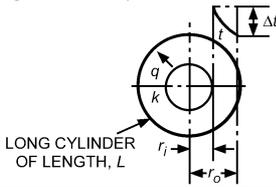

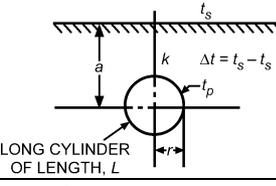

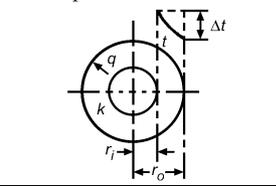

**Local Overall Heat Transfer Coefficient—Resistance Method**

Consider heat transfer from one fluid to another by a three-step steady-state process: from a warmer fluid to a solid wall, through the wall, then to a colder fluid. An **overall heat transfer coefficient  $U$**  based on the difference between the bulk temperatures  $t_1 - t_2$  of the two fluids is defined as follows:

$$q = UA(t_1 - t_2) \tag{3}$$

where  $A$  is the surface area. Because Equation (3) is a definition of  $U$ , the surface area  $A$  on which  $U$  is based is arbitrary; it should always be specified in referring to  $U$ .

**Table 2 Solutions for Some Steady-State Thermal Conduction Problems**

System	$R$ in Equation $q = \Delta t/R$
Flat wall or curved wall if curvature is small (wall thickness less than 0.1 of inside diameter) 	$R = \frac{L}{kA}$
Radial flow through a right circular cylinder 	$R = \frac{\ln(r_o / r_i)}{2\pi kL}$
Buried cylinder 	$R = \frac{\ln \left[ (a + \sqrt{a^2 - r^2}) / r \right]}{2\pi kL}$ $= \frac{\cosh^{-1}(a/r)}{2\pi kL} \quad (L \gg 2r)$
Radial flow in a hollow sphere 	$R = \frac{(1/r_i - 1/r_o)}{4\pi k}$
$L, r, a$ = dimensions, m $k$ = thermal conductivity at average material temperature, W/(m·K) $A$ = surface area, m <sup>2</sup>	

The temperature drops across each part of the heat flow path are

$$\begin{aligned}
 t_1 - t_{s1} &= qR_1 \\
 t_{s1} - t_{s2} &= qR_2 \\
 t_{s2} - t_2 &= qR_3
 \end{aligned}$$

where  $t_{s1}$ , and  $t_{s2}$  are the warm and cold surface temperatures of the wall, respectively, and  $R_1, R_2$ , and  $R_3$  are the thermal resistances. Because the same quantity of heat flows through each thermal resistance, these equations combined yield the following:

$$\frac{t_1 - t_2}{q} = \frac{1}{UA} = R_1 + R_2 + R_3 \quad (4)$$

As shown above, the equations are analogous to those for electrical circuits; for thermal current flowing through  $n$  resistances in *series*, the resistances are additive.

$$R_o = R_1 + R_2 + R_3 + \dots + R_n \quad (5)$$

Similarly, **conductance** is the reciprocal of resistance, and for heat flow through resistances in *parallel*, the conductances are additive:

$$C = \frac{1}{R_o} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \dots + \frac{1}{R_n} \quad (6)$$

For convection, the thermal resistance is inversely proportional to the **convection coefficient**  $h_c$  and the applicable surface area:

$$R_c = \frac{1}{h_c A} \quad (7)$$

The thermal resistance for radiation is written similarly to that for convection:

$$R_r = \frac{1}{h_r A} \quad (8)$$

The **radiation coefficient**  $h_r$  is a function of the temperatures, radiation properties, and geometrical arrangement of the enclosure and the body in question.

**Resistance Method Analysis.** Analysis by the resistance method can be illustrated by considering heat transfer from air outside to cold water inside an insulated pipe. The temperature gradients and the nature of the resistance analysis are shown in Figure 1.

Because air is sensibly transparent to radiation, some heat transfer occurs by both radiation and convection to the outer insulation surface. The mechanisms act in parallel on the air side. The total transfer then passes through the insulating layer and the pipe wall by thermal conduction, and then by convection and radiation into the cold water stream. (Radiation is not significant on the water side because liquids are sensibly opaque to radiation, although water transmits energy in the visible region.) The contact resistance between the insulation and the pipe wall is assumed negligible.

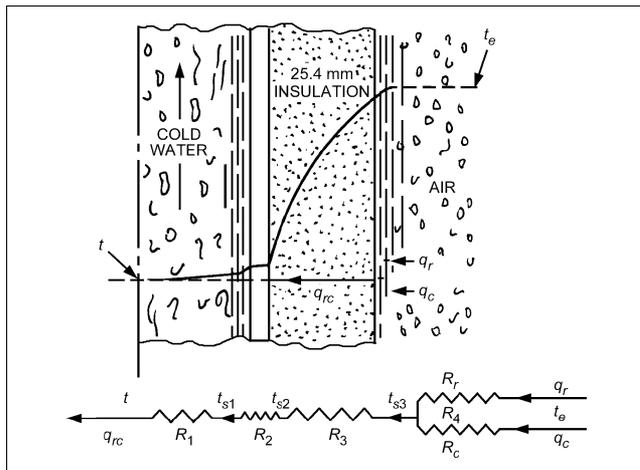

Fig. 1 Thermal Circuit Diagram for Insulated Cold Water Line

The heat transfer rate  $q_{rc}$  for a given length  $L$  of pipe may be thought of as the sum of the rates  $q_r$  and  $q_c$  flowing through the parallel resistances  $R_r$  and  $R_c$  associated with the surface radiation and convection coefficients. The total flow then proceeds through the resistance  $R_3$  offered to thermal conduction by the insulation, through the pipe wall resistance  $R_2$ , and into the water stream through the convection resistance  $R_1$ . Note the analogy to direct-current electricity. A temperature (potential) drop is required to overcome resistances to the flow of thermal current. The total resistance to heat transfer  $R_o$  is the sum of the individual resistances:

$$R_o = R_1 + R_2 + R_3 + R_4 \quad (9)$$

where the resultant parallel resistance  $R_4$  is obtained from

$$\frac{1}{R_4} = \frac{1}{R_r} + \frac{1}{R_c} \quad (10)$$

If the individual resistances can be evaluated, the total resistance can be obtained from this relation. The heat transfer rate for the length of pipe  $L$  can be established by

$$q_{rc} = \frac{t_e - t_i}{R_o} \quad (11)$$

For a unit length of the pipe, the heat transfer rate is

$$\frac{q_{rc}}{L} = \frac{t_e - t_i}{R_o L} \quad (12)$$

The temperature drop  $\Delta t$  through each individual resistance may then be calculated from the relation:

$$\Delta t_n = R_n q_{rc} \quad (13)$$

where  $n = 1, 2, \text{ and } 3$ .

### Mean Temperature Difference

When heat is exchanged between two fluids flowing through a heat exchanger, the local temperature difference  $\Delta t$  varies along the flow path. Heat transfer may be calculated using

$$q = UA \Delta t_m \quad (14)$$

where  $U$  is the overall uniform coefficient of heat transfer from fluid to fluid,  $A$  is the area associated with the coefficient  $U$ , and  $\Delta t_m$  is the appropriate mean temperature difference.

For parallel flow or counterflow exchangers and for any exchanger in which one fluid temperature is substantially constant, the mean temperature difference is

$$\Delta t_m = \frac{\Delta t_1 - \Delta t_2}{\ln(\Delta t_1 / \Delta t_2)} = \frac{\Delta t_1 - \Delta t_2}{2.3 \log(\Delta t_1 / \Delta t_2)} \quad (15)$$

where  $\Delta t_1$  and  $\Delta t_2$  are the temperature differences between the fluids at each end of the heat exchanger.  $\Delta t_m$  is called the **logarithmic mean temperature difference**. For the special case of  $\Delta t_1 = \Delta t_2$  (possible only with a counterflow heat exchanger with equal capacities), which leads to an indeterminate form of Equation (15),  $\Delta t_m = \Delta t_1 = \Delta t_2$ .

Equation (15) for  $\Delta t_m$  is true only if the overall coefficient and the specific heat of the fluids are constant through the heat exchanger, and no heat losses occur (often well-approximated in practice). Parker et al. (1969) give a procedure for cases with variable overall coefficient  $U$ .

Calculations using Equation (14) and  $\Delta t_m$  are convenient when terminal temperatures are known. In many cases, however, the temperatures of the fluids leaving the exchanger are not known. To avoid trial-and-error calculations, an alternate method involves the use of three nondimensional parameters, defined as follows:

### 1. Exchanger Heat Transfer Effectiveness $\varepsilon$

$$\varepsilon = \frac{(t_{hi} - t_{ho})}{(t_{hi} - t_{ci})} \quad \text{when } C_h = C_{min}$$

$$\varepsilon = \frac{(t_{co} - t_{ci})}{(t_{hi} - t_{ci})} \quad \text{when } C_c = C_{min}$$
(16)

where

- $C_h = (\dot{m} c_p)_h$  = hot fluid capacity rate, W/K
- $C_c = (\dot{m} c_p)_c$  = cold fluid capacity rate, W/K
- $C_{min}$  = smaller of capacity rates  $C_h$  and  $C_c$
- $t_h$  = terminal temperature of hot fluid, °C. Subscript  $i$  indicates entering condition; subscript  $o$  indicates leaving condition.
- $t_c$  = terminal temperature of cold fluid, °C. Subscripts  $i$  and  $o$  are the same as for  $t_h$ .

### 2. Number of Exchanger Heat Transfer Units (NTU)

$$NTU = \frac{AU_{avg}}{C_{min}} = \frac{1}{C_{min}} \int_A U dA$$
(17)

where  $A$  is the area used to define overall coefficient  $U$ .

### 3. Capacity Rate Ratio $Z$

$$Z = \frac{C_{min}}{C_{max}}$$
(18)

For a given exchanger, the heat transfer effectiveness can generally be expressed for a given exchanger as a function of the number of transfer units and the capacity rate ratio:

$$\varepsilon = f(NTU, Z, \text{flow arrangement})$$
(19)

The effectiveness is independent of the temperatures in the exchanger. For any exchanger in which the capacity rate ratio  $Z$  is zero (where one fluid undergoes a phase change; e.g., in a condenser or evaporator), the effectiveness is

$$\varepsilon = 1 - \exp(-NTU)$$
(20)

Heat transferred can be determined from

$$q = C_h(t_{hi} - t_{ho}) = C_c(t_{co} - t_{ci})$$
(21)

Combining Equations (16) and (21) produces an expression for heat transfer rate in terms of entering fluid temperatures:

$$q = \varepsilon C_{min}(t_{hi} - t_{ci})$$
(22)

The proper mean temperature difference for Equation (14) is then given by

$$\Delta t_m = \frac{(t_{hi} - t_{ci})\varepsilon}{NTU}$$
(23)

The effectiveness for **parallel flow exchangers** is

$$\varepsilon = \frac{1 - \exp[-NTU(1 + Z)]}{1 + Z}$$
(24)

For  $Z = 1$ ,

$$\varepsilon = \frac{1 - \exp(-2 NTU)}{2}$$
(25)

The effectiveness for **counterflow exchangers** is

$$\varepsilon = \frac{1 - \exp[-NTU(1 - Z)]}{1 - Z \exp[-NTU(1 - Z)]}$$
(26)

$$\varepsilon = \frac{NTU}{1 + NTU} \quad \text{for } Z = 1$$
(27)

Incropera and DeWitt (1996) and Kays and London (1984) show the relations of  $\varepsilon$ , NTU, and  $Z$  for other flow arrangements. These authors and Afgan and Schlunder (1974) present graphical representations for convenience.

## TRANSIENT HEAT FLOW

Often, the heat transfer and temperature distribution under unsteady-state (varying with time) conditions must be known. Examples are (1) cold storage temperature variations on starting or stopping a refrigeration unit; (2) variation of external air temperature and solar irradiation affecting the heat load of a cold storage room or wall temperatures; (3) the time required to freeze a given material under certain conditions in a storage room; (4) quick freezing of objects by direct immersion in brines; and (5) sudden heating or cooling of fluids and solids from one temperature to a different temperature.

The equations describing transient temperature distribution and heat transfer are presented in this section. Numerical methods are the simplest means of solving these equations because numerical data are easy to obtain. However, with some numerical solutions and off-the-shelf software, the physics that drives the energy transport can be lost. Thus, analytical solution techniques are also included in this section.

The fundamental equation for unsteady-state conduction in solids or fluids in which there is no substantial motion is

$$\frac{\partial t}{\partial \tau} = \alpha \left( \frac{\partial^2 t}{\partial x^2} + \frac{\partial^2 t}{\partial y^2} + \frac{\partial^2 t}{\partial z^2} \right)$$
(28)

where thermal diffusivity  $\alpha$  is the ratio  $k/\rho c_p$ ;  $k$  is thermal conductivity;  $\rho$ , density; and  $c_p$ , specific heat. If  $\alpha$  is large (high conductivity, low density and specific heat, or both), heat will diffuse faster.

One of the most elementary transient heat transfer models predicts the rate of temperature change of a body or material being held at constant volume with uniform temperature, such as a well-stirred reservoir of fluid whose temperature is changing because of a net rate of heat gain or loss:

$$q_{net} = (M c_p) \frac{dt}{d\tau}$$
(29)

where  $M$  is the mass of the body,  $c_p$  is the specific heat at constant pressure, and  $q_{net}$  is the net heat transfer rate to the substance (heat transfer into the substance is positive, and heat transfer out of the substance is negative). Equation (29) is applicable when the pressure around the substance is constant; if the volume of the substance is constant,  $c_p$  should be replaced by the constant volume specific heat  $c_v$ . It should be noted that with the density of solids and liquids being almost constant, the two specific heats are almost equal. The term  $q_{net}$  may include heat transfer by conduction, convection, or radiation and is the difference between the heat transfer rates into and out of the body.

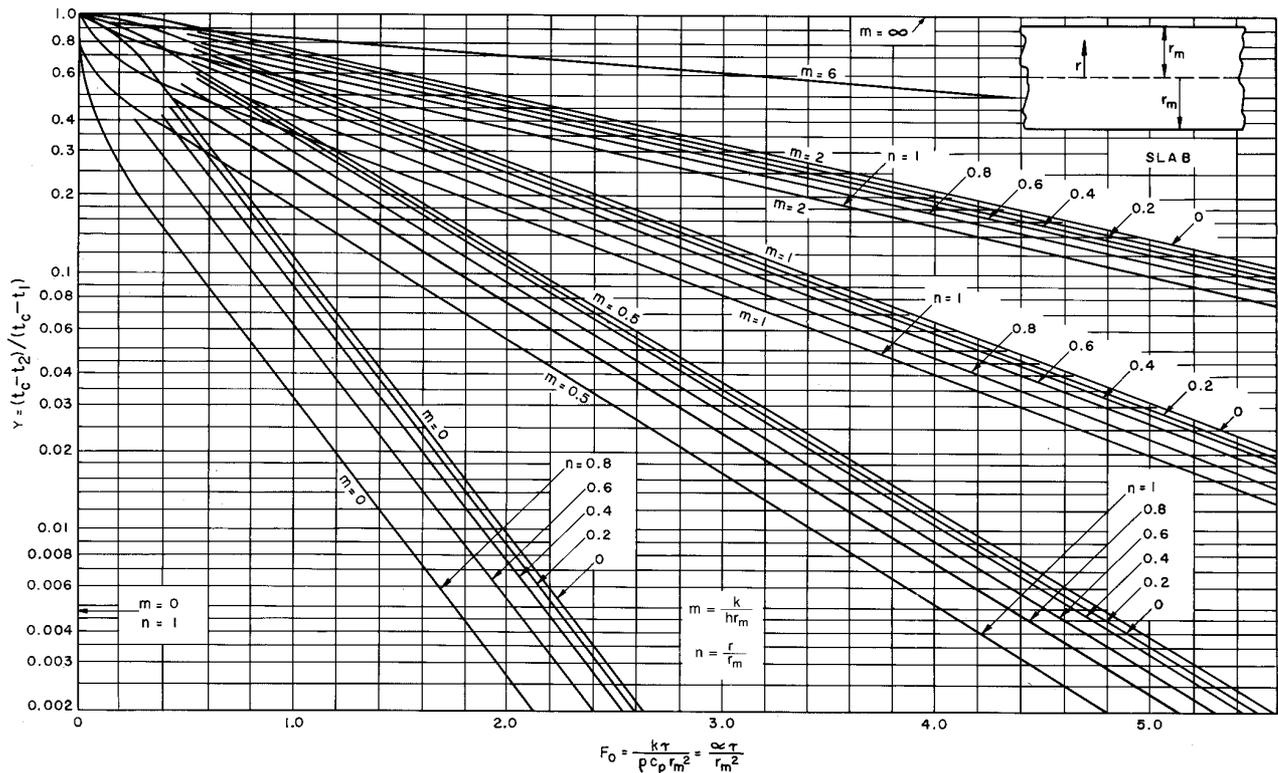

Fig. 2 Transient Temperatures for Infinite Slab

From Equations (28) and (29), it is possible to derive expressions for temperature and heat flow variations at different instants and different locations. Most common cases have been solved and presented in graphical forms (Jakob 1957, Schneider 1964, Myers 1971). In other cases, it is simpler to use numerical methods (Croft and Lilley 1977, Patankar 1980). When convective boundary conditions are required in the solution of Equations (28) and (29),  $h$  values based on steady-state correlations are often used. However, this approach may not be valid when rapid transients are involved.

### Estimating Cooling Times

Cooling times for materials can be estimated (McAdams 1954) by Gurnie-Lurie charts (Figures 2, 3, and 4), which are graphical solutions for the heating or cooling of infinite slabs, infinite cylinders, and spheres. These charts assume an initial uniform temperature distribution and no change of phase. They apply to a body exposed to a constant temperature fluid with a constant surface convection coefficient of  $h$ .

Using Figures 2, 3, and 4, it is possible to estimate both the temperature at any point and the average temperature in a homogeneous mass of material as a function of time in a cooling process. It is possible to estimate cooling times for rectangular-shaped solids, cubes, cylinders, and spheres.

From the point of view of heat transfer, a cylinder insulated on its ends behaves like a cylinder of infinite length, and a rectangular solid insulated so that only two parallel faces allow heat transfer behaves like an infinite slab. A thin slab or a long, thin cylinder may be also considered infinite objects.

Consider a slab having insulated edges being cooled. If the cooling time is the time required for the center of the slab to reach a temperature of  $t_2$ , the cooling time can be calculated as follows:

1. Evaluate the temperature ratio  $(t_c - t_2)/(t_c - t_1)$ .

where

- $t_c$  = temperature of cooling medium
- $t_1$  = initial temperature of product
- $t_2$  = final temperature of product at center

Note that in Figures 2, 3, and 4, the temperature ratio  $(t_c - t_2)/(t_c - t_1)$  is designated as  $Y$  to simplify the equations.

2. Determine the radius ratio  $r/r_m$  designated as  $n$  in Figures 2, 3, and 4.

where

- $r$  = distance from centerline
- $r_m$  = half thickness of slab

3. Evaluate the resistance ratio  $k/hr_m$  designated as  $m$  in Figures 2, 3, and 4.

where

- $k$  = thermal conductivity of material
- $h$  = heat transfer coefficient

4. From Figure 2 for infinite slabs, select the appropriate value of  $kτ/ρ c_p r_m^2$  designated as  $F_0$  in Figures 2, 3, and 4.

where

- $τ$  = time elapsed
- $c_p$  = specific heat
- $ρ$  = density

5. Determine  $τ$  from the value of  $kτ/ρ c_p r_m^2$ .

### Multidimensional Temperature Distribution

The solution for semi-infinite slabs and cylinders (shown in Figures 2, 3, and 4) can be used to find the temperatures in finite rectangular solids or cylinders.

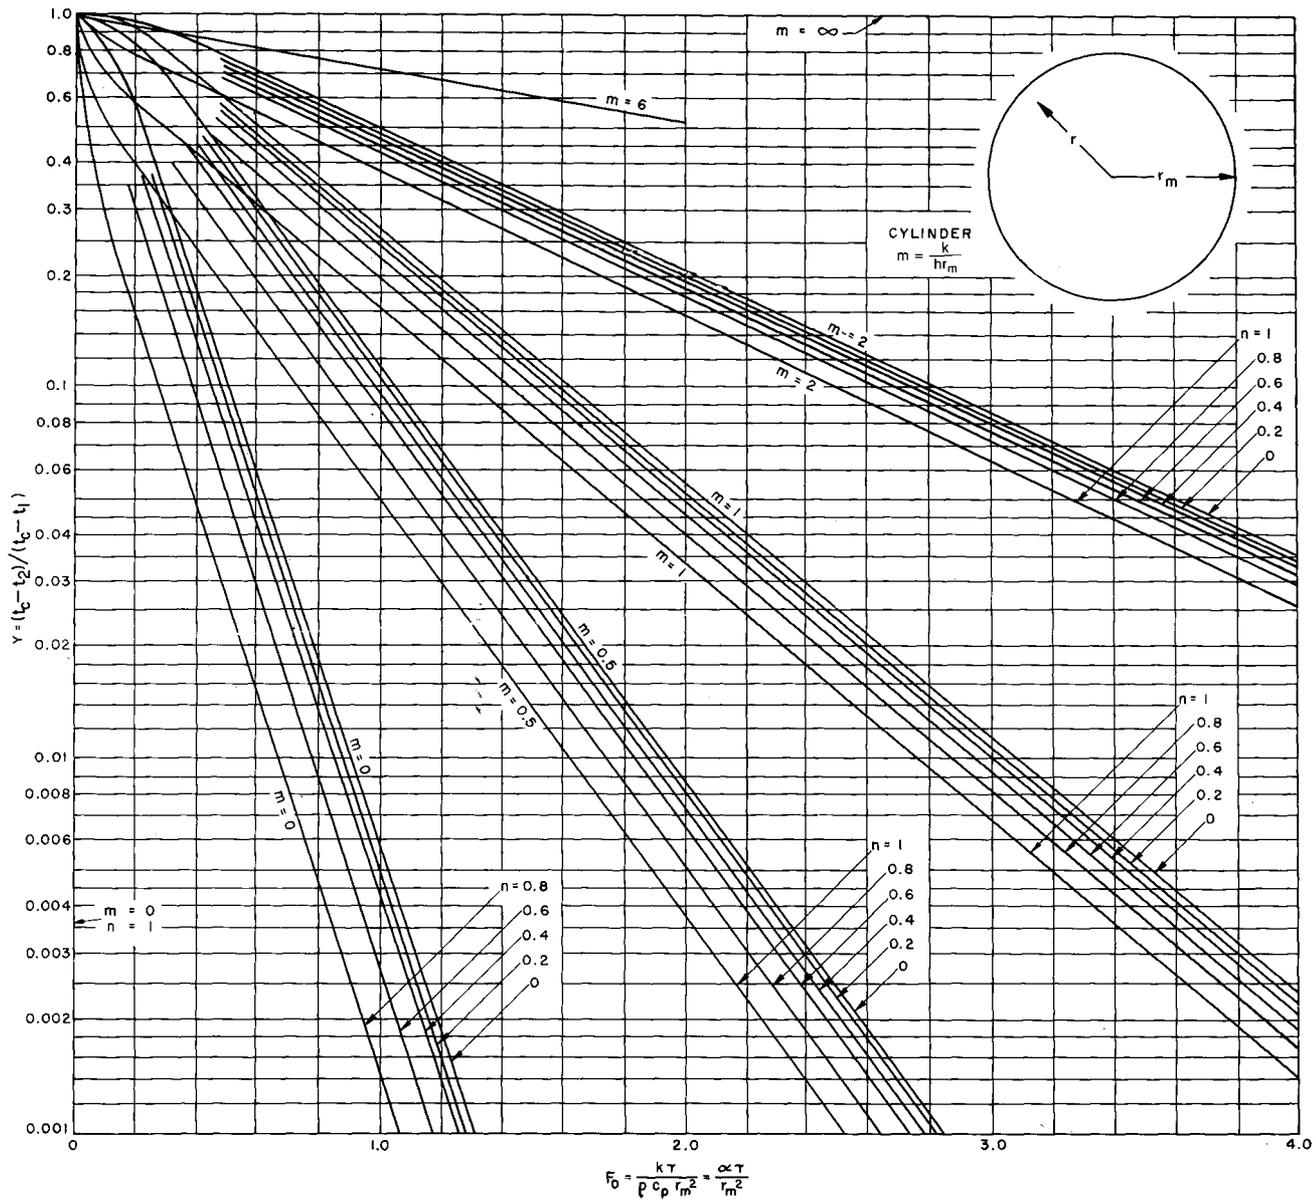

Fig. 3 Transient Temperatures for Infinite Cylinder

The temperature in the finite object can be calculated from the temperature ratio  $Y$  of the infinite objects that intersect to form the finite object. The product of the temperature ratios of the infinite objects is the temperature ratio of the finite object; for example, for the finite cylinder of Figure 5,

$$Y_{fc} = Y_{is} Y_{ic} \tag{30}$$

where

- $Y_{fc}$  = temperature ratio of finite cylinder
- $Y_{is}$  = temperature ratio of infinite slab
- $Y_{ic}$  = temperature ratio of infinite cylinder

For a finite rectangular solid,

$$Y_{frs} = (Y_{is})_1 (Y_{is})_2 (Y_{is})_3 \tag{31}$$

where  $Y_{frs}$  = temperature ratio of finite rectangular solid, and subscripts 1, 2, and 3 designate three infinite slabs. The convective heat transfer coefficients associated with one pair of parallel surfaces

need not be equal to the coefficient associated with another pair. However, the temperature of the fluid adjacent to every surface should be the same. In evaluating the resistance ratio and the Fourier number  $Fo$ , the appropriate values of the heat transfer coefficient and the characteristic dimension should be used.

### Heat Exchanger Transients

Determination of the transient behavior of heat exchangers is becoming increasingly important in evaluating the dynamic behavior of heating and air-conditioning systems. Many studies of the transient behavior of counterflow and parallel flow heat exchangers have been conducted; some are listed in the section on Bibliography.

### THERMAL RADIATION

Radiation, one of the basic mechanisms for energy transfer between different temperature regions, is distinguished from conduction and convection in that it does not depend on an intermediate

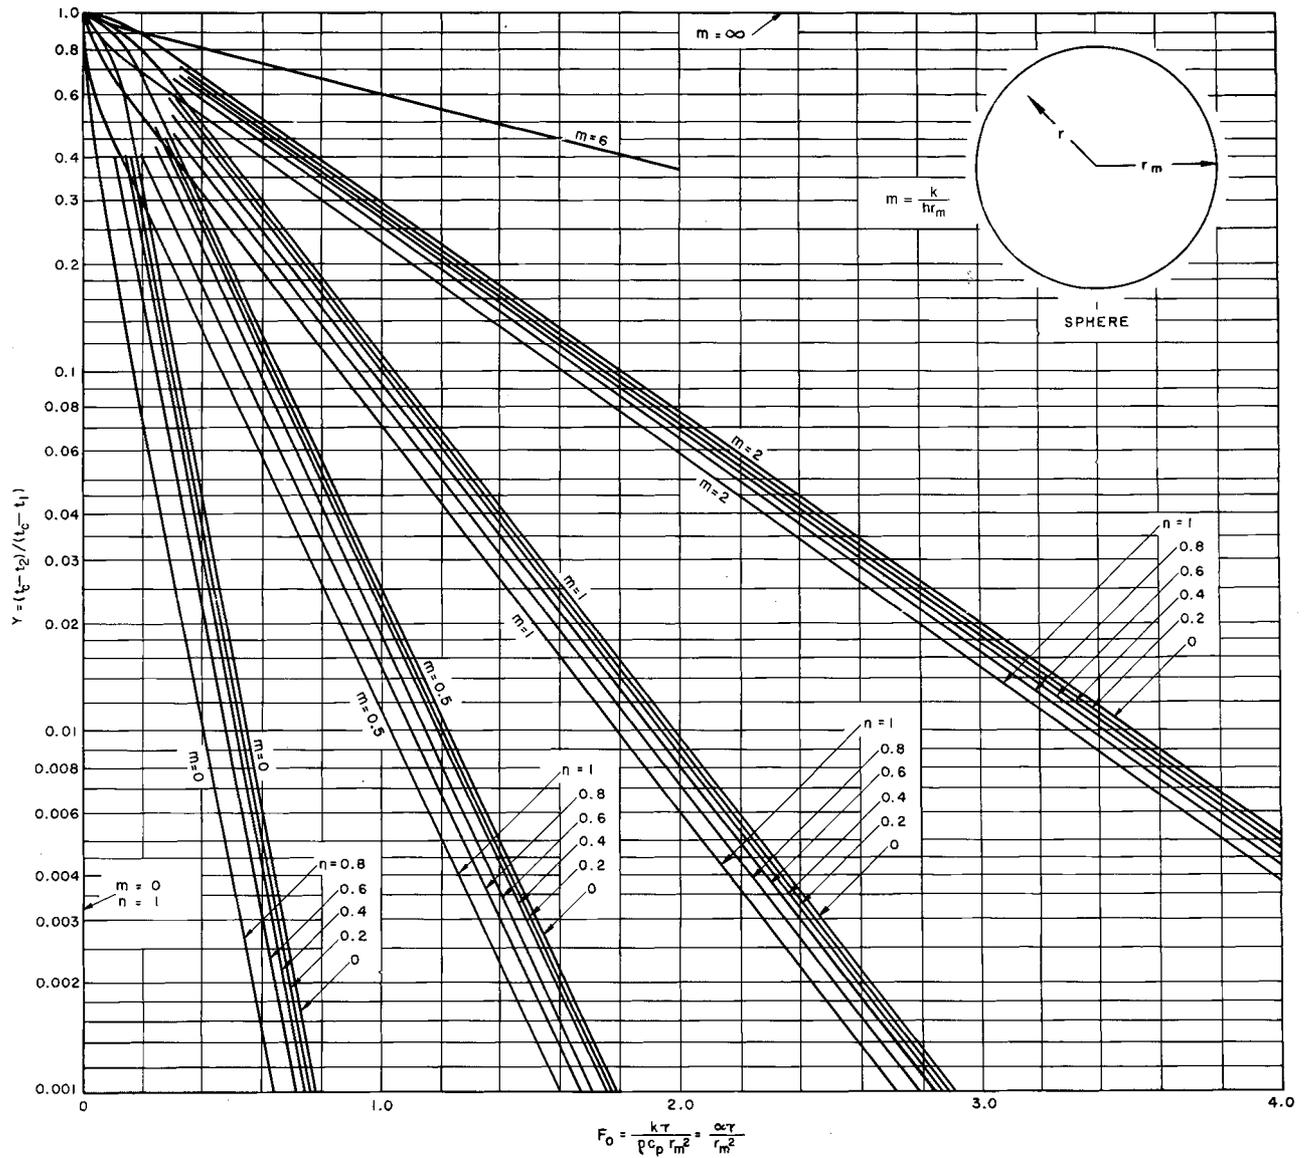

Fig. 4 Transient Temperatures for Spheres

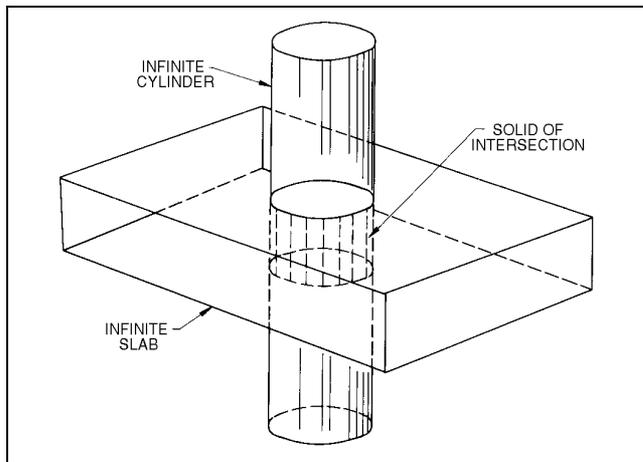

Fig. 5 Finite Cylinder of Intersection from Intersection of Infinite Cylinder and Infinite Slab

material as a carrier of energy but rather is impeded by the presence of material between the regions. The radiation energy transfer process is the consequence of energy-carrying electromagnetic waves that are emitted by atoms and molecules due to changes in their energy content. The amount and characteristics of radiant energy emitted by a quantity of material depend on the nature of the material, its microscopic arrangement, and its absolute temperature. Although rate of energy emission is independent of the surroundings, the **net** energy transfer rate depends on the temperatures and spatial relationships of the surface and its surroundings.

**Blackbody Radiation**

The rate of thermal radiant energy emitted by a surface depends on its absolute temperature. A surface is called **black** if it can absorb all incident radiation. The total energy emitted per unit time per unit area of black surface  $W_b$  to the hemispherical region above it is given by the **Stefan-Boltzmann law**.

$$W_b = \sigma T^4 \tag{32}$$

Table 3 Emittances and Absorptances for Some Surfaces<sup>a</sup>

Class	Surfaces	Total Normal Emittance <sup>b</sup>		Absorptance for Solar Radiation
		At 10 to 40 °C	At 500 °C	
1	A small hole in a large box, sphere, furnace, or enclosure .....	0.97 to 0.99	0.97 to 0.99	0.97 to 0.99
2	Black nonmetallic surfaces such as asphalt, carbon, slate, paint, paper .....	0.90 to 0.98	0.90 to 0.98	0.85 to 0.98
3	Red brick and tile, concrete and stone, rusty steel and iron, dark paints (red, brown, green, etc.) .....	0.85 to 0.95	0.75 to 0.90	0.65 to 0.80
4	Yellow and buff brick and stone, firebrick, fireclay .....	0.85 to 0.95	0.70 to 0.85	0.50 to 0.70
5	White or light cream brick, tile, paint or paper, plaster, whitewash .....	0.85 to 0.95	0.60 to 0.75	0.30 to 0.50
6	Window glass .....	0.90	—	c
7	Bright aluminum paint; gilt or bronze paint .....	0.40 to 0.60	—	0.30 to 0.50
8	Dull brass, copper, or aluminum; galvanized steel; polished iron .....	0.20 to 0.30	0.30 to 0.50	0.40 to 0.65
9	Polished brass, copper, monel metal .....	0.02 to 0.05	0.05 to 0.15	0.30 to 0.50
10	Highly polished aluminum, tin plate, nickel, chromium .....	0.02 to 0.04	0.05 to 0.10	0.10 to 0.40
11	Selective surfaces			
	Stainless steel wire mesh .....	0.23 to 0.28	—	0.63 to 0.86
	White painted surface .....	0.92	—	0.23 to 0.49
	Copper treated with solution of NaClO <sub>2</sub> and NaOH .....	0.13	—	0.87
	Copper, nickel, and aluminum plate with CuO coating .....	0.09 to 0.21	—	0.08 to 0.93

<sup>a</sup>See also Chapter 36, McAdams (1954), and Siegel and Howell (1981).

<sup>c</sup>Absorbs 4 to 40% depending on its transmittance.

<sup>b</sup>Hemispherical and normal emittance are unequal in many cases. The hemispherical emittance may vary from up to 30% greater for polished reflectors to 7% lower for nonconductors.

where  $W_b$  is the total rate of energy emission per unit area, and  $\sigma$  is the Stefan-Boltzmann constant [ $5.670 \times 10^{-8} \text{ W}/(\text{m}^2 \cdot \text{K}^4)$ ].

The heat radiated by a body comprises electromagnetic waves of many different frequencies or wavelengths. Planck showed that the spectral distribution of the energy radiated by a blackbody is

$$W_{b\lambda} = \frac{C_1 \lambda^{-5}}{e^{\frac{C_2}{\lambda T}} - 1} \quad (33)$$

where

- $W_{b\lambda}$  = monochromatic emissive power of blackbody,  $\text{W}/\text{m}^3$
- $\lambda$  = wavelength,  $\mu\text{m}$
- $T$  = temperature,  $\text{K}$
- $C_1$  = first Planck's law constant =  $3.742 \times 10^{-16} \text{ W} \cdot \text{m}^2$
- $C_2$  = second Planck's law constant =  $0.014388 \text{ m} \cdot \text{K}$

$W_{b\lambda}$  is the **monochromatic emissive power**, defined as the energy emitted per unit time per unit surface area at wavelength  $\lambda$  per unit wavelength interval around  $\lambda$ ; that is, the energy emitted per unit time per unit surface area in the interval  $d\lambda$  is equal to  $W_{b\lambda}d\lambda$ .

The Stefan-Boltzmann equation can be obtained by integrating Planck's equation:

$$W_b = \sigma T^4 = \int_0^\infty W_{b\lambda} d\lambda \quad (34)$$

Wien showed that the wavelength of maximum emissive power multiplied by the absolute temperature is a constant:

$$\lambda_{max} T = 2898 \mu\text{m} \cdot \text{K} \quad (35)$$

where  $\lambda_{max}$  is the wavelength at which the monochromatic emissive power is a maximum and not the maximum wavelength. Equation (35) is known as **Wien's displacement law**. According to this law, the maximum spectral emissive power is displaced to shorter wavelengths with increasing temperature, such that significant emission eventually occurs over the entire visible spectrum as shorter wavelengths become more prominent. For additional details, see Incropera and DeWitt (1996).

**Actual Radiation**

Substances and surfaces diverge variously from the Stefan-Boltzmann and Planck laws.  $W_b$  and  $W_{b\lambda}$  are the maximum emissive powers at a surface temperature. Actual surfaces emit and absorb

less than these maximums and are called **nonblack**. The emissive power of a nonblack surface at temperature  $T$  radiating to the hemispherical region above it is written as

$$W = \epsilon W_b = \epsilon \sigma T^4 \quad (36)$$

where  $\epsilon$  is known as the **hemispherical emittance**. The term emittance conforms to physical and electrical terminology; the suffix "ance" denotes a property of a piece of material as it exists. The ending "ivity" denotes a property of the bulk material independent of geometry or surface condition. Thus, emittance, reflectance, absorptance, and transmittance refer to actual pieces of material. Emissivity, reflectivity, absorptivity, and transmissivity refer to the properties of materials that are optically smooth and thick enough to be opaque.

The emittance is a function of the material, the condition of its surface, and the temperature of the surface. Table 3 lists selected values; Siegel and Howell (1981) and Modest (1993) have more extensive lists.

The monochromatic emissive power of a nonblack surface is similarly written as

$$W_\lambda = \epsilon_\lambda W_{b\lambda} = \epsilon_\lambda \left( \frac{C_1 \lambda^{-5}}{e^{\frac{C_2}{\lambda T}} - 1} \right) \quad (37)$$

where  $\epsilon_\lambda$  is the monochromatic hemispherical emittance. The relationship between  $\epsilon$  and  $\epsilon_\lambda$  is given by

$$\epsilon = \frac{1}{\sigma T^4} \int_0^\infty W_\lambda d\lambda = \frac{1}{\sigma T^4} \int_0^\infty \epsilon_\lambda W_{b\lambda} d\lambda$$

or

$$\epsilon = \frac{1}{\sigma T^4} \int_0^\infty \epsilon_\lambda W_{b\lambda} d\lambda \quad (38)$$

If  $\epsilon_\lambda$  does not depend on  $\lambda$ , then, from Equation (38),  $\epsilon = \epsilon_\lambda$ . Surfaces with this characteristic are called **gray**. Gray surface characteristics are often assumed in calculations. Several classes of surfaces approximate this condition in some regions of the spectrum. The simplicity is desirable, but care must be exercised, especially if

temperatures are high. Assumption of grayness is sometimes made because of the absence of information relating  $\epsilon_\lambda$  and  $\lambda$ .

When radiant energy falls on a surface, it can be absorbed, reflected, or transmitted through the material. Therefore, from the first law of thermodynamics,

$$\alpha + \tau + \rho = 1 \quad (39)$$

where

- $\alpha$  = fraction of incident radiation absorbed or **absorptance**
- $\tau$  = fraction of incident radiation transmitted or **transmittance**
- $\rho$  = fraction of incident radiation reflected or **reflectance**

If the material is opaque, as most solids are in the infrared,  $\tau = 0$  and  $\alpha + \rho = 1$ . For a black surface,  $\alpha = 1$ ,  $\rho = 0$ , and  $\tau = 0$ . Platinum black and gold black are as black as any actual surface and have absorptances of about 98% in the infrared. Any desired degree of blackness can be simulated by a small hole in a large enclosure. Consider a ray of radiant energy entering the opening. It will undergo many internal reflections and be almost completely absorbed before it has a reasonable probability of passing back out of the opening.

Certain flat black paints also exhibit emittances of 98% over a wide range of conditions. They provide a much more durable surface than gold or platinum black and are frequently used on radiation instruments and as standard reference in emittance or reflectance measurements.

**Kirchhoff's law** relates emittance and absorptance of any opaque surface from thermodynamic considerations; it states that for any surface where the incident radiation is independent of angle or where the surface is diffuse,  $\epsilon_\lambda = \alpha_\lambda$ . If the surface is gray, or the incident radiation is from a black surface at the same temperature, then  $\epsilon = \alpha$  as well, but many surfaces are not gray. For most surfaces listed in Table 3, absorptance for solar radiation is different from emittance for low-temperature radiation. This is because the wavelength distributions are different in the two cases, and  $\epsilon_\lambda$  varies with wavelength.

The foregoing discussion relates to total hemispherical radiation from surfaces. Energy distribution over the hemispherical region above the surface also has an important effect on the rate of heat transfer in various geometric arrangements.

**Lambert's law** states that the emissive power of radiant energy over a hemispherical surface above the emitting surface varies as the cosine of the angle between the normal to the radiating surface and the line joining the radiating surface to the point of the hemispherical surface. This radiation is **diffuse radiation**. The Lambert emissive power variation is equivalent to assuming that radiation from a surface in a direction other than normal occurs as if it came from an equivalent area with the same emissive power (per unit area) as the original surface. The equivalent area is obtained by projecting the original area onto a plane normal to the direction of radiation. Black surfaces obey the Lambert law exactly. The law is approximate for many actual radiation and reflection processes, especially those involving rough surfaces and nonmetallic materials. Most radiation analyses are based on the assumption of gray diffuse radiation and reflection.

In estimating heat transfer rates between surfaces of different geometries, radiation characteristics, and orientations, it is usually assumed that

- All surfaces are gray or black
- Radiation and reflection are diffuse
- Properties are uniform over the surfaces
- Absorptance equals emittance and is independent of the temperature of the source of incident radiation
- The material in the space between the radiating surfaces neither emits nor absorbs radiation

These assumptions greatly simplify problems, although results must be considered approximate.

### Angle Factor

The distribution of radiation from a surface among the surfaces it irradiates is indicated by a quantity variously called an interception, a view, a configuration, a shape factor, or an angle factor. In terms of two surfaces  $i$  and  $j$ , the **angle factor**  $F_{ij}$  from surface  $i$  to surface  $j$  is the ratio of the radiant energy leaving surface  $i$  and directly reaching surface  $j$  to the total radiant energy leaving surface  $i$ . The angle factor from  $j$  to  $i$  is similarly defined, merely by interchanging the roles of  $i$  and  $j$ . This second angle factor is not, in general, numerically equal to the first. However, the reciprocity relation  $F_{ij}A_i = F_{ji}A_j$ , where  $A$  is the surface area, is always valid. Note that a concave surface may "see itself" ( $F_{ii} \neq 0$ ), and that if  $n$  surfaces form an enclosure,

$$\sum_{j=1}^n F_{ij} = 1 \quad (40)$$

The angle factor  $F_{12}$  between two surfaces is

$$F_{12} = \frac{1}{A_1} \int_{A_1} \int_{A_2} \frac{\cos \phi_1 \cos \phi_2}{\pi r^2} dA_1 dA_2 \quad (41)$$

where  $dA_1$  and  $dA_2$  are elemental areas of the two surfaces,  $r$  is the distance between  $dA_1$  and  $dA_2$ , and  $\phi_1$  and  $\phi_2$  are the angles between the respective normals to  $dA_1$  and  $dA_2$  and the connecting line  $r$ . Numerical, graphical, and mechanical techniques can solve this equation (Siegel and Howell 1981, Modest 1993). Numerical values of the angle factor for common geometries are given in Figure 6.

### Calculation of Radiant Exchange Between Surfaces Separated by Nonabsorbing Media

A surface radiates energy at a rate independent of its surroundings and absorbs and reflects incident energy at a rate dependent on its surface condition. The net energy exchange per unit area is denoted by  $q$  or  $q_j$  for unit area  $A_j$ . It is the rate of emission of the surface minus the total rate of absorption at the surface from all radiant effects in its surroundings, possibly including the return of some of its own emission by reflection off its surroundings. The rate at which energy must be supplied to the surface by other exchange processes if its temperature is to remain constant is  $q$ ; therefore, to define  $q$ , the total radiant surroundings (in effect, an enclosure) must be specified.

Several methods have been developed to solve certain problems. To calculate the radiation exchange at each surface of an enclosure of  $n$  opaque surfaces by simple, general equations convenient for machine calculation, two terms must be defined:

- $G$  = irradiation; total radiation incident on surface per unit time and per unit area
- $J$  = radiosity; total radiation that leaves surface per unit time and per unit area

The radiosity is the sum of the energy emitted and the energy reflected:

$$J = \epsilon W_b + \rho G \quad (42)$$

Because the transmittance is zero, the reflectance is

$$\rho = 1 - \alpha = 1 - \epsilon$$

Thus,

$$J = \epsilon W_b + (1 - \epsilon)G \quad (43)$$

The net energy lost by a surface is the difference between the radiosity and the irradiation:

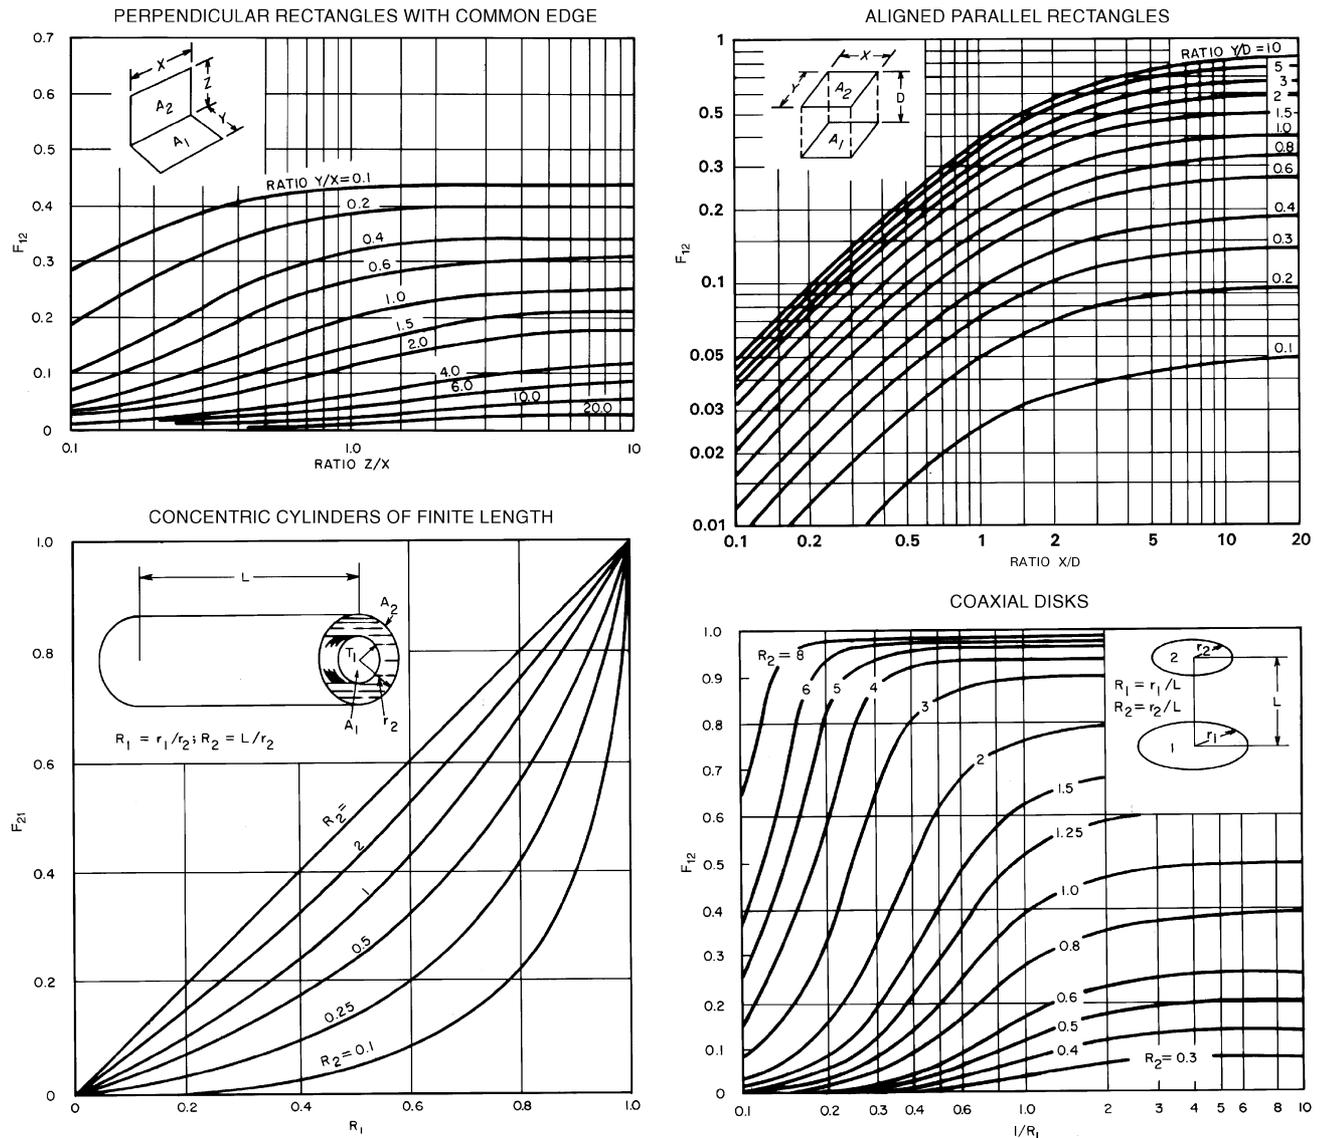

Fig. 6 Radiation Angle Factor for Various Geometries

$$l/A = J - G = \epsilon W_b + (1 - \epsilon)G - G \quad (44)$$

Substituting for  $G$  in terms of  $J$  from Equation (43),

$$l = \frac{W_b - J}{(1 - \epsilon)/\epsilon A} \quad (45)$$

Consider an enclosure of  $n$  isothermal surfaces with areas of  $A_1, A_2, \dots, A_n$ , emittances of  $\epsilon_1, \epsilon_2, \dots, \epsilon_n$ , and reflectances of  $\rho_1, \rho_2, \dots, \rho_n$ , respectively.

The irradiation of surface  $i$  is the sum of the radiation incident on it from all  $n$  surfaces:

$$G_i A_i = \sum_{j=1}^n F_{ji} J_j A_j = \sum_{j=1}^n F_{ij} J_j A_i$$

or

$$G_i = \sum_{j=1}^n F_{ij} J_j$$

Substituting in Equation (44) yields the following simultaneous equations when each of the  $n$  surfaces is considered:

$$J_i = \epsilon_i W_{bi} + (1 - \epsilon_i) \sum_{j=1}^n F_{ij} J_j \quad i = 1, 2, \dots, n \quad (46)$$

Equation (46) can be solved manually for the unknown  $J$ s if the number of surfaces is small. The solution for more complex enclosures requires a computer.

Once the radiosities ( $J$ s) are known, the net radiant energy lost by each surface is determined from Equation (45) as

$$l_i = \frac{W_{bi} - J_i}{(1 - \epsilon_i)/\epsilon_i A}$$

If the surface is black, Equation (45) becomes indeterminate, and an alternate expression must be used, such as

$$q_i = \sum_{j=1}^n J_i A_i F_{ij} - J_j A_j F_{ji}$$

or

$$q_i = \sum_{j=1}^n F_{ij} A_i (J_i - J_j) \quad (47)$$

since

$$F_{ij} A_i = F_{ji} A_j$$

All diffuse radiation processes are included in the aforementioned enclosure method, and surfaces with special characteristics are assigned consistent properties. An opening is treated as an equivalent surface area  $A_e$  with a reflectance of zero. If energy enters the enclosure diffusely through the opening,  $A_e$  is assigned an equivalent temperature; otherwise, its temperature is taken as zero. If the loss through the opening is desired,  $q_2$  is found. A window in the enclosure is assigned its actual properties.

A surface in **radiant balance** is one for which radiant emission is balanced by radiant absorption; heat is neither removed from nor supplied to the surface. Reradiating surfaces (insulated surfaces with  $q_{net} = 0$ ), can be treated in Equation (46) as being perfectly reflective (i.e.,  $\varepsilon = 0$ ). The equilibrium temperature of such a surface can be found from

$$T_k = \left( \frac{J_k}{\sigma} \right)^{0.25}$$

once Equation (46) has been solved for the radiosities.

Use of angle factors and radiation properties as defined assumes that the surfaces are diffuse radiators—a good assumption for most nonmetals in the infrared region, but a poor assumption for highly polished metals. Subdividing the surfaces and considering the variation of radiation properties with angle of incidence improves the approximation but increases the work required for a solution.

### Radiation in Gases

Elementary gases such as oxygen, nitrogen, hydrogen, and helium are essentially transparent to thermal radiation. Their absorption and emission bands are confined mainly to the ultraviolet region of the spectrum. The gaseous vapors of most compounds, however, have absorption bands in the infrared region. Carbon monoxide, carbon dioxide, water vapor, sulfur dioxide, ammonia, acid vapors, and organic vapors absorb and emit significant amounts of energy.

Radiation exchange by opaque solids is considered a surface phenomenon. Radiant energy does, however, penetrate the surface of all materials. The absorption coefficient gives the rate of exponential attenuation of the energy. Metals have large absorption coefficients, and radiant energy penetrates less than 100 nm at most. Absorption coefficients for nonmetals are lower. Radiation may be considered a surface phenomenon unless the material is transparent. Gases have small absorption coefficients, so the path length of radiation through gas becomes very significant.

**Beer's law** states that the attenuation of radiant energy in a gas is a function of the product  $p_g L$  of the partial pressure of the gas and the path length. The monochromatic absorptance of a body of gas of thickness  $L$  is then given by

$$\alpha_{\lambda L} = 1 - e^{-\alpha \lambda L} \quad (48)$$

Because absorption occurs in discrete wavelengths, the absorptances must be summed over the spectral region corresponding to the temperature of the blackbody radiation passing through the gas.

**Table 4** Emittance of CO<sub>2</sub> and Water Vapor in Air at 24°C

Path Length, m	CO <sub>2</sub> , % by Volume		Relative Humidity, %			
	0.1	0.3	1.0	10	50	100
	0.03	0.06	0.09	0.06	0.17	0.22
30	0.09	0.12	0.16	0.22	0.39	0.47
300	0.16	0.19	0.23	0.47	0.64	0.70

The monochromatic absorption coefficient  $\alpha_\lambda$  is also a function of temperature and pressure of the gas; therefore, detailed treatment of gas radiation is quite complex.

Estimated emittance for carbon dioxide and water vapor in air at 24°C is a function of concentration and path length (Table 4). The values are for a hemispherically shaped body of gas radiating to an element of area at the center of the hemisphere. Among others, Modest (1993), Siegel and Howell (1981), and Hottel and Sarofim (1967) describe geometrical calculations in their texts on radiation transfer. Generally, at low values of  $p_g L$ , the mean path length  $L$  (or equivalent hemispherical radius for a gas body radiating to its surrounding surfaces) is four times the mean hydraulic radius of the enclosure. A room with a dimensional ratio of 1:1:4 has a mean path length of 0.89 times the shortest dimension when considering radiation to all walls. For a room with a dimensional ratio of 1:2:6, the mean path length for the gas radiating to all surfaces is 1.2 times the shortest dimension. The mean path length for radiation to the 2 by 6 face is 1.18 times the shortest dimension. These values are for cases where the partial pressure of the gas times the mean path length approaches zero ( $p_g L \approx 0$ ). The factor decreases with increasing values of  $p_g L$ . For average rooms with approximately 2.4 m ceilings and relative humidity ranging from 10 to 75% at 24°C, the effective path length for carbon dioxide radiation is about 85% of the ceiling height, or 2.0 m. The effective path length for water vapor is about 93% of the ceiling height, or 2.3 m. The effective emittance of the water vapor and carbon dioxide radiating to the walls, ceiling, and floor of a room 4.9 m by 14.6 m with 2.4 m ceilings is in the following tabulation.

Relative Humidity, %	$\varepsilon_g$
10	0.10
50	0.19
75	0.22

The radiation heat transfer from the gas to the walls is then

$$q = \alpha A_w \varepsilon_g (T_g^4 - T_w^4) \quad (49)$$

The examples in Table 4 and the preceding text indicate the importance of gas radiation in environmental heat transfer problems. Gas radiation in large furnaces is the dominant mode of heat transfer, and many additional factors must be considered. Increased pressure broadens the spectral bands, and interaction of different radiating species prohibits simple summation of the emittance factors for the individual species. Departures from blackbody conditions necessitate separate calculations of the emittance and absorptance. McAdams (1954) and Hottel and Sarofim (1967) give more complete treatments of gas radiation.

### NATURAL CONVECTION

Heat transfer involving motion in a fluid due to the difference in density and the action of gravity is called **natural convection** or **free convection**. Heat transfer coefficients associated with gases for natural convection are generally much lower than those for forced convection, and it is therefore important not to ignore radiation in calculating the total heat loss or gain. Radiant transfer may be

Table 5 Natural Convection Heat Transfer Coefficients

<b>I. General relationships</b>	$Nu = c(Gr Pr)^n$	(1)
	$h = c \frac{k}{L} \left( \frac{L^3 \rho^2 \beta g \Delta t}{\mu^2} \right)^n \left( \frac{\mu c_p}{k} \right)^n$	(2)
Characteristic length <i>L</i>		
Vertical plates or pipes	<i>L</i> = height	
Horizontal plates	<i>L</i> = length	
Horizontal pipes	<i>L</i> = diameter	
Spheres	<i>L</i> = 0.5 × diameter	
Rectangular block, with horizontal length <i>L<sub>h</sub></i> and vertical length <i>L<sub>v</sub></i>	$1/L = (1/L_h) + (1/L_v)$	
<b>II. Planes and pipes</b>		
Horizontal or vertical planes, pipes, rectangular blocks, and spheres (excluding horizontal plates facing downward for heating and upward for cooling)		
(a) Laminar range, when <i>Gr Pr</i> is between 10 <sup>4</sup> and 10 <sup>8</sup>	$Nu = 0.56(Gr Pr)^{0.25}$	(3)
(b) Turbulent range, when <i>Gr Pr</i> is between 10 <sup>8</sup> and 10 <sup>12</sup>	$Nu = 0.13(Gr Pr)^{0.33}$	(4)
<b>III. Wires</b>		
For horizontal or vertical wires, use <i>L</i> = diameter, for <i>Gr Pr</i> between 10 <sup>-7</sup> and 1	$Nu = (Gr Pr)^{0.1}$	(5)
<b>IV. With air</b>		
$Gr Pr = 1.6 \times 10^6 L^3 \Delta t$ (at 21 °C, <i>L</i> in m, $\Delta t$ in K)		
(a) Horizontal cylinders		
Small cylinder, laminar range	$h = 1.32(\Delta t/L)^{0.25}$	(6)
Large cylinder, turbulent range	$h = 1.24(\Delta t)^{0.33}$	(7)
(b) Vertical plates		
Small plates, laminar range	$h = 1.42(\Delta t/L)^{0.25}$	(8)
Large plates, turbulent range	$h = 1.31(\Delta t)^{0.33}$	(9)
(c) Horizontal plates, facing upward when heated or downward when cooled		
Small plates, laminar range	$h = 1.32(\Delta t/L)^{0.25}$	(10)
Large plates, turbulent range	$h = 1.52(\Delta t)^{0.33}$	(11)
(d) Horizontal plates, facing downward when heated or upward when cooled		
Small plates	$h = 0.59(\Delta t/L)^{0.25}$	(12)

of the same order of magnitude as natural convection, even at room temperatures, because wall temperatures in a room can affect human comfort (see Chapter 8).

Natural convection is important in a variety of heating and refrigeration equipment: (1) gravity coils used in high-humidity cold storage rooms and in roof-mounted refrigerant condensers, (2) the evaporator and condenser of household refrigerators, (3) baseboard radiators and convectors for space heating, and (4) cooling panels for air conditioning. Natural convection is also involved in heat loss or gain to equipment casings and interconnecting ducts and pipes.

Consider heat transfer by natural convection between a cold fluid and a hot surface. The fluid in immediate contact with the surface is heated by conduction, becomes lighter, and rises because of the difference in density of the adjacent fluid. The viscosity of the fluid resists this motion. The heat transfer is influenced by (1) gravitational force due to thermal expansion, (2) viscous drag, and (3) thermal diffusion. Gravitational acceleration *g*, coefficient of thermal expansion  $\beta$ , kinematic viscosity  $\nu = \mu/\rho$ , and thermal diffusivity  $\alpha = k/\rho c_p$  affect natural convection. These variables are included in the dimensionless numbers given in Equation (1) in Table 5. The Nusselt number *Nu* is a function of the product of the Prandtl number *Pr* and the Grashof number *Gr*. These numbers, when combined, depend on the fluid properties, the temperature difference  $\Delta t$  between the surface and the fluid, and the characteristic length *L* of the surface. The constant *c* and the exponent *n* depend on the physical configuration and the nature of flow.

Natural convection cannot be represented by a single value of exponent *n*, but it can be divided into three regions:

1. **Turbulent** natural convection, for which *n* equals 0.33
2. **Laminar** natural convection, for which *n* equals 0.25

3. A region that has *GrPr* less than for laminar natural convection, for which the exponent *n* gradually diminishes from 0.25 to lower values

Note that for wires, the *GrPr* is likely to be very small, so that the exponent *n* is 0.1 [Equation (5) in Table 5].

To calculate the natural-convection heat transfer coefficient, determine *GrPr* to find whether the boundary layer is laminar or turbulent; then apply the appropriate equation from Table 5. The correct characteristic length indicated in the table must be used. Because the exponent *n* is 0.33 for a turbulent boundary layer, the characteristic length cancels out in Equation (2) in Table 5, and the heat transfer coefficient is independent of the characteristic length, as seen in Equations (7), (9), and (11) in Table 5. Turbulence occurs when length or temperature difference is large. Because the length of a pipe is generally greater than its diameter, the heat transfer coefficient for vertical pipes is larger than for horizontal pipes.

Convection from horizontal plates facing downward when heated (or upward when cooled) is a special case. Because the hot air is above the colder air, theoretically no convection should occur. Some convection is caused, however, by secondary influences such as temperature differences on the edges of the plate. As an approximation, a coefficient of somewhat less than half the coefficient for a heated horizontal plate facing upward can be used.

Because air is often the heat transport fluid, simplified equations for air are given in Table 5. Other information on natural convection is available in the section on Bibliography under Heat Transfer, General.

Observed differences in the comparison of recent experimental and numerical results with existing correlations for natural convective heat transfer coefficients indicate that caution should be used when applying coefficients for (isolated) vertical plates to vertical surfaces in enclosed spaces (buildings). Bauman et al. (1983) and

Altmayer et al. (1983) developed improved correlations for calculating natural convective heat transfer from vertical surfaces in rooms under certain temperature boundary conditions.

Natural convection can affect the heat transfer coefficient in the presence of weak forced convection. As the forced-convection effect (i.e., the Reynolds number) increases, "mixed convection" (superimposed forced-on-free convection) gives way to the pure forced-convection regime. In these cases, other sources describing combined free and forced convection should be consulted, since the heat transfer coefficient in the mixed-convection region is often larger than that calculated based on the natural- or forced-convection calculation alone. Metz and Eckert (1964) summarize natural-, mixed-, and forced-convection regimes for vertical and horizontal tubes. Figure 7 shows the approximate limits for horizontal tubes. Other studies are described by Grigull et al. (1982).

**FORCED CONVECTION**

Forced air coolers and heaters, forced air- or water-cooled condensers and evaporators, and liquid suction heat exchangers are examples of equipment that transfer heat primarily by forced convection.

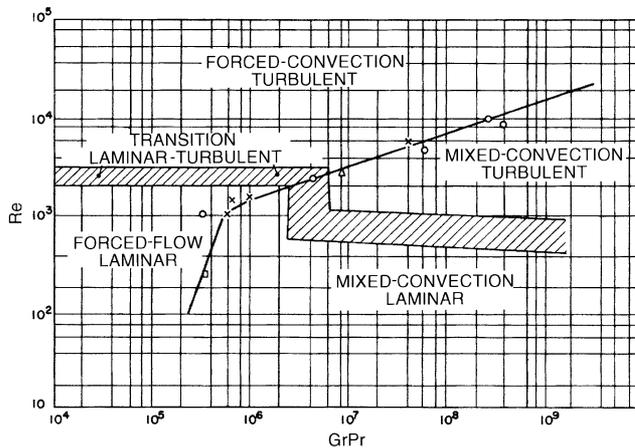

When fluid flows over a flat plate, a **boundary layer** forms adjacent to the plate. The velocity of the fluid at the plate surface is zero and increases to its maximum free stream value just past the edge of the boundary layer (Figure 8). Boundary layer formation is important because the temperature change from plate to fluid (thermal resistance) is concentrated here. Where the boundary layer is thick, thermal resistance is great and the heat transfer coefficient is small. Flow within the boundary layer immediately downstream from the leading edge is laminar and is known as **laminar forced convection**. As flow proceeds along the plate, the laminar boundary layer

increases in thickness to a critical value. Then, turbulent eddies develop within the boundary layer, except for a thin **laminar sub-layer** adjacent to the plate.

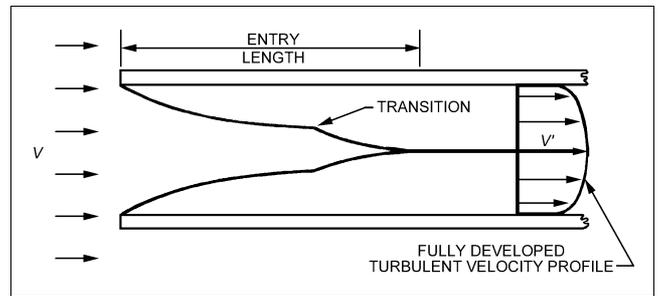

The boundary layer beyond this point is a **turbulent boundary layer**, and the flow is **turbulent forced convection**. The region between the breakdown of the laminar boundary layer and the establishment of the turbulent boundary layer is the **transition region**. Because the turbulent eddies greatly enhance heat transport into the main stream, the heat transfer coefficient begins to increase rapidly through the transition region. For a flat plate with a smooth leading edge, the turbulent boundary layer starts at Reynolds numbers, based on distance from the leading edge, of about 300 000 to 500 000. In blunt-edged plates, it can start at much smaller Reynolds numbers.

For long tubes or channels of small hydraulic diameter, at sufficiently low flow velocity, the laminar boundary layers on each wall grow until they meet. Beyond this point, the velocity distribution does not change, and no transition to turbulent flow takes place. This is called **fully developed laminar flow**. For tubes of large diameter or at higher velocities, transition to turbulence takes place and **fully developed turbulent flow** is established (Figure 9). Therefore, the length dimension that determines the critical Reynolds number is the hydraulic diameter of the channel. For smooth circular tubes, flow is laminar for Reynolds numbers below 2100 and turbulent above 10 000.

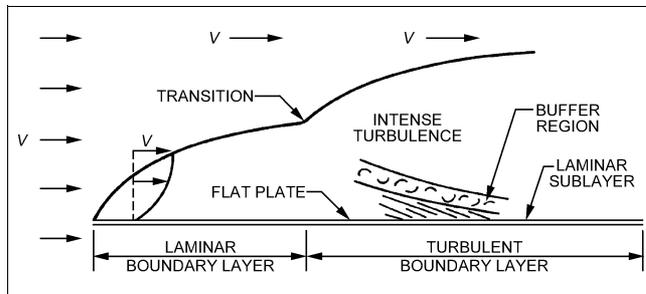

Table 6 lists various forced-convection correlations. In the generalized, dimensionless formula of Equation (1) in Table 6, heat transfer is determined by flow conditions and by the fluid properties, as indicated by the Reynolds number and the Prandtl number. This equation can be modified to Equation (4) in Table 6 to get the **heat transfer factor  $j$** . The heat transfer factor is related to the **friction factor  $f$**  by the interrelationship of the transport of momentum and heat; it is approximately  $f/2$  for turbulent flow in straight ducts. These factors are plotted in Figure 10.

(c) Fluorinated hydrocarbon refrigerant gas at ordinary pressures	Obtained from Eq. (2)			$h = 155.2c (G^{0.8} / D^{0.2})$ (See Note b) (10)
(d) Ammonia gas at approximately 65°C, 2 MPa	Obtained from Eq. (2)			$h = 6.663 (G^{0.8} / D^{0.2})$ (11)
At -18°C, 165 kPa (gage)	Obtained from Eq. (2)			$h = 5.323 (G^{0.8} / D^{0.2})$ (12)
<b>III. Simplified equations for liquids, turbulent flow inside tubes</b> [ $h$ in $W/(m^2 \cdot K)$ , $G$ in $kg/(m^2 \cdot s)$ , $V$ in $m/s$ , $D$ in $m$ , $t$ in °C, $\mu$ in $N \cdot s/m^2$ ]				
(a) Water at ordinary temperatures, 4 to 93°C. $V$ is velocity in $m/s$ , $D$ is tube ID in metres.	McAdams	228	(9-19)	$h = \frac{1057(1.352 + 0.0198t)V^{0.8}}{D^{0.2}}$ (13)
(b) Fluorinated hydrocarbon refrigerant liquid	Obtained from Eq. (2)			$h = 155.2c (G^{0.8} / D^{0.2})$ (See Note b) (14)
(c) Ammonia liquid at approximately 38°C	Obtained from Eq. (2)			$h = 13.75 (G^{0.8} / D^{0.2})$ (15)
(d) Oil heating, approximate equation	Brown and Marco	146	(7-15)	$h = 0.0047 V / \mu_f^{0.63}$ (16)
(e) Oil cooling, approximate equation	Brown and Marco	146	(7-15)	$h = 0.0035 V / \mu_f^{0.63}$ (17)
<b>IV. Simplified equations for air</b>				
(a) Vertical plane surfaces, $V$ of 5 to 30 m/s (room temperature) <sup>c</sup>	McAdams	249	(9-42)	$h' = 7.2V^{0.78}$ (18)
(b) Vertical plane surfaces, $V < 5$ m/s (room temperature) <sup>c</sup>	McAdams	249	(9-42)	$h' = 5.62 + 3.9V$ (19)
(c) Single cylinder cross flow (film temperature = 93°C) $1000 < GD/\mu_f < 50\,000$	McAdams	261	(10-3c)	$h = 4.83 (G^{0.6} / D^{0.4})$ (20)
(d) Single sphere $17 < GD/\mu_f < 70\,000$	McAdams	265	(10-6)	$h = 0.37 \frac{k_f}{D} \left( \frac{GD}{\mu_f} \right)^{0.6}$ (21)
<b>V. Gases flowing normal to pipes (dimensionless)</b>				
(a) Single cylinder Re from 0.1 to 1000	McAdams	260	(10-3)	$\frac{hD}{k_f} = 0.32 + 0.43 \left( \frac{GD}{\mu} \right)^{0.52}$ (22)
Re from 1000 to 50 000	McAdams	260	(10-3)	$\frac{hD}{k_f} = 0.24 \left( \frac{GD}{\mu_f} \right)^{0.6}$ (23)
(b) Unbaffled staggered tubes, 10 rows. Approximate equation for turbulent flow <sup>d</sup>	McAdams	272	(10-11a)	$\frac{hD}{k_f} = 0.33 \left( \frac{G_{max} D}{\mu_f} \right)^{0.6} \left( \frac{\mu c_p}{k} \right)_f^{1/3}$ (24)
(c) Unbaffled in-line tubes, 10 rows. Approximate equation for turbulent flow <sup>d</sup> $(G_{max} D/\mu_f)$ from 2000 to 32 000	McAdams	272	(10-11a)	$\frac{hD}{k_f} = 0.26 \left( \frac{G_{max} D}{\mu_f} \right)^{0.6} \left( \frac{\mu c_p}{k} \right)_f^{1/3}$ (25)

<sup>a</sup>McAdams (1954) recommends this equation for heating and cooling. Others recommend exponents of 0.4 for heating and 0.3 for cooling, with a change in constant.

<sup>b</sup>Table 7 in Chapter 2 of the 1981 ASHRAE Handbook—Fundamentals lists values for  $c$ .

<sup>c</sup> $h'$  is expressed in  $W/(m^2 \cdot K)$  based on initial temperature difference.

<sup>d</sup> $G_{max}$  is based on minimum free area. Coefficients for tube banks depend greatly on geometrical details. These values approximate only.

**Fig. 11 Heat Transfer Coefficient for Turbulent Flow of Water Inside Tubes**

The characteristic length  $D$  is the diameter of the tube, outside or inside, or the length of the plane plate. For other shapes, the hydraulic diameter  $D_h$  is used. With a uniform surface temperature and assuming uniform heat transfer coefficient the inlet and exit temperatures are related by:

$$D_h = 2r_h = 4 \times \frac{\text{Cross-sectional area for flow}}{\text{Total wetted perimeter}}$$

This reduces to twice the distance between surfaces for parallel plates or an annulus.

Simplified equations applicable to common fluids under normal operating conditions appear in Equations (8) through (25) of Table 6. Figure 11 gives graphical solutions for water. However, the value of the convective heat transfer coefficient with internal flows varies in the direction of the flow because of the temperature dependence of the properties of the fluids. In such a case a representative value of the heat transfer coefficient evaluated at the inlet and exit temperatures can be used in the above equation.

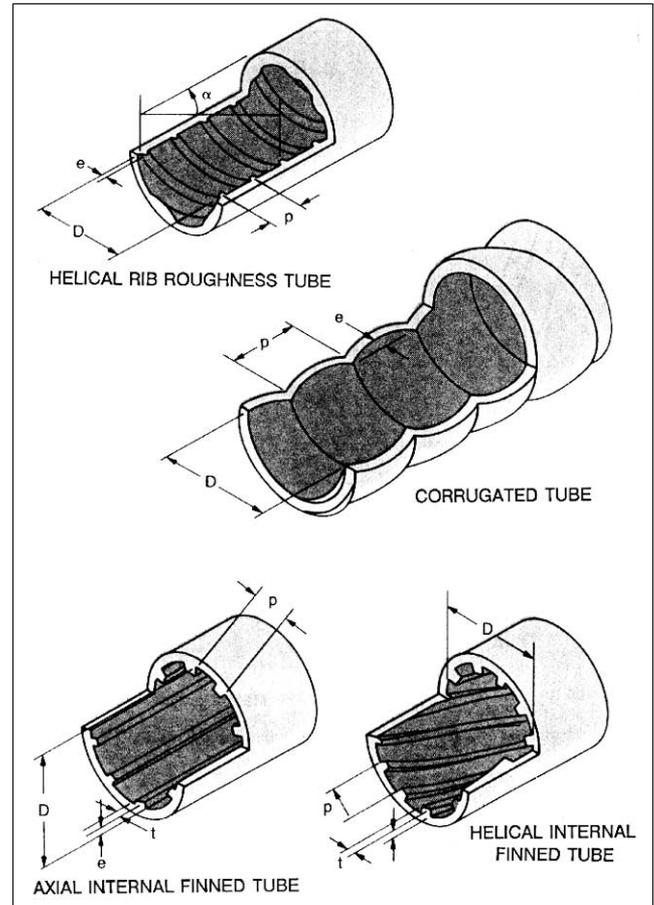

### HEAT TRANSFER AUGMENTATION TECHNIQUES

As discussed by Bergles (1998), techniques applied to augment (enhance) heat transfer can be classified as passive methods, which require no direct application of external power, or as active schemes, which require external power. Examples of passive techniques include rough surfaces, extended surfaces, displaced promoters, and vortex flow devices. Examples of active techniques include mechanical aids, surface vibration, fluid vibration, and electrostatic fields. The effectiveness of a given augmentation technique depends largely on the mode of heat transfer or the type of heat exchanger to which it is applied.

When augmentation is used, the dominant thermal resistances in Equation (9) should be considered; that is, do not invest in reducing an already low thermal resistance (increasing an already high heat transfer coefficient). Additionally, heat exchangers with a large number of heat transfer units (NTU) show relatively small gains in effectiveness with augmentation [see Equations (24) and (26)]. Finally, the increased friction factor that usually accompanies the heat transfer augmentation must be considered.

#### Passive Techniques

Several examples of tubes with internal roughness or fins are shown in Figure 12. Rough surfaces of the spiral repeated rib variety are widely used to improve in-tube heat transfer with water, as in

**Fig. 12 Typical Tube-Side Enhancements**

flooded chillers. The roughness may be produced by spirally indenting the outer wall, forming the inner wall, or inserting coils. Longitudinal or spiral internal fins in tubes can be produced by extrusion or forming and give a substantial increase in the surface area. The fin efficiency (see the section on Fin Efficiency on p. 3.20) can usually be taken as unity. Twisted strips (vortex flow devices) can be inserted as original equipment or as retrofit devices. From a practical point of view, the twisted tape width should be such that the tape can be easily inserted or removed. Ayub and Al-Fahed (1993) addressed the issue of the clearance between the twisted tape and tube inside dimension.

Microfin tubes (internally finned tubes with about 60 short fins around the circumference) are widely used in refrigerant evaporation and condensers. Since the gas entering the condenser in vapor-compression refrigeration is superheated, a considerable portion of the condenser acts to desuperheat the flow (i.e., it is single phase). Some data on the single-phase performance of microfin tubes, showing considerably higher heat transfer coefficients than for plain tubes, are available (e.g., Khanpara et al. 1986, Al-Fahed et al. 1993), but the upper Reynolds numbers of about 10,000 are lower than those found in practice. This deficiency is being addressed in a current ASHRAE research project.

The increased friction factor may not require increased pumping power if the flow rate can be adjusted or if the length of the heat exchanger can be reduced. Nelson and Bergles (1986) discuss this issue of performance evaluation criteria, especially for HVAC applications.

Of concern in chilled water systems is the fouling that in some cases may seriously reduce the overall heat transfer coefficient  $U$ . In general, fouled enhanced tubes perform better than fouled plain tubes,

Table 7 Equations for Augmented Forced Convection (Single Phase)

Description	Equation	
<b>I. Turbulent in-tube flow of liquids</b>		
(a) Spiral repeated rib <sup>a</sup>	$\frac{h_a}{h_s} = \left\{ \left[ 1 + 2.64 \left( \frac{GD}{\mu} \right)^{0.036} \left( \frac{e}{d} \right)^{0.212} \left( \frac{p}{d} \right)^{-0.21} \left( \frac{\alpha}{90} \right)^{0.29} \left( \frac{c_p \mu}{k} \right)^{-0.024} \right]^7 \right\}^{1/7}$ $\frac{f_a}{f_s} = \left\{ 1 + \left[ 29.1 \left( \frac{GD}{\mu} \right)^w \left( \frac{e}{d} \right)^x \left( \frac{p}{d} \right)^y \left( \frac{\alpha}{90} \right)^z \left( 1 + \frac{2.94}{n} \right) \sin \beta \right]^{15/16} \right\}^{16/15}$	
	<p>where</p> $w = 0.67 - 0.06(p/d) - 0.49(\alpha/90)$ $x = 0.37 - 0.157(p/d)$ $y = -1.66 \times 10^{-6}(GD/\mu) - 0.33(\alpha/90)$ $z = 4.59 + 4.11 \times 10^{-6}(GD/\mu) - 0.15(p/d)$ $f_s = \frac{(k/D)(f_s/2) \left( \frac{GD}{\mu} \right) \left( \frac{c_p \mu}{k} \right)}{1 + 12.7(f_s/2)^{0.5} \left[ \left( \frac{c_p \mu}{k} \right)^{2/3} - 1 \right]}$ $f_s = \left[ 1.58 \ln \left( \frac{GD}{\mu} \right) - 3.28 \right]^{-2}$	
(b) Fins <sup>b</sup>	$\frac{hD_h}{k} = 0.023 \left( \frac{c_p \mu}{k} \right)^{0.4} \left( \frac{GD_h}{\mu} \right)^{0.8} \left( \frac{A_F}{A_{Fi}} \right)^{0.1} \left( \frac{A_i}{A} \right)^{0.5} (\sec \alpha)^3$ $f_h = 0.046 \left( \frac{GD_h}{\mu} \right)^{-0.2} \left( \frac{A_F}{A_{Fi}} \right)^{0.5} (\sec \alpha)^{0.75}$	<p>Note that in computing the Reynolds number for (b) and (c) there is allowance for the reduced cross-sectional area.</p>
(c) Twisted-strip inserts <sup>c</sup>	$\left( \frac{hd}{k} \right) / \left( \frac{hd}{k} \right)_{y=\infty} = [1 + 0.769/y]$ $\left( \frac{hd}{k} \right)_{y=\infty} = 0.023 \left( \frac{GD}{\mu} \right)^{0.8} \left( \frac{c_p \mu}{k} \right)^{0.4} \left( \frac{\pi}{\pi - 4\delta/d} \right)^{0.8} \left( \frac{\pi + 2 - 2\delta/d}{\pi - 4\delta/d} \right)^{0.2} \phi$ <p>where</p> $\phi = (\mu_b / \mu_w)^n$ $n = \begin{cases} 0.18 & \text{for liquid heating} \\ 0.30 & \text{for liquid cooling} \end{cases}$ $f = \frac{0.0791}{(GD/\mu)^{0.25}} \left( \frac{\pi}{\pi - 4\delta/d} \right)^{1.75} \left( \frac{\pi + 2 - 2\delta/d}{\pi - 4\delta/d} \right)^{1.25} \left( 1 + \frac{2.752}{y^{1.29}} \right)$	
<b>II. Turbulent in-tube flow of gases</b>		
(a), (b) Bent-strip inserts <sup>d</sup>	$\frac{hD}{k} \left( \frac{T_w}{T_b} \right)^{0.45} = 0.258 \left( \frac{GD}{\mu} \right)^{0.6}$ $\frac{hD}{k} \left( \frac{T_w}{T_b} \right)^{0.45} = 0.208 \left( \frac{GD}{\mu} \right)^{0.63}$	
(c) Twisted-strip inserts <sup>d</sup>	$\frac{hD}{k} \left( \frac{T_w}{T_b} \right)^{0.45} = 0.122 \left( \frac{GD}{\mu} \right)^{0.65}$	
(d) Bent-tab inserts <sup>d</sup>	$\frac{hD}{k} \left( \frac{T_w}{T_b} \right)^{0.45} = 0.406 \left( \frac{GD}{\mu} \right)^{0.54}$	<p>Note that in computing the Reynolds number there is no allowance for the flow blockage of the insert.</p>
<b>III. Offset strip fins for plate-fin heat exchangers<sup>e</sup></b>	$\frac{h}{c_p G} = 0.6522 \left( \frac{GD_h}{\mu} \right)^{-0.5403} \alpha^{-0.1541} \delta^{-0.1499} \gamma^{-0.0678} \left[ 1 + 5.269 \times 10^{-5} \left( \frac{GD_h}{\mu} \right)^{1.340} \alpha^{0.504} \delta^{0.456} \gamma^{-1.055} \right]^{0.1}$ $f_h = 9.6243 \left( \frac{GD_h}{\mu} \right)^{-0.7422} \alpha^{-0.1856} \delta^{-0.3053} \gamma^{-0.2659} \left[ 1 + 7.669 \times 10^{-8} \left( \frac{GD_h}{\mu} \right)^{4.429} \alpha^{0.920} \delta^{3.767} \gamma^{0.236} \right]^{0.1}$	
	<p>where <math>h/c_p G</math>, <math>f_h</math>, and <math>GD_h/\mu</math> are based on the hydraulic diameter, given by</p> $D_h = 4shl/[2(sl + hl + th) + ts]$

as shown in studies of scaling due to cooling tower water (Knudsen and Roy 1983) and particulate fouling (Somerscales et al. 1991). A comprehensive review of fouling with enhanced surfaces is presented by Somerscales and Bergles (1997).

Fire-tube boilers are frequently fitted with **turbulators** to improve the turbulent convective heat transfer coefficient constituting the dominant thermal resistance. Also, due to the high gas temperatures, radiation from the convectively heated insert to the tube wall can represent as much as 50% of the total heat transfer. (Note, however, that the magnitude of the convective contribution decreases as the radiative contribution increases because of the reduced temperature difference.) Two commercial bent-strip inserts, a twisted-strip insert, and a simple bent-tab insert are depicted in Figure 13. Design equations, for convection only, are included in Table 7. Beckermann and Goldschmidt (1986) present procedures to include radiation, and Junkhan et al. (1985, 1988) give friction factor data and performance evaluations.

Several enhanced surfaces for gases are depicted in Figure 14. The offset strip fin is an example of an interrupted fin that is often found in compact plate fin heat exchangers used for heat recovery from exhaust air. Design equations are included in Table 7. These equations are comprehensive in that they apply to laminar and transitional flow as well as to turbulent flow, which is a necessary feature because the small hydraulic diameter of these surfaces drives the Reynolds number down. Data for other surfaces (wavy, spine, louvered, etc.) are given in the section on Bibliography.

Plastic heat exchangers have been suggested for HVAC applications (Pescod 1980) and are being manufactured for refrigerated sea water (RSW) applications. They could be made of materials impervious to corrosion, say from acidic condensate when cooling a gaseous stream (flue gas heat recovery), and could easily be manufactured with enhanced surfaces. Several companies now offer heat exchangers in plastic, including various enhancements.

### Active Techniques

Unlike the passive techniques, active techniques require use of external power to sustain the enhancement mechanism.

Table 8 provides a list of the more commonly known active heat transfer augmentation techniques and the corresponding heat transfer mode believed most applicable to the particular technique. A listing of the various active techniques and their world-wide status is given in Table 9. The rankings in Tables 8 and 9 are based on a comprehensive review of the pertinent literature (Ohadi et al. 1996). Table 9 shows that among the eight listed active techniques, the electrostatic/electrohydrodynamic and rotation appear to apply to almost all important heat transfer modes, at least from an enhancement applicability view point. The information in Table 9 suggests that aside from the mechanical aids technique, which is universally used for selected applications, most other active techniques have limited commercial use so far and are still in the development stage. However, the significant research progress in recent years is now promising expedited commercialization for some of the active techniques, such as the electrostatic/electrohydrodynamic (EHD) technique. The following is a brief summary of the enhancement techniques listed in Table 9.

**Mechanical Aids.** Augmentation by mechanical aids involves stirring the fluid by mechanical means, such as mixers, stirrers, or

surface scrapers. Stirrers and mixers that scrape the surface are extensively used in the chemical processing of highly viscous fluids, such as the flow of highly viscous plastic with air. Heat exchangers that employ mechanical aids for enhancement are often called **mechanically assisted heat exchangers**. The surface scraping method is widely used for viscous liquids in the chemical processing industry and can be applied to duct flow of gases. Hagge and Junkhan (1974) reported tenfold improvement in heat transfer coefficient for laminar flow of air over a flat plate. Table 10 provides a listing of selected works on mechanical aids, suction, and injection.

**Injection.** This method involves supplying a gas to a flowing liquid through a porous heat transfer surface or injecting a fluid of a similar type upstream of the heat transfer test section. Injected bubbles produce an agitation similar to that of nucleate boiling. Gose et al. (1957) bubbled gas through sintered or drilled heated surfaces and found that the heat transfer coefficient increased 500% in laminar flow and about 50% in turbulent flow. Wayner and Bankoff (1965) demonstrated that the heat transfer coefficient could be increased by 150% if a porous block was placed on the surface to stabilize the flow of liquid toward the surface. Tauscher et al. (1970) demonstrated up to a five-fold increase in local heat transfer coefficients by injecting a similar fluid into a turbulent tube flow, but the effect dies out at a length-to-diameter ratio of 10.

NA = Not Available; P = EHD Power; Q = Heat Exchanger Capacity

The practical application of injection appears to be rather limited because of difficulty of cost-effective supplying and removing of the injection fluid.

**Suction.** The suction method involves fluid removal through a porous heated surface leading to reduced heat/mass transfer resistance at the surface. Kinney (1968) and Kinney and Sparrow (1970) reported that applying suction at the surface increased heat transfer coefficients for laminar film and turbulent flows, respectively. For laminar film condensation, Antonir and Tamir (1977) and Lienhard and Dhir (1972) indicated that heat transfer coefficient can be improved by several hundred percent when film thickening is reduced by suction. Jeng et al. (1995) conducted experiments on a vertical parallel channel with asymmetric, isothermal walls. A porous wall segment was embedded into a segment of the test section wall, and enhancement occurred as the hot air was sucked from the channel. The local heat transfer coefficient increased with increasing porosity. The maximum heat transfer enhancement obtained was 140%.

**Fluid or Surface Vibration.** Fluid or surface vibrations are natural processes that occur in most heat exchangers; however, naturally occurring vibration is rarely factored into thermal design. Vibration equipment is expensive, and use of this technique for heat transfer enhancement does not have industrial applications at this stage of development. Vibrations of a wire in a forced convecting airflow enhanced the heat transfer to air up to 300% (Nesis et al. 1994), depending on the amplitude of vibrations and frequency. By using standing waves in a fluid, the input power was reduced by 75% compared with a fan that provides the same heat transfer rate (Woods 1992). Lower frequencies are preferable because they are less harmful to those who use this method of augmenting heat transfer.

**Rotation.** Rotation is a type of heat transfer enhancement that occurs naturally in rotating electrical machinery, gas turbine blades, and some other equipment. The rotating evaporator, the rotating heat pipe, the Hige distillation column, and the Rotex absorption cycle heat pump are typical examples of previous work in this area. In rotating evaporators, the rotation effectively distributes the liquid on the outside surface of the rotating surface. Rotation of the heat transfer surface also seems to be a promising method for effectively removing the condensate and decreasing liquid film thickness. Substantial increases in heat transfer coefficients have been

demonstrated by using centrifugal force, which may be several times greater than the gravity force.

As shown in Table 11, the heat transfer enhancement obtained in the various studies varies from slight improvement up to 450%, depending on the system and rotation speed. The rotation technique is of particular interest for use in two-phase flows, particularly in boiling and condensation. It has been demonstrated that this technique is not effective in the gas-to-gas heat recovery mode in laminar flow, but its application is more likely in turbulent flow. High power consumption, sealing and vibration problems, moving parts, and the expensive equipment required for rotation are some drawbacks of the rotation technique.

**Electrohydrodynamics.** The electrohydrodynamic (EHD) enhancement of heat transfer refers to the coupling of an electric field with the fluid field in a dielectric fluid medium. The net effect is the production of secondary motions that destabilize the thermal boundary layer near the heat transfer surface, leading to heat transfer coefficients that are often an order of magnitude higher than those achievable by any of the conventional enhancement techniques. Among the various active augmentation techniques, EHD has benefited the most from substantial research in the past two decades in Japan, the United States, and the United Kingdom (Ohadi 1991). Its applicability for heat transfer enhancement in many applications has already been demonstrated, including for refrigeration/HVAC systems, process heat exchangers, waste heat recovery devices, cryogenics, aircraft environmental control systems, avionic cooling systems, and space thermal systems.

Selected work on EHD heat transfer enhancement is listed in Table 12. The work has involved studies on phase change processes as well as the indicated single-phase process. In fact, EHD-enhanced boiling and condensation have attracted the most attention from industrial and academic researchers.

The EHD effect is generally applied by placing wire or plate electrodes parallel and adjacent to the heat transfer surface. Figure 15 presents four electrode configurations for augmentation of forced-convection heat/mass transfer in-tube flows. A high-voltage, low-current electric field charges the electrode and establishes the electrical body force required to initiate and sustain augmentation.

When compared with other active techniques, a number of important advantages have contributed to the fast progress of the

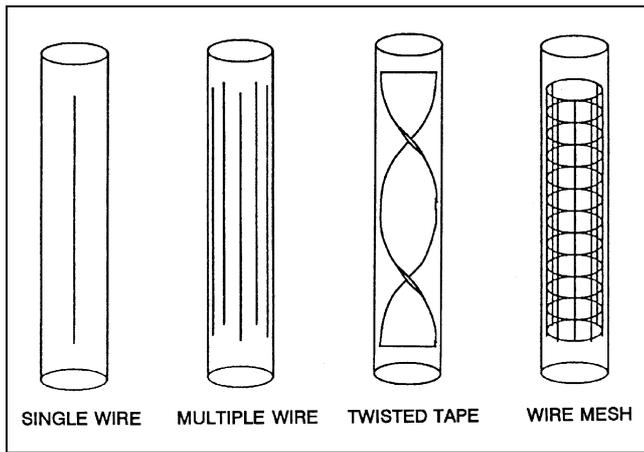

Fig. 15 Electrode Configurations for Internal Forced-Convection Flow

EHD technique in recent years. Rotation, injection, and vibration are generally mechanically complex and somewhat cumbersome to manufacture. Furthermore, the energy required to operate these systems can be a significant fraction of the power employed in pumping the fluid. In these respects, the EHD method of enhancement is superior.

The safety aspect of the EHD technique may be misjudged if careful attention is not paid to the manner in which these systems operate. Although EHD systems work at high voltages, the fact that very small currents are employed reduces the hazard of EHD fields to well below that of conventional low-voltage household appliances and ensures that the electrical power consumed by the EHD process is extremely small (less than 1% in most cases). Although the EHD technique appears to be well ahead of other active techniques, a number of issues remain to be addressed before successful implementation of this technique in practical heat exchangers can be realized. The most important issues include (1) any long-term effects the electric field may have on the heat exchanger, working fluid, and components, (2) the development of low-cost, high-voltage power supplies, and (3) identifying manufacturing processes that can lead to inexpensive mass production of EHD-enhanced heat exchangers. The encouraging news is that research work addressing some of the issues has already been initiated by researchers in the academic and government sectors and in private companies and research institutions. Additional details on the principles, applicability, and limitations of the EHD technique can be found elsewhere (Ohadi et al. 1991; Ohadi et al. 1999; Yabe 1991).

### EXTENDED SURFACE

Heat transfer from a prime surface can be increased by attaching **fins** or **extended surfaces** to increase the area available for heat transfer. Fins provide a more compact heat exchanger with lower material costs for a given performance. To achieve optimum design, fins are generally located on the side of the heat exchanger where the heat transfer coefficients are low (such as the air side of an air-to-water coil). Equipment with an extended surface includes natural- and forced-convection coils and shell-and-tube evaporators and condensers. Fins are also used inside tubes in condensers and dry expansion evaporators.

#### Fin Efficiency

As heat flows from the root of a fin to its tip, temperature drops because of the thermal resistance of the fin material. The temperature difference between the fin and the surrounding fluid is therefore

greater at the root than at the tip, causing a corresponding variation in the heat flux. Therefore, increases in fin length result in proportionately less additional heat transfer. To account for this effect, **fin efficiency**  $\phi$  is defined as the ratio of the actual heat transferred from the fin to the heat that would be transferred if the entire fin were at its root or base temperature:

$$\phi = \frac{\int h(t - t_e)dA}{\int h(t_r - t_e)dA} \quad (50)$$

where  $\phi$  is the fin efficiency,  $t_e$  is the temperature of the surrounding environment, and  $t_r$  is the temperature at the fin root. Fin efficiency is low for long fins, thin fins, or fins made of low thermal conductivity material. Fin efficiency decreases as the heat transfer coefficient increases because of the increased heat flow. For natural convection in air-cooled condensers and evaporators, where  $h$  for the air side is low, fins can be fairly large and fabricated from low-conductivity materials such as steel instead of from copper or aluminum. For condensing and boiling, where large heat transfer coefficients are involved, fins must be very short for optimum use of material.

The heat transfer from a finned surface, such as a tube, which includes both finned or secondary area  $A_s$  and unfinned or prime area  $A_p$  is given by the following equation:

$$q = (h_p A_p + \phi h_s A_s)(t_r - t_e) \quad (51)$$

Assuming the heat transfer coefficients for the finned surface and prime surface are equal, a *surface efficiency*  $\phi_s$  can be derived for use in Equation (52).

$$\phi_s = 1 - \left(\frac{A_s}{A}\right)(1 - \phi) \quad (52)$$

$$q = \phi_s h A (t_r - t_e) \quad (53)$$

where  $A$  is the total surface area, equal to the sum of the finned and prime areas ( $A = A_s + A_p$ ).

Temperature distribution and fin efficiencies for various fin shapes are derived in most heat transfer texts. Figures 16 through 19 show curves and equations for annular fins, straight fins, and spines. For constant thickness square fins, the efficiency of a constant thickness annular fin of the same area can be used. More accuracy, particularly with rectangular fins of large aspect ratio, can be obtained by dividing the fin into circular sectors (Rich 1966).

Rich (1966) presents results for a wide range of geometries in a compact form for equipment designers by defining a dimensionless thermal resistance  $\Phi$ :

$$\Phi = \frac{R_f t_o k}{l^2} \quad (54)$$

$$R_f = \left(\frac{1}{h}\right)\left(\frac{1}{\phi} - 1\right) \quad (55)$$

where

- $\Phi$  = dimensionless thermal resistance
- $\phi$  = fin efficiency
- $t_o$  = fin thickness at fin base
- $l$  = length dimension =  $r_i - r_o$  for annular fins
- $W$  = for rectangular fins

Rich (1966) also developed expressions for  $\Phi_{max}$ , the maximum limiting value of  $\Phi$ . Figure 20 gives  $\Phi_{max}$  for annular fins of constant and tapered cross section as a function of  $R = r_i/r_o$  (i.e., the

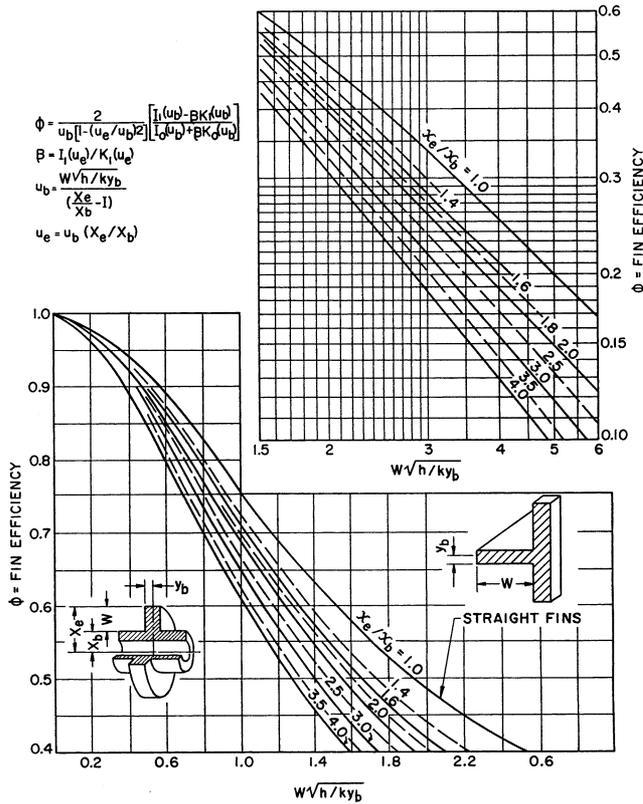

Fig. 16 Efficiency of Annular Fins of Constant Thickness

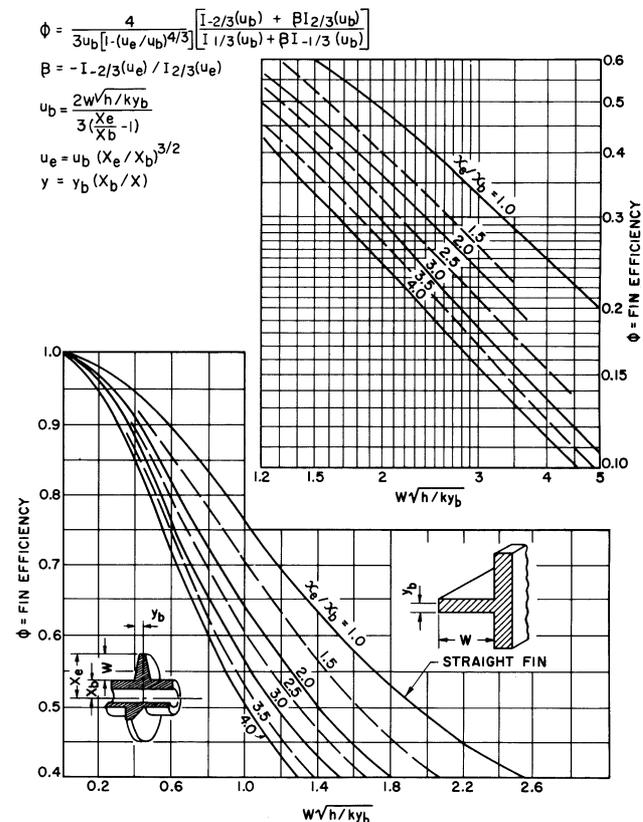

Fig. 17 Efficiency of Annular Fins with Constant Metal Area for Heat Flow

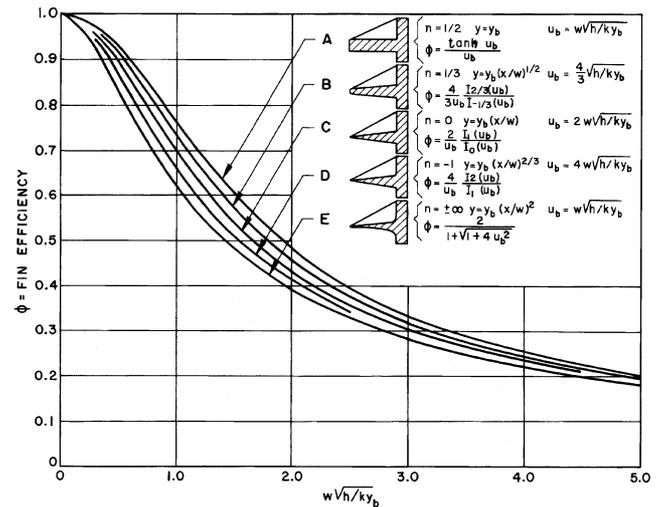

Fig. 18 Efficiency of Several Types of Straight Fin

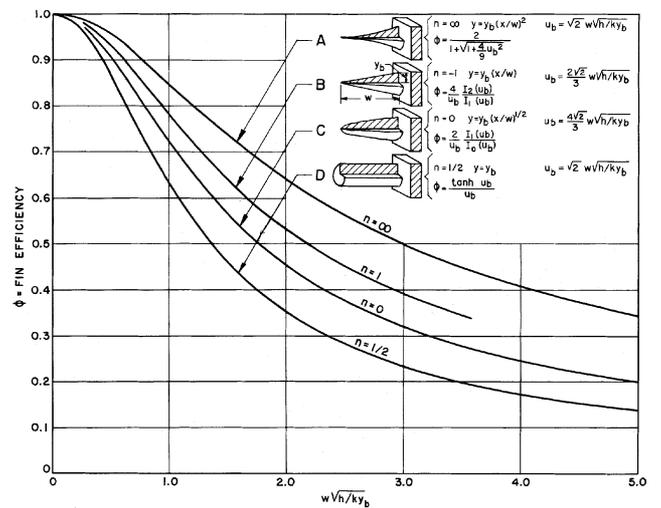

Fig. 19 Efficiency of Four Types of Spine

ratio of the fin tip-to-root radii). Figure 21 gives  $\Phi_{max}$  for rectangular fins of a given geometry as determined by the sector method. Figure 22 gives correction factors ( $\Phi/\Phi_{max}$ ) for the determination of  $\Phi$  from  $\Phi_{max}$  for both annular and rectangular fins.

**Example.** This example illustrates the use of the fin resistance for a rectangular fin typical of that for an air-conditioning coil.

- Given:**  $L = 18 \text{ mm}$   $t_o = 0.15 \text{ mm}$   
 $W = 12 \text{ mm}$   $h = 60 \text{ W/(m}^2 \cdot \text{K)}$   
 $r_o = 6 \text{ mm}$   $k = 170 \text{ W/(m} \cdot \text{K)}$

**Solution:** From Figure 18 at  $W/r_o = 2.0$  and  $L/W = 1.5$ ,

$$\Phi_{max} = R_{f(max)} t_o k / W^2 = 1.12$$

$$r_{f(max)} = \frac{1.12 \times 12^2}{0.15 \times 170 \times 1000} = 0.00632 \text{ m}^2 \cdot \text{K} / \text{W}$$

The correction factor  $\Phi/\Phi_{max}$ , which is multiplied by  $R_{f(max)}$  to give  $R_f$  is given in Figure 22 as a function of the fin efficiency. As a first approximation, the fin efficiency is calculated from Equation (54a) assuming  $R_f = R_{f(max)}$ .

$$\eta = 1 / (1 + hR_f) \approx 0.72$$

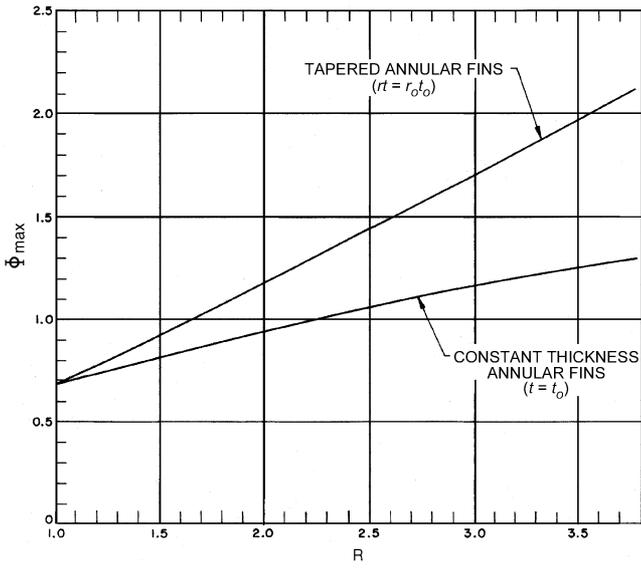

Fig. 20 Maximum Fin Resistance of Annular Fins (Gardner 1945)

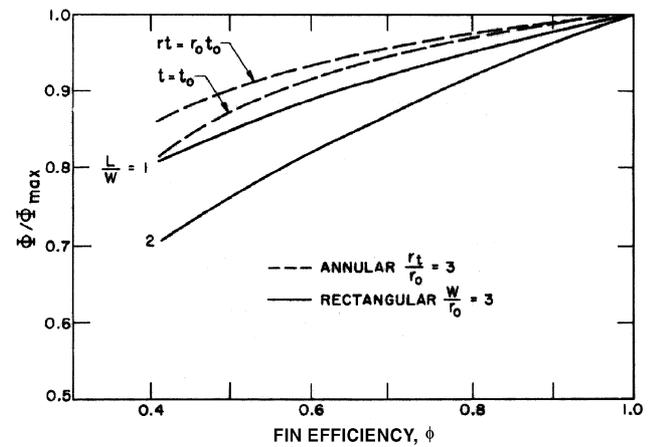

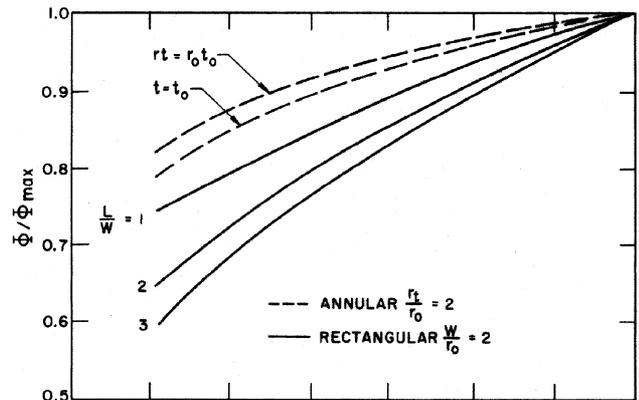

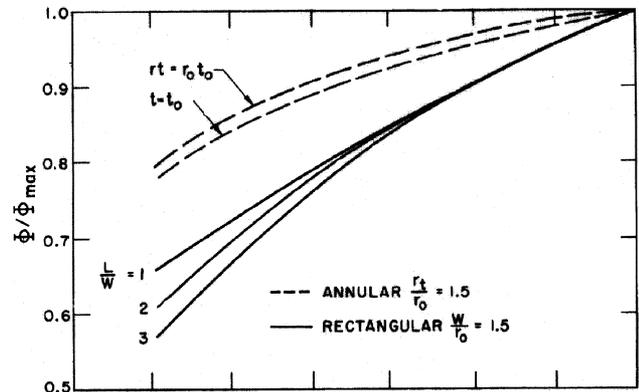

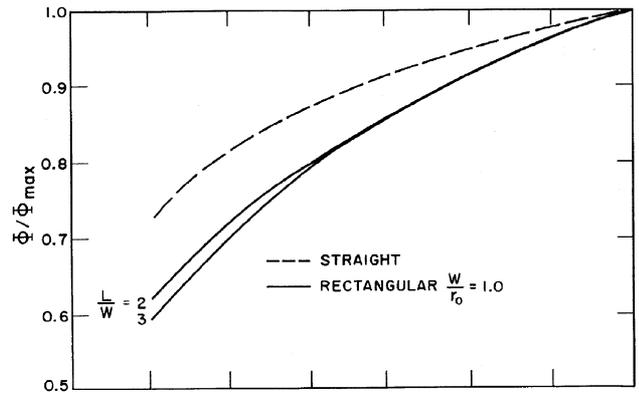

Fig. 22 Variation of Fin Resistance with Efficiency for Annular and Rectangular Fins (Gardner 1945)

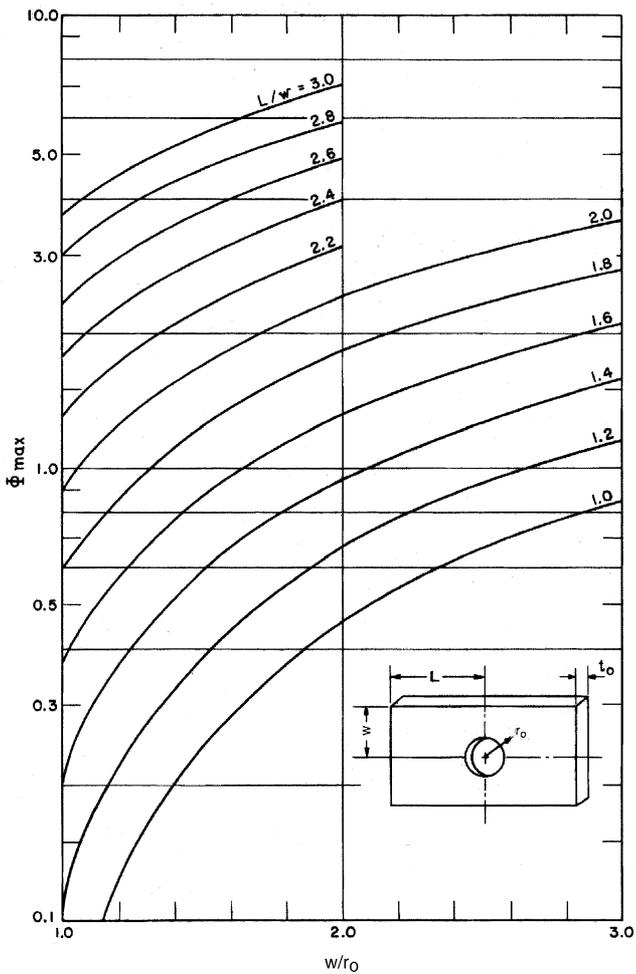

Fig. 21 Maximum Fin Resistance of Rectangular Fins Determined by Sector Method

Interpolating between  $L/W = 1$  and  $L/W = 2$  at  $W/r_o = 2$  gives

$$\Phi / \Phi_{max} = 0.88$$

Therefore,

$$R_f = 0.88 \times 0.00632 = 0.00556 \text{ m}^2 \cdot \text{K} / \text{W}$$

The above steps may now be repeated using the corrected value of fin resistance.

$$\begin{aligned} \phi &= 0.745 \\ \Phi / \Phi_{max} &= 0.9 \\ R_f &= 0.00569 \text{ m}^2 \cdot \text{K} / \text{W} \end{aligned}$$

Note that the improvement in accuracy by reevaluating  $\Phi / \Phi_{max}$  is less than 1% of the overall thermal resistance (environment to fin base). The error produced by using  $R_{f(max)}$  without correction is less than 3%. For many practical cases where greater accuracy is not warranted, a single value of  $R_f$ , obtained by estimating  $\Phi / \Phi_{max}$ , can be used over a range of heat transfer coefficients for a given fin. For approximate calculations, the fin resistance for other values of  $k$  and  $t_o$  can be obtained by simple proportion if the range covered is not excessive.

Schmidt (1949) presents approximate, but reasonably accurate, analytical expressions (for computer use) for circular, rectangular, and hexagonal fins. Hexagonal fins are the representative fin shape for the common staggered tube arrangement in finned-tube heat exchangers.

Schmidt's empirical solution is given by

$$\phi = \frac{\tanh(mr_i\Phi)}{mr_i\Phi}$$

where  $m = \sqrt{2h / kt}$  and  $\Phi$  is given by

$$\Phi = [(r_e / r_i) - 1][1 + 0.35 \ln(r_e / r_i)]$$

For **circular fins**,

$$r_e / r_i = r_o / r$$

For **rectangular fins**,

$$r_e / r_i = 1.28\psi\sqrt{\beta - 0.2}, \quad \psi = M / r_i, \quad \beta = L / M \geq 1$$

where  $M$  and  $L$  are defined by Figure 23 as  $a/2$  or  $b/2$ , depending on which is greater.

For **hexagonal fins**,

$$r_e / r_i = 1.27\psi\sqrt{\beta - 0.3}$$

where  $\psi$  and  $\beta$  are defined as above and  $M$  and  $L$  are defined by Figure 24 as  $a/2$  or  $b$  (whichever is less) and  $0.5\sqrt{(a^2 / 2)^2 + b^2}$ , respectively.

The section on Bibliography lists other sources of information on finned surfaces.

### Thermal Contact Resistance

Fins can be extruded from the prime surface (e.g., the short fins on the tubes in flooded evaporators or water-cooled condensers) or they can be fabricated separately, sometimes of a different material, and bonded to the prime surface. Metallurgical bonds are achieved by furnace-brazing, dip-brazing, or soldering. Nonmetallic bonding materials, such as epoxy resin, are also used. Mechanical bonds are obtained by tension-winding fins around tubes (spiral fins) or expanding the tubes into the fins (plate fins). Metallurgical bonding, properly done, leaves negligible thermal resistance at the joint but is not always economical. Thermal resistance of a mechanical bond

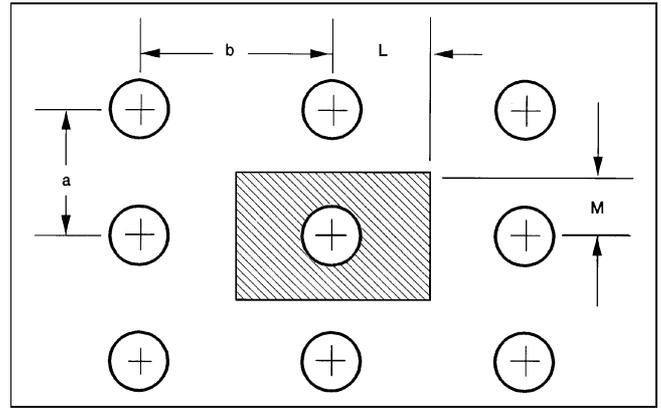

Fig. 23 Rectangular Tube Array

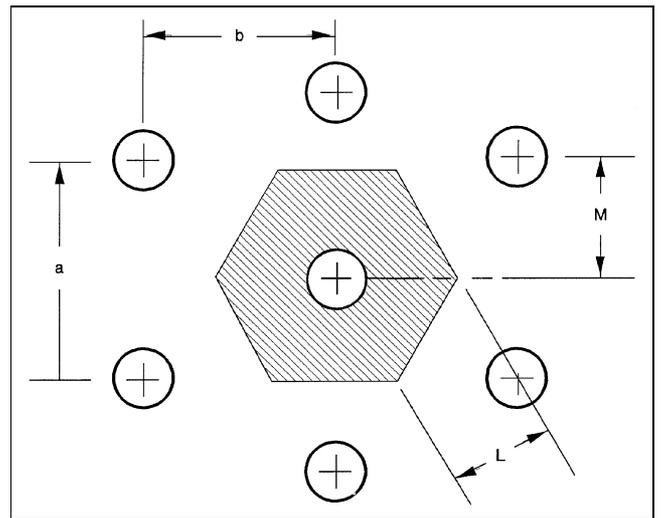

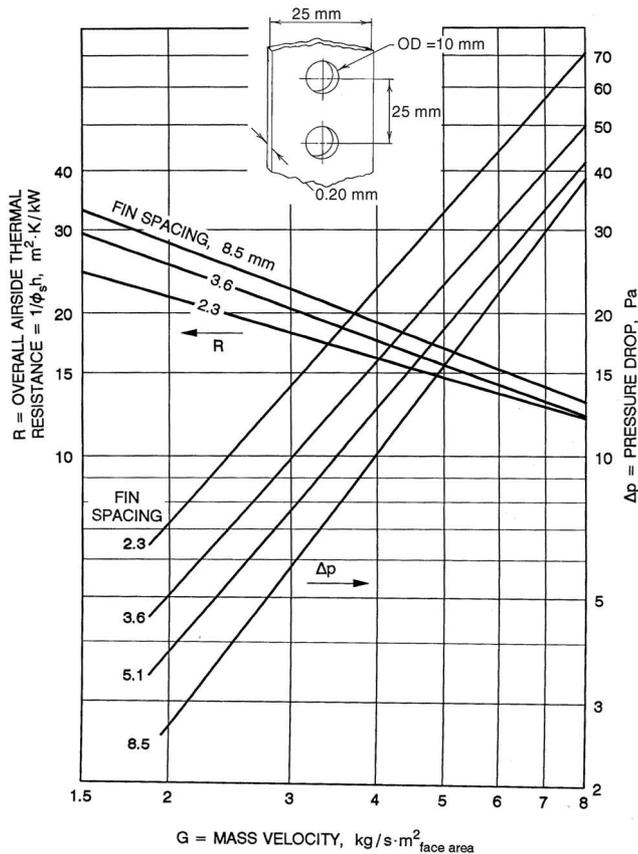

Fig. 24 Hexagonal Tube Array

may or may not be negligible, depending on the application, quality of manufacture, materials, and temperatures involved. Tests of plate fin coils with expanded tubes have indicated that substantial losses in performance can occur with fins that have cracked collars; but negligible thermal resistance was found in coils with continuous collars and properly expanded tubes (Dart 1959).

Thermal resistance at an interface between two solid materials is largely a function of the surface properties and characteristics of the solids, the contact pressure, and the fluid in the interface, if any. Eckels (1977) models the influence of fin density, fin thickness, and tube diameter on contact pressure and compared it to data for wet and dry coils. Shlykov (1964) shows that the range of attainable contact resistances is large. Sonokama (1964) presents data on the effects of contact pressure, surface roughness, hardness, void material, and the pressure of the gas in the voids. Lewis and Sauer (1965) show the resistance of adhesive bonds, and Kaspereck (1964) and Clausing (1964) give data on the contact resistance in a vacuum environment.

### Finned-Tube Heat Transfer

The heat transfer coefficients for finned coils follow the basic equations of convection, condensation, and evaporation. The arrangement of the fins affects the values of constants and the exponential powers in the equations. It is generally necessary to refer to test data for the exact coefficients.

**Fig. 25 Overall Air-Side Thermal Resistance and Pressure Drop for 1-Row Coils**  
(Shepherd 1946)

For natural-convection finned coils (gravity coils), approximate coefficients can be obtained by considering the coil to be made of tubular and vertical fin surfaces at different temperatures and then applying the natural-convection equations to each. This calculation is difficult because the natural-convection coefficient depends on the temperature difference, which varies at different points on the fin.

Fin efficiency should be high (80 to 90%) for optimum natural-convection heat transfer. A low fin efficiency reduces the temperature near the tip. This reduces  $\Delta t$  near the tip and also the coefficient  $h$ , which in natural convection depends on  $\Delta t$ . The coefficient of heat transfer also decreases as the fin spacing decreases because of interfering convection currents from adjacent fins and reduced free-flow passage; 50 to 100 mm spacing is common. Generally, high coefficients result from large temperature differences and small flow restriction.

Edwards and Chaddock (1963) give coefficients for several circular fin-on-tube arrangements, using fin spacing  $\delta$  as the characteristic length and in the form  $Nu = f(GrPr\delta/D_o)$ , where  $D_o$  is the fin diameter.

Forced-convection finned coils are used extensively in a wide variety of equipment. The fin efficiency for optimum performance is smaller than that for gravity coils because the forced-convection coefficient is almost independent of the temperature difference between the surface and the fluid. Very low fin efficiencies should be avoided because an inefficient surface gives a high (uneconomical) pressure drop. An efficiency of 70 to 90% is often used.

As fin spacing is decreased to obtain a large surface area for heat transfer, the coefficient generally increases because of higher air

velocity between fins at the same face velocity and reduced equivalent diameter. The limit is reached when the boundary layer formed on one fin surface (Figure 8) begins to interfere with the boundary layer formed on the adjacent fin surface, resulting in a decrease of the heat transfer coefficient, which may offset the advantage of larger surface area.

Selection of the fin spacing for forced-convection finned coils usually depends on economic and practical considerations, such as fouling, frost formation, condensate drainage, cost, weight, and volume. Fins for conventional coils generally are spaced 1.8 to 4.2 mm apart, except where factors such as frost formation necessitate wider spacing.

Several means are used to obtain higher coefficients with a given air velocity and surface, usually by creating air turbulence, generally with a higher pressure drop: (1) staggered tubes instead of in-line tubes for multiple-row coils; (2) artificial additional tubes, or collars or fingers made by suitably forming the fin materials; (3) corrugated fins instead of plane fins; and (4) louvered or interrupted fins.

Figure 25 shows data for one-row coils. The thermal resistances plotted include the temperature drop through the fins, based on one square metre of total external surface area.

The section on Bibliography lists other sources of information on fins.

### SYMBOLS

- $A$  = surface area for heat transfer
- $A_F$  = cross-sectional flow area
- $C$  = conductance; or fluid capacity rate
- $C_1, C_2$  = Planck's law constants [see Equation (33)]
- $c$  = coefficient or constant
- $c_p$  = specific heat at constant pressure
- $c_v$  = specific heat at constant volume
- $D$  = tube (inside) or rod diameter; or diameter of the vessel
- $d$  = diameter; or prefix meaning differential
- $E$  = electric field
- $e$  = emissivity; or protuberance height
- $F$  = angle factor [see Equations (40) and (41)]
- $Fo$  = Fourier number (see Table 1 and Figures 2, 3, and 4)
- $f$  = Fanning friction factor for single-phase flow; or electric body force
- $G$  = mass velocity; or irradiation
- $Gr$  = Grashof number
- $g$  = gravitational acceleration
- $h$  = heat transfer coefficient; or offset strip fin height
- $I$  = modified Bessel function
- $ID$  = inside diameter
- $J$  = mechanical equivalent of heat; or radiosity
- $j$  = heat transfer factor [see Equation (4), Table 6]
- $k$  = thermal conductivity
- $L$  = length; or height of liquid film
- $l$  = length; or length of one module of offset strip fins
- $M$  = mass; or molecular mass
- $m$  = general exponent
- $\dot{m}$  = mass rate of flow
- $n$  = general number [see Equation (2) in Table 5 or Table 7 (c)]; or ratio  $r/r_m$  (see Figures 2, 3, and 4); or number of blades
- NTU = number of exchanger heat transfer units [see Equation (17)]
- Nu = Nusselt number
- $p$  = pressure; or fin pitch; or repeated rib pitch
- Pr = Prandtl number
- $q$  = rate of heat transfer
- $q''$  = heat flux
- $R$  = thermal resistance
- Re = pipe Reynolds number ( $GD/\mu$ ); or film Reynolds number ( $4\Gamma/\eta$ )
- Re\* = rotary Reynolds number ( $D^2N_p/\eta$ )
- $r$  = radius
- $s$  = lateral spacing of offset fin strips
- $T$  = absolute temperature
- $t$  = temperature; or fin thickness at base
- $U$  = overall heat transfer coefficient
- $V$  = linear velocity
- $W$  = work; or total rate of energy emission; or fin dimension

- $W_\lambda$  = monochromatic emissive power  
 $x, y, z$  = lengths along principal coordinate axes  
 $Y$  = temperature ratio (see Figures 2, 3, and 4)  
 $y$  = one-half diametrical pitch of a twisted tape: length of 180° revolution/tube diameter  
 $Z$  = ratio of fluid capacity rates [see Equation (18)]  
 $\alpha$  = thermal diffusivity =  $k/\rho c_p$  [Equation (28)]; or absorptance; or spiral angle for helical fins; or aspect ratio of offset strip fins,  $s/h$ ; or enhancement factor: ratio of enhanced to unenhanced heat transfer coefficient—conditions remaining the same.  
 $\beta$  = coefficient of thermal expansion; or contact angle of rib profile  
 $\Gamma$  = mass flow of liquid per unit length  
 $\gamma$  = ratio,  $t/s$   
 $\Delta$  = difference between values  
 $\delta$  = distance between fins; or ratio  $t/l$ ; or thickness of twisted tape  
 $\epsilon$  = hemispherical emittance; or exchanger heat transfer effectiveness [see Equation (16)]; or dielectric constant  
 $\lambda$  = wavelength  
 $\mu$  = absolute viscosity  
 $\nu$  = kinematic viscosity  
 $\rho$  = density; or reflectance  
 $\sigma$  = Stefan-Boltzmann constant  
 $\tau$  = time; or transmittance [see Equation (39)]  
 $\Phi$  = fin resistance defined by Equation (54);  $\Phi_{max}$  is maximum limiting value of  $\Phi$   
 $\phi$  = fin efficiency [see Equation (50)]; or angle [see Equation (41)]; or temperature correction factor [see Table 7(c)]

### Subscripts

- $a$  = augmented  
 $b$  = blackbody; or based on bulk fluid temperature  
 $c$  = convection; or critical; or cold (fluid)  
 $e$  = equivalent; or environment  
 $f$  = film; or fin  
 $fc$  = finite cylinder  
 $frs$  = finite rectangular solid  
 $g$  = gas  
 $h$  = horizontal; or hot (fluid); or hydraulic  
 $i$  = inlet; or inside; or particular surface (radiation); or based on maximum inside (envelope) diameter  
 $ic$  = infinite cylinder  
 $if$  = interface  
 $is$  = infinite slab  
 $iso$  = isothermal conditions  
 $j$  = particular surface (radiation)  
 $k$  = particular surface (radiation)  
 $L$  = thickness  
 $l$  = liquid  
 $m$  = mean  
 $max$  = maximum  
 $min$  = minimum  
 $n$  = counter variable  
 $o$  = outside; or outlet; or overall; or at base of fin  
 $p$  = prime heat transfer surface  
 $r$  = radiation; or root (fin); or reduced  
 $s$  = surface; or secondary heat transfer surface; or straight or plain; or accounting for flow blockage of twisted tape  
 $st$  = static (pressure)  
 $t$  = temperature; or terminal temperature; or tip (fin)  
 $v$  = vapor; or vertical  
 $w$  = wall; or wafer  
 $\lambda$  = monochromatic  
 $\infty$  = bulk

## CHAPTER 4

# TWO-PHASE FLOW

<i>Boiling</i> .....	4.1
<i>Condensing</i> .....	4.7
<i>Pressure Drop</i> .....	4.11
<i>Enhanced Surfaces</i> .....	4.13
<i>Symbols</i> .....	4.13

**T**WO-PHASE FLOW is encountered extensively in the air-conditioning, heating, and refrigeration industries. A combination of liquid and vapor refrigerant exists in flooded coolers, direct-expansion coolers, thermosiphon coolers, brazed and gasketed plate evaporators and condensers, and tube-in-tube evaporators and condensers, as well as in air-cooled evaporators and condensers. In the pipes of heating systems, steam and liquid water may both be present. Because the hydrodynamic and heat transfer aspects of two-phase flow are not as well understood as those of single-phase flow, no single set of correlations can be used to predict pressure drops or heat transfer rates. Instead, the correlations are for specific thermal and hydrodynamic operating conditions.

This chapter presents the basic principles of two-phase flow and provides information on the vast number of correlations that have been developed to predict heat transfer coefficients and pressure drops in these systems.

### BOILING

Commonly used refrigeration evaporators are (1) flooded evaporators, where refrigerants at low fluid velocities boil outside or inside tubes; and (2) dry expansion shell-and-tube evaporators, where refrigerants at substantial fluid velocities boil outside or inside tubes.

Two-phase heat and mass transport are characterized by various flow and thermal regimes, whether vaporization takes place under natural convection or in forced flow. Unlike single-phase flow

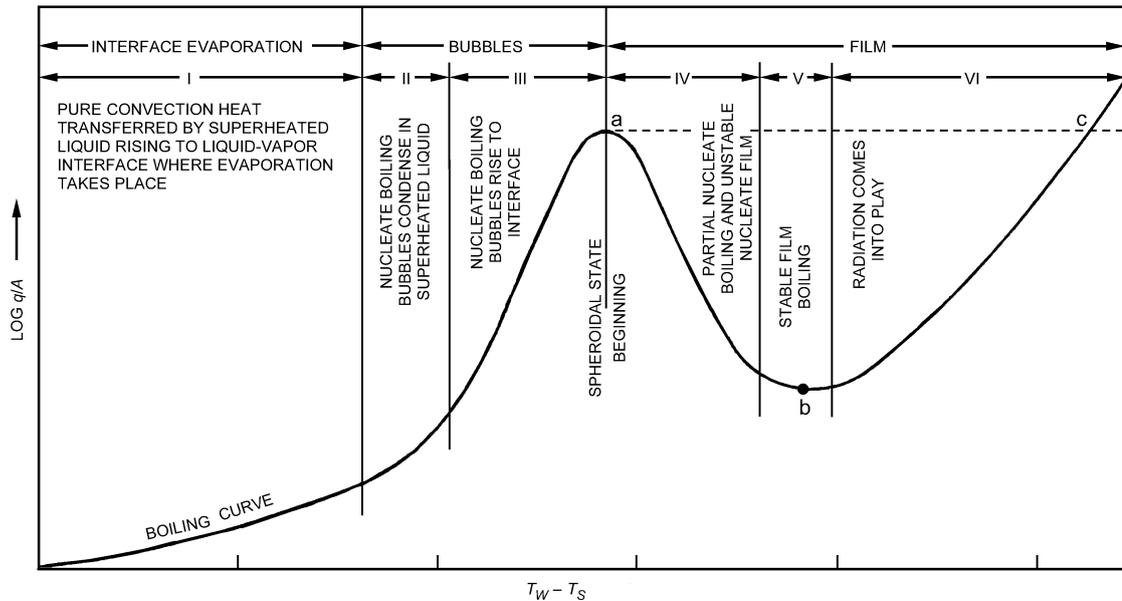

systems, the heat transfer coefficient for a two-phase mixture depends on the flow regime, the thermodynamic and transport properties of both the vapor and the liquid, the roughness of the heating surface, the wetting characteristics of the surface-liquid pair, and other parameters. Therefore, it is necessary to consider each flow and boiling regime separately to determine the heat transfer coefficient.

Accurate data defining limits of regimes and determining the effects of various parameters are not available. The accuracy of correlations in predicting the heat transfer coefficient for two-phase flow is in most cases not known beyond the range of the test data.

### Boiling and Pool Boiling in Natural Convection Systems

**Regimes of Boiling.** The different regimes of pool boiling described by Farber and Scoriah (1948) verified those suggested by Nukiyama (1934). The regimes are illustrated in Figure 1. When the temperature of the heating surface is near the fluid saturation temperature, heat is transferred by convection currents to the free surface where evaporation occurs (Region I). Transition to nucleate boiling occurs when the surface temperature exceeds saturation by a few degrees (Region II).

In **nucleate boiling** (Region III), a thin layer of superheated liquid is formed adjacent to the heating surface. In this layer, bubbles nucleate and grow from spots on the surface. The thermal resistance

**Fig. 1 Characteristic Pool Boiling Curve**

The preparation of this chapter is assigned to TC 1.3, Heat Transfer and Fluid Flow.

of the superheated liquid film is greatly reduced by bubble-induced agitation and vaporization. Increased wall temperature increases bubble population, causing a large increase in heat flux.

As heat flux or temperature difference increases further and as more vapor forms, the flow of the liquid toward the surface is interrupted, and a vapor blanket forms. This gives the **maximum heat flux**, which is at the departure from nucleate boiling (DNB) at point a, Figure 1. This flux is often termed the **burnout heat flux** or **boiling crisis** because, for constant power-generating systems, an increase of heat flux beyond this point results in a jump of the heater temperature (to point c, Figure 1), often beyond the melting point of a metal heating surface.

In systems with controllable surface temperature, an increase beyond the temperature for DNB causes a decrease of heat flux density. This is the **transition boiling regime** (Region IV); liquid alternately falls onto the surface and is repulsed by an explosive burst of vapor.

At sufficiently high surface temperatures, a stable vapor film forms at the heater surface; this is the **film boiling regime** (Regions V and VI). Because heat transfer is by conduction (and some radiation) across the vapor film, the heater temperature is much higher than for comparable heat flux densities in the nucleate boiling regime. The minimum film boiling (MFB) heat flux (point b) is the lower end of the film boiling curve.

**Free Surface Evaporation.** In Region I, where surface temperature exceeds liquid saturation temperature by less than a few degrees, no bubbles form. Evaporation occurs at the free surface by convection of superheated liquid from the heated surface. Correlations of heat transfer coefficients for this region are similar to those for fluids under ordinary natural convection [Equations (1) through (4) in Table 1].

**Nucleate Boiling.** Much information is available on boiling heat transfer coefficients, but no universally reliable method is available for correlating the data. In the nucleate boiling regime, heat flux density is not a single, valued function of the temperature but depends also on the nucleating characteristics of the surface, as illustrated by Figure 2 (Berenson 1962).

The equations proposed for correlating nucleate boiling data can be put in a form that relates heat transfer coefficient  $h$  to temperature difference ( $t_w - t_{sat}$ ):

$$h = \text{constant} (t_w - t_{sat})^a \quad (1)$$

Exponent  $a$  is normally about 3 for a plain, smooth surface; its value depends on the thermodynamic and transport properties of the vapor and the liquid. Nucleating characteristics of the surface, including the size distribution of surface cavities and the wetting characteristics of the surface-liquid pair, affect the value of the multiplying constant and the value of the exponent  $a$  in Equation (1).

A generalized correlation cannot be expected without consideration of the nucleating characteristics of the heating surface. A statistical analysis of data for 25 liquids by Hughmark (1962) shows that in a correlation not considering surface condition, deviations of more than 100% are common.

In the following sections, correlations and nomographs for prediction of nucleate and flow boiling of various refrigerants are given. For most cases, these correlations have been tested for refrigerants, such as R-11, R-12, R-113, and R-114, that have now been identified as environmentally harmful and are no longer being used in new equipment. Extensive research on the thermal and fluid characteristics of alternative refrigerants/refrigerant mixtures has taken place in recent years, and some correlations have been suggested.

Stephan and Abdelsalam (1980) developed a statistical approach for estimating the heat transfer during nucleate boiling. The correlation [Equation (5) in Table 1] should be used with a fixed contact angle  $\theta$  regardless of the fluid. Cooper (1984) proposed a dimensional correlation for nucleate boiling, shown as Equation (6) in Table 1. The dimensions required are listed in Table 1. This correlation is recommended for fluids with poorly defined physical properties.

Gorenflo (1993) proposed a nucleate boiling correlation based on a set of reference conditions and a base heat transfer coefficient as shown in Equation (7) in Table 1. The correlation was developed for a reduced pressure  $p_r$  of 0.1 and the reference conditions given in Table 1. Base heat transfer coefficients are given for three fluids in Table 1, and Gorenflo (1993) should be consulted for additional fluids.

In addition to correlations dependent on thermodynamic and transport properties of the vapor and the liquid, Borishansky et al. (1962) and Lienhard and Schrock (1963) documented a correlating method based on the law of corresponding states. The properties can be expressed in terms of fundamental molecular parameters, leading to scaling criteria based on the reduced pressure,  $p_r = p/p_c$ , where  $p_c$  is the critical thermodynamic pressure for the coolant. An example of this method of correlation is shown in Figure 3. The reference pressure  $p^*$  was chosen as  $p^* = 0.029p_c$ . This correlation provides a simple method for scaling the effect of pressure if data are available for one pressure level. It also has an advantage if the thermodynamic and particularly the transport properties used in several equations in Table 1 are not accurately known. In its present form, this correlation gives a value of  $a = 2.33$  for the exponent in Equation (1) and consequently should apply for typical aged metal surfaces.

There are explicit heat transfer coefficient correlations based on the law of corresponding states for various substances (Borishansky and Kosyrev 1966), halogenated refrigerants (Danilova 1965), and flooded evaporators (Starczewski 1965). Other investigations examined the effects of oil on boiling heat transfer from diverse configurations, including boiling from a flat plate (Stephan 1963b); a 14.0 mm OD horizontal tube using an oil-R-12 mixture (Tschernobyiski and Ratiani 1955); inside horizontal tubes using an oil-R-12 mixture (Breber et al. 1980, Worsoe-Schmidt 1959, Green and Furse 1963); and commercial copper tubing using R-11 and R-113 with oil content to 10% (Dougherty and Sauer 1974). Additionally, Furse (1965) examined R-11 and R-12 boiling over a flat horizontal copper surface.

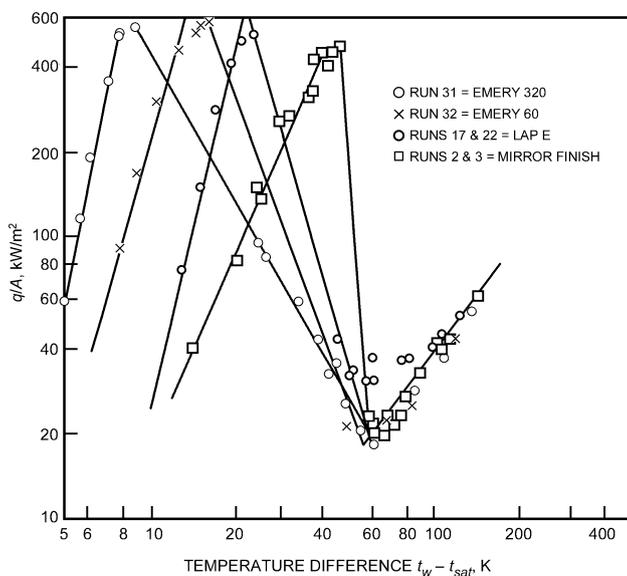

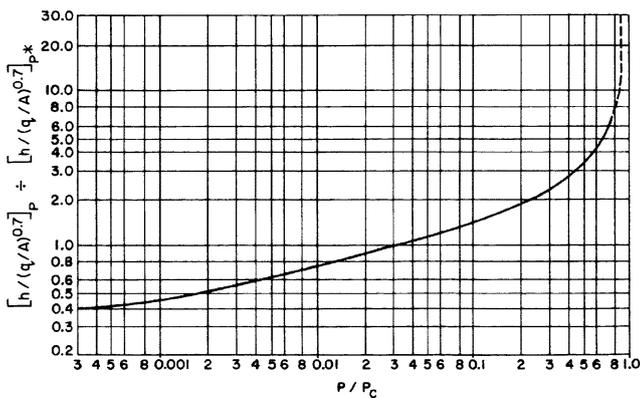

Fig. 2 Effect of Surface Roughness on Temperature in Pool Boiling of Pentane

Table 1 Equations for Boiling Heat Transfer

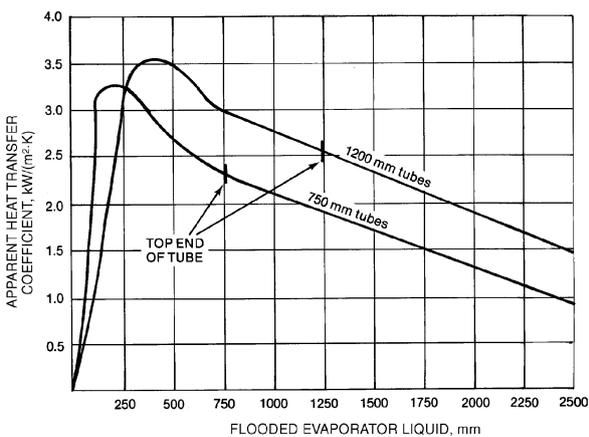

Description	References	Equations								
Free convection	Jakob (1949 and 1957)	$Nu = C(Gr)^m(Pr)^n$ (1)								
Free convection boiling, or boiling without bubbles for low $\Delta t$ and $GrPr < 10^8$ (all properties based on liquid state)		$Nu = 0.61(Gr)^{0.25}(Pr)^{0.25}$ (2)								
Vertical submerged surface		$Nu = 0.16(Gr)^{1/3}(Pr)^{1/3}$ (3)

**Fig. 3 Correlation of Pool Boiling Data in Terms of Reduced Pressure**

**Fig. 4 Boiling Heat Transfer Coefficients for Flooded Evaporator**

**Maximum Heat Flux and Film Boiling**

Maximum or critical heat flux and the film boiling region are not as strongly affected by conditions of the heating surface as the heat flux in the nucleate boiling region, making analysis of DNB and of film boiling more tractable.

Carey (1992) provides a review of the mechanisms that have been postulated to cause the DNB phenomenon in pool boiling. Each model is based on the scenario that vapor blankets, which lead to an increased thermal resistance, exist on portions of the heat transfer surface. It has been proposed that these blankets may result from Helmholtz instabilities.

When DNB (point *a*, Figure 1) is assumed to be a hydrodynamic instability phenomenon, a simple relation, Equation (10) in Table 1, can be derived to predict this flux for pure, wetting liquids (Kutateladze 1951, Zuber et al. 1962). The dimensionless constant *K* varies from approximately 0.12 to 0.16 for a large variety of liquids. The effect of wettability is still in question. Van Stralen (1959) found that for liquid mixtures, DNB is a function of the concentration.

The minimum heat flux density (point *b*, Figure 1) in film boiling from a horizontal surface and a horizontal cylinder can be predicted by Equations (11) and (12) in Table 1. The numerical factors 0.09 and 0.114 were adjusted to fit experimental data; values predicted by two analyses were approximately 30% higher. Equation (13) in Table 1 predicts the temperature difference at minimum heat flux of film boiling.

The heat transfer coefficient in film boiling from a horizontal surface can be predicted by Equation (14) in Table 1; and from a horizontal cylinder by Equation (15) in Table 1 (Bromley 1950),

which has been generalized to include the effect of surface tension and cylinder diameter, as shown in Equations (16), (17), and (18) in Table 1 (Breen and Westwater 1962).

Frederking and Clark (1962) found that for turbulent film boiling, Equation (19) in Table 1 agrees with data from experiments at reduced gravity (Rohsenow 1963, Westwater 1963, Kutateladze 1963, Jakob 1949 and 1957).

**Flooded Evaporators**

Equations in Table 1 merely approximate heat transfer rates in flooded evaporators. One reason is that vapor entering the evaporator combined with vapor generated within the evaporator can produce significant forced convection effects superimposed on those caused by nucleation. Nonuniform distribution of the two-phase, vapor-liquid flow within the tube bundle of shell-and-tube evaporators or the tubes of vertical-tube flooded evaporators is also important.

Bundle data and design methods for plain, low fin, and enhanced tubes have been reviewed in Thome (1990) and Collier and Thome (1996).

Typical performance of vertical tube natural circulation evaporators, based on data for water, is shown in Figure 4 (Perry 1950). Low coefficients are at low liquid levels because insufficient liquid covers the heating surface. The lower coefficient at high levels is the result of an adverse effect of hydrostatic pressure on temperature difference and circulation rate. Perry (1950) noted similar effects in horizontal shell-and-tube evaporators.

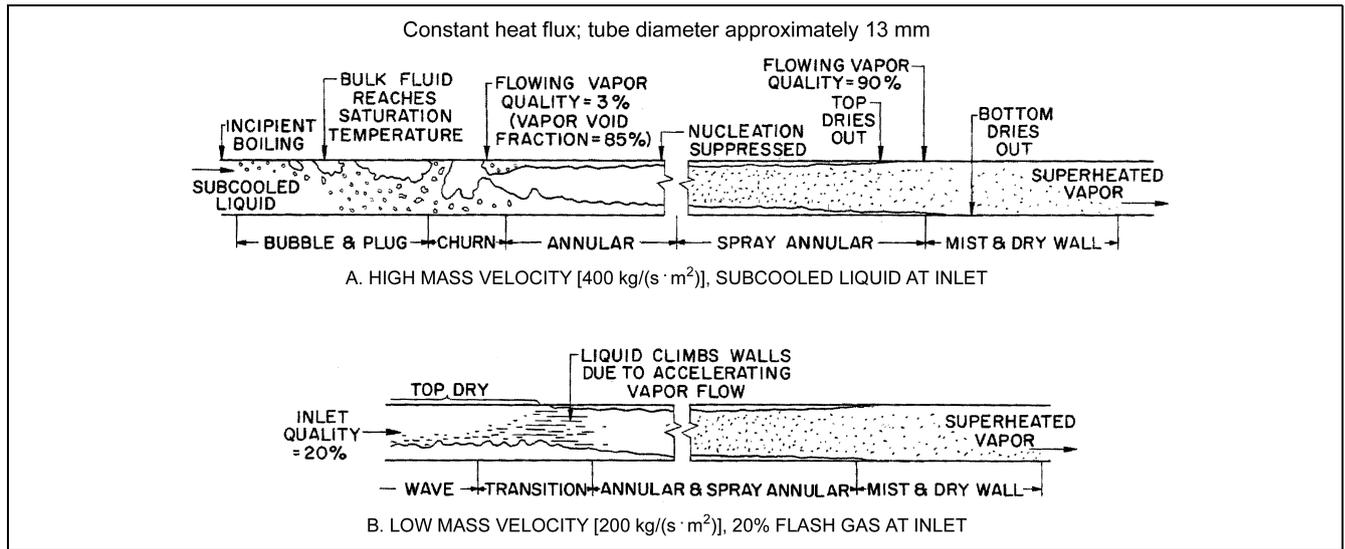

Fig. 5 Flow Regimes in Typical Smooth Horizontal Tube Evaporator

### Forced-Convection Evaporation in Tubes

**Flow Mechanics.** When a mixture of liquid and vapor flows inside a tube, a number of flow patterns occur, depending on the mass fraction of liquid, the fluid properties of each phase, and the flow rate. In an evaporator tube, the mass fraction of liquid decreases along the circuit length, resulting in a series of changing vapor-liquid flow patterns. If the fluid enters as a subcooled liquid, the first indications of vapor generation are bubbles forming at the heated tube wall (nucleation). Subsequently, bubble, plug, churn (or semiannular), annular, spray annular, and mist flows can occur as the vapor content increases for two-phase flows in horizontal tubes. Idealized flow patterns are illustrated in Figure 5A for a horizontal tube evaporator.

Because nucleation occurs at the heated surface in a thin sublayer of superheated liquid, boiling in forced convection may begin while the bulk of the liquid is subcooled. Depending on the nature of the fluid and the amount of subcooling, the bubbles formed can either collapse or continue to grow and coalesce (Figure 5A), as Gouse and Coumou (1965) observed for R-113. Bergles and Rohsenow (1964) developed a method to determine the point of incipient surface boiling.

After nucleation begins, bubbles quickly agglomerate to form vapor plugs at the center of a vertical tube, or, as shown in Figure 5A, vapor plugs form along the top surface of a horizontal tube. At the point where the bulk of the fluid reaches saturation temperature, which corresponds to local static pressure, there will be up to 1% vapor quality because of the preceding surface boiling (Guerrieri and Talty 1956).

Further coalescence of vapor bubbles and plugs results in churn, or semiannular flow. If the fluid velocity is high enough, a continuous vapor core surrounded by a liquid annulus at the tube wall soon forms. This annular flow occurs when the ratio of the tube cross section filled with vapor to the total cross section is approximately 85%. With common refrigerants, this equals a vapor quality of about 0% to 30%. **Vapor quality** is the ratio of mass (or mass flow rate) of vapor to total mass (or mass flow rate) of the mixture. The usual flowing vapor quality or vapor fraction is referred to throughout this discussion. Static vapor quality is smaller because the vapor in the core flows at a higher average velocity than the liquid at the walls (see Chapter 2).

If two-phase mass velocity is high [greater than 200 kg/(s · m<sup>2</sup>) for a 12 mm tube], annular flow with small drops of entrained liquid

in the vapor core (spray) can persist over a vapor quality range from about 10% to more than 90%. Refrigerant evaporators are fed from an expansion device at vapor qualities of approximately 20%, so that annular and spray annular flow predominate in most tube lengths. In a vertical tube, the liquid annulus is distributed uniformly over the periphery, but it is somewhat asymmetric in a horizontal tube (Figure 5A). As vapor quality reaches about 80%, the surface dries out. Chaddock and Noerager (1966) found that in a horizontal tube, dryout occurs first at the top of the tube and progresses toward the bottom with increasing vapor quality (Figure 5A).

If two-phase mass velocity is low [less than 200 kg/(s · m<sup>2</sup>) for a 12 mm horizontal tube], liquid occupies only the lower cross section of the tube. This causes a wavy type of flow at vapor qualities above about 5%. As the vapor accelerates with increasing evaporation, the interface is disturbed sufficiently to develop annular flow (Figure 5B). Liquid slugging can be superimposed on the flow configurations illustrated; the liquid forms a continuous, or nearly continuous, sheet over the tube cross section. The slugs move rapidly and at irregular intervals. Kattan et al. (1998a) presented a general method for prediction of flow pattern transitions (i.e., a flow pattern map) based on observations for R-134a, R-125, R-502, R-402A, R-404A, R-407C, and ammonia.

**Heat Transfer.** It is difficult to develop a single relation to describe the heat transfer performance for evaporation in a tube over the full quality range. For refrigerant evaporators with several percentage points of flash gas at entrance, it is less difficult because annular flow occurs in most of the tube length. The reported data are accurate only within geometry, flow, and refrigerant conditions tested; therefore, a large number of methods for calculating heat transfer coefficients for evaporation in tubes is presented in Table 2 (also see Figures 6 through 8).

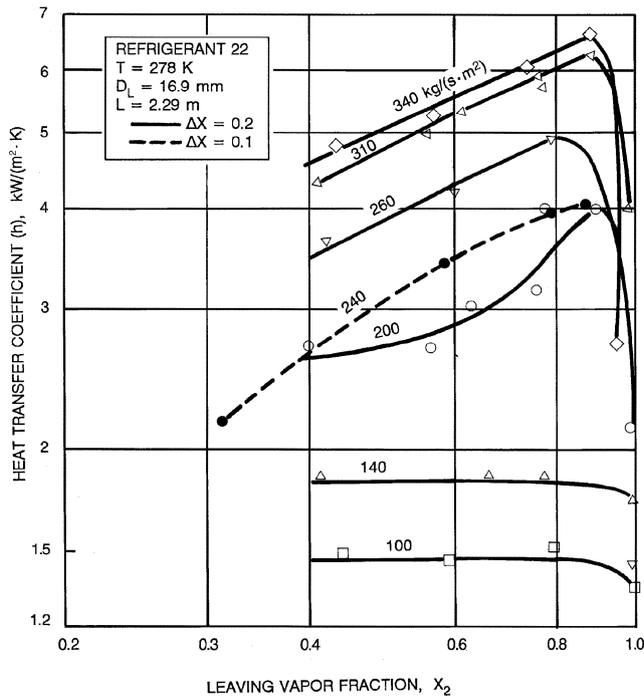

Figure 6 gives heat transfer data for R-22 evaporating in a 19.6 mm tube (Gouse and Coumou 1965). At low mass velocities [below 200 kg/(s · m<sup>2</sup>)], the wavy flow regime shown in Figure 5B probably exists, and the heat transfer coefficient is nearly constant along the tube length, dropping at the tube exit as complete vaporization occurs. At higher mass velocities, the flow pattern is usually annular, and the coefficient increases as vapor accelerates. As the surface dries and the flow reaches a 90% vapor quality, the coefficient drops sharply.

Equation (1) in Table 2 is used to estimate average heat transfer coefficients for refrigerants evaporating in horizontal tubes (Pierre

Note: Except for dimensionless equations, inch-pound units (lb<sub>m</sub>, h, ft, °F, and Btu) must be used.

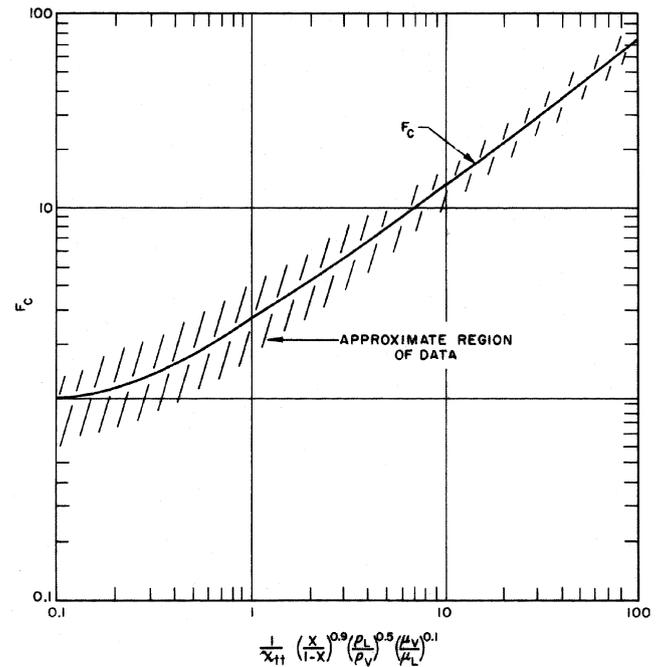

**Fig. 6 Heat Transfer Coefficient Versus Vapor Fraction for Partial Evaporation**

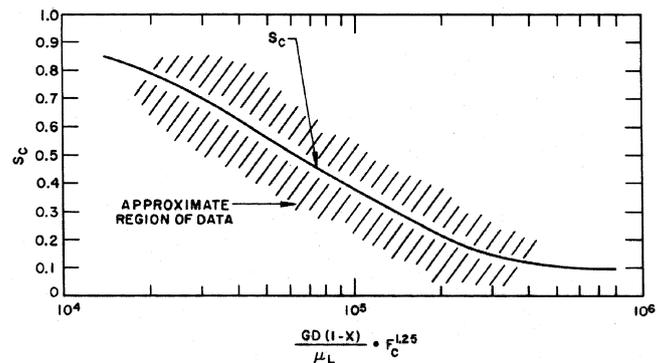

1955, 1957). A number of methods are also available to estimate local heat transfer coefficients during evaporation. Equations (2) through (6) in Table 2 summarize the Gungor and Winterton (1986) model, while Equation (7) gives the Kandlikar (1990) model. In addition, the Shah (1982) model is also recommended for estimating local heat transfer coefficients during annular flow. These local models have been found accurate for a wide range of refrigerants but do not include mechanisms to model dryout. The flow pattern based model of Kattan et al. (1998b) includes specific models for each flow pattern type and has been tested with the newer refrigerants such as R-134a and R-407C.

Heat transfer coefficients during flow in vertical tubes can be estimated with Equations (8), (9), and (10) in Table 2. The Chen correlation shown in Equations (11) through (13) in Table 2 includes terms for the velocity effect (convection) and heat flux (nucleation) and produces local heat transfer coefficients as a function of local vapor quality. The method developed by Steiner and Taborek (1992) includes an asymptotic model for the convection and nucleation component of heat transfer and is recommended for most situations.

The effect of lubricant on the evaporation heat transfer coefficients has been studied by a number of authors (Schalger et al. 1988, Eckels et al. 1993, and Zeurcher et al. 1999). Schalger et al. and Eckels et al. showed that the average heat transfer coefficients during evaporation of R-22 and R-134a in smooth and enhanced tubes are in general decreased by presence of lubricant (up to a 20% reduction at a 5% lubricant concentration by mass). Slight enhancements at lubricant concentrations under 3% are observed with some refrigerant lubricant mixtures. Zeurcher et al. (1999) studied local heat transfer coefficients of refrigerant/lubricant mixtures in the dry wall region of the evaporator (see Figure 5) and proposed prediction methods. The effect of lubricant concentration on local heat transfer coefficients was shown to be dependent on the mass flux and vapor quality. At low mass fluxes, the oil sharply decreased performance, while at higher mass fluxes, enhancements at certain vapor qualities were seen.

## CONDENSING

In most applications that use the condensation process, condensation is initiated by removing heat at a solid-vapor interface, either through the walls of the vessel containing the saturated vapor or through the solid surface of a cooling mechanism placed within the saturated vapor. If a sufficient amount of energy is removed, the local temperature of the vapor near the interface will drop below its equilibrium saturation temperature. Because the heat removal process creates a temperature gradient with the lowest temperature near the interface, vapor droplets most likely form at this location. This defines one type of heterogeneous nucleation that can result in either dropwise condensation or film condensation, depending on the physical characteristics of the solid surface and the working fluid.

**Dropwise condensation** occurs on the cooling solid surface when its surface free energy is relatively low compared to that of the liquid. Examples of this type of interface include highly polished or fatty acid-impregnated surfaces in contact with steam. **Film condensation** occurs when a cooling surface having relatively high surface free energy contacts a fluid having lower surface free energy

(see Isrealachvili 1991). This is the type of condensation that occurs in most systems.

The rate of heat transport depends on the condensate film thickness, which depends on the rate of vapor condensation and the rate of condensate removal. At high reduced pressures, the heat transfer coefficients for dropwise condensation are higher than those available in the presence of film condensation at the same surface loading. At low reduced pressures, the reverse is true. For example, there is a reduction of 6 to 1 in the dropwise condensation coefficient of steam when saturation pressure is decreased from 90 to 16 kPa. One method for correlating the dropwise condensation heat transfer coefficient employs nondimensional parameters, including the effect of surface tension gradient, temperature difference, and fluid properties.

When condensation occurs on horizontal tubes and short vertical plates, the condensate film motion is laminar. On vertical tubes and long vertical plates, the film motion can become turbulent. Grober et al. (1961) suggest using a Reynolds number (Re) of 1600 as the critical point at which the flow pattern changes

from laminar to turbulent. This Reynolds number is based on condensate flow rate divided by the breadth of the condensing surface. For a vertical tube, the breadth is the circumference of the tube; for a horizontal tube, the breadth is twice the length of the tube.  $Re = 4\Gamma/\mu_f$ , where  $\Gamma$  is the mass flow of condensate per unit of breadth, and  $\mu_f$  is the absolute (dynamic) viscosity of the condensate at the film temperature  $t_f$ . In practice, condensation is usually laminar in shell-and-tube condensers with the vapor outside horizontal tubes.

**Vapor velocity** also affects the condensing coefficient. When this is small, condensate flows primarily by gravity and is resisted by the viscosity of the liquid. When vapor velocity is high relative to the condensate film, there is appreciable drag at the vapor-liquid interface. The thickness of the condensate film, and hence the heat transfer coefficient, is affected. When vapor flow is upward, a retarding force is added to the viscous shear, increasing the film thickness. When vapor flow is downward, the film thickness decreases and the heat transfer coefficient increases. For condensation inside horizontal tubes, the force of the vapor velocity causes

**Table 3 Heat Transfer Coefficients for Film-Type Condensation**

For $\frac{DG_l}{\mu_l} > 5000$ and $\frac{DG_v}{\mu_l} \left( \frac{\rho_l}{\rho_v} \right)^{0.5} > 20\,000$	Ackers et al. (1959)	$\frac{hD}{k_l} = 0.026 \left( \frac{c_p \mu_l}{k_l} \right)^{1/3} \left( \frac{DG_e}{\mu_l} \right)^{0.8}$ (13)
		where
		$G_e = G_v(\rho_l/\rho_v)^{0.5} + G_l$

Notes: 1. Equations (1) through (10) are dimensional; inch-pound units (Btu, h, ft, °F, and lb<sub>m</sub>) must be used.

2.  $t_f$  = liquid film temperature =  $t_{sat} - 0.75\Delta t$

the condensate to flow. When the vapor velocity is high, the transition from laminar to turbulent flow occurs at Reynolds numbers lower than previously described [i.e., 1600 according to Grober et al. (1961)].

When **superheated** vapor is condensed, the heat transfer coefficient depends on the surface temperature. When the surface temperature is *below* saturation temperature, using the value of  $h$  for condensation of saturated vapor that incorporates the difference between the *saturation* temperature and the surface temperature leads to insignificant error (McAdams 1954). If the surface temperature is *above* the saturation temperature, there is no condensation and the equations for gas convection apply.

Correlation equations for condensing heat transfer are given in Table 3. Factors  $F_1$  and  $F_2$ , which depend only on the physical properties of the working fluid and which occur often in these equations, have been computed for some commonly used refrigerants in Table 4. Refrigerant properties used in the calculations may be found in Chapter 19.

In some cases, the equations are given in two forms: one is convenient when the amount of refrigerant to be condensed or the condensing load is known; the second is useful when the difference between the vapor temperature and the condensing surface temperature is known.

**Condensation on Outside Surface of Vertical Tubes**

For film-type condensation on the outside surface of vertical tubes and on vertical surfaces, Equations (1) and (2) in Table 3 are recommended when  $4\Gamma/\mu_f$  is less than 1800 (McAdams 1954). For these equations, fluid properties are evaluated at the mean film temperature. When  $4\Gamma/\mu_f$  is greater than 1800 (tall vertical plates or tubes), use Equation (3) or (4) in Table 3. Equations (2) and (4) in Table 3 are plotted in Figure 9. The theoretical curve for laminar film-type condensation is shown for comparison. A semitheoretical relationship for turbulent film-type condensation is also shown for Pr values of 1.0 and 5.0 (Colburn 1933-34).

**Condensation on Outside Surface of Horizontal Tubes**

For a bank of  $N$  tubes, Nusselt's equations, increased by 10% (Jakob 1949 and 1957), are given in Equations (5) and (6) in Table 3. Experiments by Short and Brown (1951) with R-11 suggest that drops of condensation falling from row to row cause local turbulence and increase heat transfer.

For condensation on the outside surface of horizontal finned tubes, Equation (7) in Table 3 is used for liquids that drain readily from the surface (Beatty and Katz 1948). For condensing steam out-

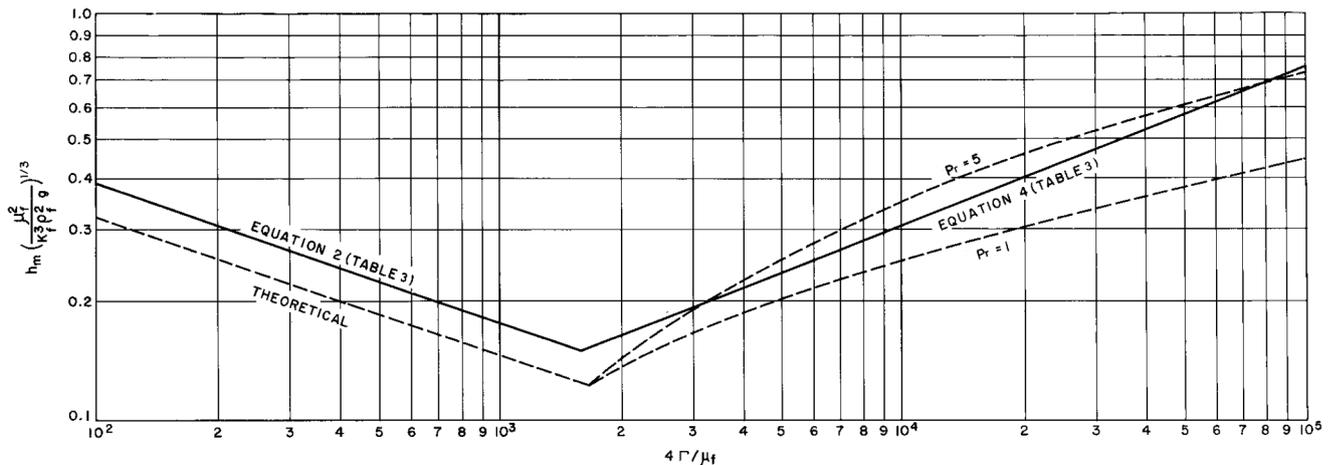

side finned tubes, where liquid is retained in the spaces between the tubes, coefficients substantially lower than those given by Equation (7) in Table 3 were reported. For additional data on condensation outside finned tubes, see Katz et al. (1947). For more on this topic, refer to Webb (1994).

**Table 4 Values of Condensing Coefficient Factors for Different Refrigerants (from Chapter 19)**

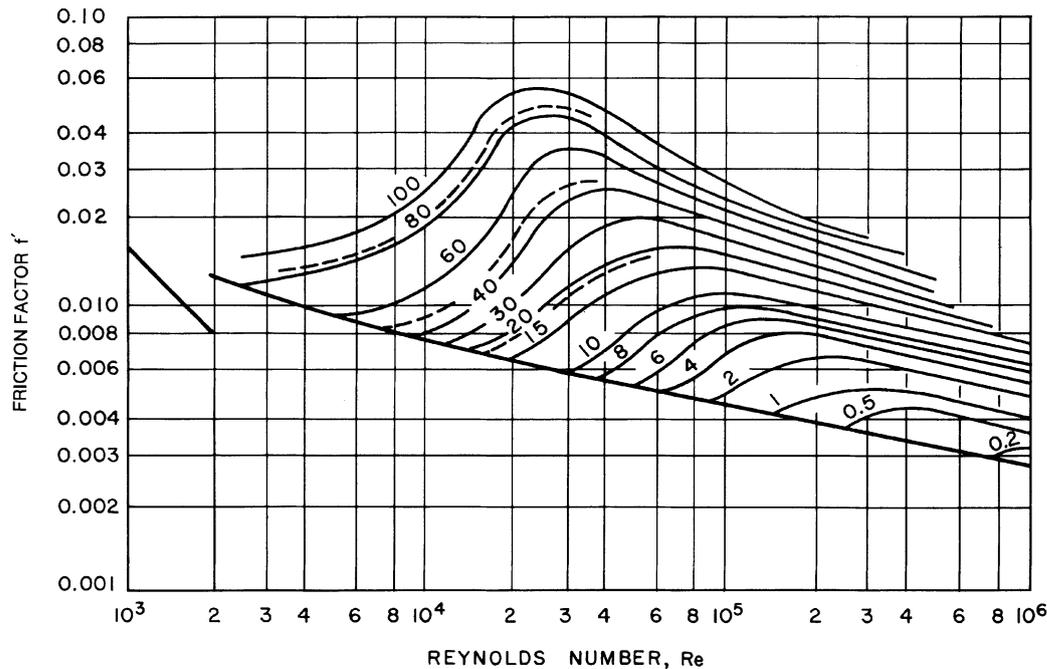

Refrigerant	Film Temperature, °C $t_f = t_{sat} - 0.75\Delta t$	$F_1$	$F_2$
Refrigerant 11	24	80.7	347.7
	38	80.3	344.7
	52	79.2	339.7
Refrigerant 12	24	69.8	284.3
	38	64.0	257.2
	52	58.7	227.6
Refrigerant 22	24	80.3	347.7
	38	75.5	319.4
	52	69.2	285.5
Sulfur Dioxide	24	152.1	812.2
	38	156.8	846.0
	52	166.8	917.9
Ammonia	24	214.5	1285.9
	38	214.0	1283.8
	52	214.0	1281.7
Propane	24	83.4	359.6
	38	82.3	357.4
	52	80.7	353.6
Butane	24	81.8	355.3
	38	81.8	356.6
	52	82.3	357.4

$$F_1 = \left( \frac{k_f^3 \rho_f^2 g}{\mu_f} \right)^{0.25} \quad \text{Units: } \left[ \frac{\text{W}^3 \cdot \text{kg}}{\text{s} \cdot \text{m}^7 \cdot \text{K}^3} \right]^{0.25}$$

$$F_2 = \left( \frac{k_f^3 \rho_f^2 g}{\mu_f} \right)^{1/3} \quad \text{Units: } \left[ \frac{\text{W}^3 \cdot \text{kg}}{\text{s} \cdot \text{m}^7 \cdot \text{K}^3} \right]^{1/3}$$

**Fig. 9 Film-Type Condensation**

Curve parameter =  $\Gamma/\rho s$ , where  $\Gamma$  = liquid flow rate,  $\rho$  = liquid density, and  $s$  = surface tension of liquid relative to water; values of gas velocity used in calculating  $f$  and  $Re$  are calculated as though no liquid were present.

Fig. 10 Friction Factors for Gas Flow Inside Pipes with Wetted Walls

### Simplified Equations for Steam

For film-type steam condensation at atmospheric pressure and film temperature drops of 5 to 85 K, McAdams (1954) recommends Equations (8) and (9) in Table 3.

### Condensation on Inside Surface of Vertical Tubes

Condensation on the inside surface of tubes is generally affected by appreciable vapor velocity. The measured heat transfer coefficients are as much as 10 times those predicted by Equation (4) in Table 3. For vertical tubes, Jakob (1949 and 1957) gives theoretical derivations for upward and downward vapor flow. For downward vapor flow, Carpenter and Colburn (1949) suggest Equation (10) in Table 3. The friction factor  $f'$  for vapor in a pipe containing condensate should be taken from Figure 10.

### Condensation on Inside Surface of Horizontal Tubes

For condensation on the inside surface of horizontal tubes (as in air-cooled condensers, evaporative condensers, and some shell-and-tube condensers), the vapor velocity and resulting shear at the vapor-liquid interface are major factors in analyzing heat transfer. Hoogendoorn (1959) identified seven types of two-phase flow patterns. For semistratified and laminar annular flow, use Equations (11) and (12) in Table 3 (Ackers and Rosson 1960). Ackers et al. (1959) recommend Equation (13) in Table 3 for turbulent annular flow (vapor Reynolds number greater than 20 000 and liquid Reynolds number greater than 5000). For high mass flux [ $> 200 \text{ kg}/(\text{m}^2 \cdot \text{s})$ ], the method of Shah (1979) is recommended for predicting local heat transfer coefficients during condensation. A method for using a flow regime map to predict the heat transfer coefficient for condensation of pure components in a horizontal tube is presented in Breber et al. (1980). More recently, the flow regime dependent method of Dobson and Chato (1998) provides a more accurate design approach.

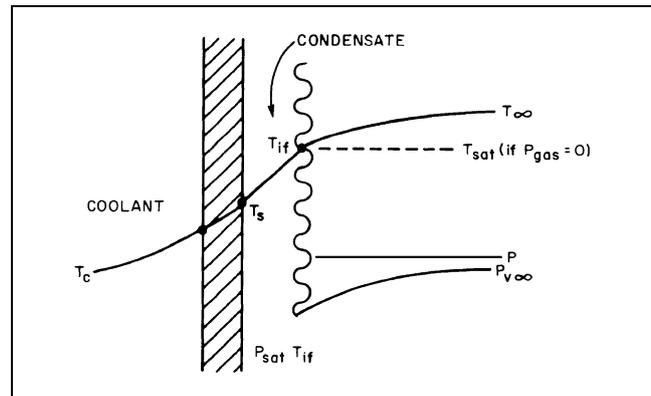

Fig. 11 Origin of Noncondensable Resistance

### Noncondensable Gases

Condensation heat transfer rates reduce drastically if one or more noncondensable gases are present in the condensing vapor/gas mixture. In mixtures, the condensable component is termed **vapor** and the noncondensable component is called **gas**. As the mass fraction of gas increases, the heat transfer coefficient decreases in an approximately linear manner. In a steam chest with 2.89% air by volume, Othmer (1929) found that the heat transfer coefficient dropped from about 11.4 to about 3.4  $\text{kW}/(\text{m}^2 \cdot \text{K})$ . Consider a surface cooled to some temperature  $t_s$  below the saturation temperature of the vapor (Figure 11). In this system, accumulated condensate falls or is driven across the condenser surface. At a finite heat transfer rate, a temperature profile develops across the condensate that can be estimated from Table 3; the interface of the condensate is at a temperature  $t_{if} > t_s$ . In the absence of gas, the interface temperature is the vapor saturation temperature at the pressure of the condenser.

The presence of noncondensable gas lowers the vapor partial pressure and hence the saturation temperature of the vapor in equilibrium with the condensate. Further, the movement of the vapor toward the cooled surface implies similar bulk motion of the gas. At the condensing interface, the vapor is condensed at temperature  $t_{if}$  and is then swept out of the system as a liquid. The gas concentration rises to ultimately diffuse away from the cooled surface at the same rate as it is convected toward the surface (Figure 11). If gas (mole fraction) concentration is  $Y_g$  and total pressure of the system is  $p$ , the partial pressure of the bulk gas is

$$p_{g\infty} = Y_{g\infty}p \quad (2)$$

The partial pressure of the bulk vapor is

$$p_{v\infty} = (1 - Y_{g\infty})p = Y_{v\infty}p \quad (3)$$

As opposing fluxes of convection and diffusion of the gas increase, the partial pressure of gas at the condensing interface is  $p_{gif} > p_{g\infty}$ . By Dalton's law, assuming isobaric condition,

$$p_{gif} + p_{vif} = p \quad (4)$$

Hence,  $p_{vif} < p_{v\infty}$ .

Sparrow et al. (1967) noted that thermodynamic equilibrium exists at the interface, except in the case of very low pressures or liquid metal condensation, so that

$$p_{vif} = p_{sat}(t_{if}) \quad (5)$$

where  $p_{sat}(t)$  is the saturation pressure of the vapor at temperature  $t$ . The available  $\Delta t$  for condensation across the condensate film is reduced from  $(t_\infty - t_s)$  to  $(t_{if} - t_s)$ , where  $t_\infty$  is the bulk temperature of the condensing vapor-gas mixture, caused by the additional noncondensable resistance.

The equations in Table 3 are still valid for the condensate resistance, but the interface temperature  $t_{if}$  must be found. The noncondensable resistance, which accounts for the temperature difference  $(t_\infty - t_{if})$ , depends on the heat flux (through the convecting flow to the interface) and the diffusion of gas away from the interface.

In simple cases, Sparrow et al. (1967), Rose (1969), and Sparrow and Lin (1964) found solutions to the combined energy, diffusion, and momentum problem of noncondensables, but they are cumbersome.

A general method given by Colburn and Hougen (1934) can be used over a wide range if correct expressions are provided for the rate equations—add the contributions of the sensible heat transport through the noncondensable gas film and the latent heat transport via condensation:

$$h_g(t_\infty - t_{if}) + K_D M_v h_{lv}(p_{v\infty} - p_{vif}) = h(t_{if} - t_s) = U(t_{if} - t_c) \quad (6)$$

where  $h$  is from the appropriate equation in Table 3.

The value of the heat transfer coefficient for the stagnant gas depends on the geometry and flow conditions. For flow parallel to a condenser tube, for example,

$$j = \left( \frac{h_g}{(c_p)_g G} \right) \left( \frac{(c_p)_g \mu_{gv}}{K_{Dg}} \right)^{2/3} \quad (7)$$

where  $j$  is a known function of  $Re = GD/\mu_{gv}$

The mass transfer coefficient  $K_D$  is

$$\frac{K_D}{M_m} \left[ \frac{p_{g\infty} - p_{gif}}{\ln(p_{g\infty}/p_{gif})} \right] \left( \frac{\mu_{gv}}{\rho_g D} \right)^{2/3} = j \quad (8)$$

The calculation method requires substitution of Equation (8) into Equation (6). For a given flow condition,  $G$ ,  $Re$ ,  $j$ ,  $M_m$ ,  $p_{g\infty}$ ,  $h_g$ , and

$h$  (or  $U$ ) are known. Assume values of  $t_{if}$ ; calculate  $p_{sat}(t_{if}) = p_{vif}$  and hence  $p_{gif}$ . If  $t_s$  is not known, use the overall coefficient  $U$  to the coolant and  $t_c$  in place of  $h$  and  $t_s$  in Equation (6). For either case, at each location in the condenser, iterate Equation (6) until it balances, giving the condensing interface temperature and, hence, the thermal load to that point (Colburn and Hougen 1934, Colburn 1951). For more detail, refer to Chapter 10 in Collier and Thome (1996).

### Other Impurities

Vapor entering the condenser often contains a small percentage of impurities such as oil. Oil forms a film on the condensing surfaces, creating additional resistance to heat transfer. Some allowance should be made for this, especially in the absence of an oil separator or when the discharge line from the compressor to the condenser is short.

### PRESSURE DROP

Total pressure drop for two-phase flow in tubes consists of friction, acceleration, and gravitational components. It is necessary to know the **void fraction** (the ratio of gas flow area to total flow area) to compute the acceleration and gravitational components. To compute the frictional component of pressure drop, either the **two-phase friction factor** or the **two-phase frictional multiplier** must be determined.

The homogeneous model provides a simple method for computing the acceleration and gravitational components of pressure drop. The homogeneous model assumes that the flow can be characterized by average fluid properties and that the velocities of the liquid and vapor phases are equal (Collier and Thome 1996, Wallis 1969).

Martinelli and Nelson (1948) developed a method for predicting the void fraction and two-phase frictional multiplier to use with a separated flow model. This method predicts the pressure drops of boiling refrigerants reasonably well. Other methods of computing the void fraction and two-phase frictional multiplier used in a separated flow model are given in (Collier and Thome 1996, Wallis 1969).

The general nature of annular gas-liquid flow in vertical, and to some extent horizontal, pipe is indicated in Figure 12 (Wallis 1970), which plots the effective gas friction factor versus the liquid fraction  $(1 - a)$ . Here  $a$  is the void fraction, or fraction of the pipe cross section taken up by the gas or vapor.

The effective gas friction factor is defined as

$$f_{eff} = \left[ \frac{a^{5/2} D}{2\rho_g (4Q_g/\pi D^2)^2} \right] \left( -\frac{dp}{ds} \right) \quad (9)$$

where  $D$  is the pipe diameter,  $\rho_g$  the gas density, and  $Q_g$  the gas volumetric flow rate. The friction factor of gas flowing by itself in the pipe (presumed smooth) is denoted by  $f_g$ . Wallis' analysis of the flow occurrences is based on interfacial friction between the gas and liquid. The wavy film corresponds to a conduit of relative roughness  $\epsilon/D$ , about four times the liquid film thickness. Thus, the pressure drop relation of vertical flow is

$$-\frac{dp}{ds} + \rho_g g = 0.01 \left( \frac{\rho_g}{D^5} \right) \left( \frac{4Q_g}{\pi} \right)^2 \frac{1 + 75(1 - a)}{a^{5/2}} \quad (10)$$

This corresponds to the Martinelli-type analysis with

$$f_{two-phase} = \phi_g^2 f_g$$

when

$$\phi_g^2 = \frac{1 + 75(1 - a)}{a^{5/2}} \quad (11)$$

The friction factor  $f_g$  (of the gas alone) is taken as 0.02, an appropriate turbulent flow value. This calculation can be modified for more detailed consideration of factors such as Reynolds number variation in friction, gas compressibility, and entrainment (Wallis 1970).

In two-phase flow inside horizontal tubes, the pressure gradient is written as the sum of frictional and momentum terms. Thus,

$$\frac{dp}{dz} = \left(\frac{dp}{dz}\right)_f + \left(\frac{dp}{dz}\right)_m \quad (12)$$

In adiabatic two-phase flow, the contribution of the momentum transfer to the overall pressure drop is negligibly small; theoretically, it is nonexistent if the flow is fully developed. In condensation heat transfer, the momentum transfer term contributes to the overall pressure drop due to the mass transfer that occurs at the liquid-vapor interface.

Two basic models were used in developing frictional pressure drop correlations for two-phase adiabatic flow. In the first, the flow of both phases is assumed to be homogeneous; the gas and liquid velocities are assumed equal. The frictional pressure drop is computed as if the flow were single phase, except for introducing modifiers to the single-phase friction coefficient. In the second model, the two phases are considered separate, and the velocities may differ. Two correlations used to predict the frictional pressure drop are those of Lockhart and Martinelli (1949) and Dukler et al. (1964).

In the Lockhart-Martinelli correlation, a parameter  $X$  was defined as

$$X = \left[ \left(\frac{dp}{dz}\right)_l \div \left(\frac{dp}{dz}\right)_v \right]^{0.5} \quad (13)$$

where

$\left(\frac{dp}{dz}\right)_l$  = frictional pressure gradient, assuming that liquid alone flows in pipe

$\left(\frac{dp}{dz}\right)_v$  = frictional pressure gradient, assuming that gas (or vapor in case of condensation) alone flows in pipe

The frictional pressure gradient due to the single-phase flow of the liquid or vapor depends on the type of flow of each phase, laminar or turbulent. For turbulent flow during condensation, replace  $X$  by  $X_{tt}$ . Thus,

$$X_{tt} = \left(\frac{1-x}{x}\right)^{0.9} \left(\frac{\mu_l}{\mu_v}\right)^{0.1} \left(\frac{\rho_v}{\rho_l}\right)^{0.5} \quad (14)$$

Lockhart and Martinelli (1949) also defined  $\phi_v$  as

$$\phi_v = \left[ \left(\frac{dp}{dz}\right)_f \div \left(\frac{dp}{dz}\right)_v \right]^{0.5} \quad (15)$$

For condensation,

$$\left(\frac{dp}{dz}\right)_v = -\frac{2f_o(xG)^2}{\rho_v D_i} \quad (16)$$

where

$$f_o = \frac{0.045}{(Gx D_i / \mu_v)^{0.2}} \quad (17)$$

Here  $f_o$  is the friction factor for adiabatic two-phase flow.

By analyzing the pressure drop data of simultaneous adiabatic flow of air and various liquids, Lockhart and Martinelli (1949) correlated the parameters  $\phi_v$  and  $X$  and reported the results graphically. Soliman et al. (1968) approximated the graphical results of  $\phi_v$  versus  $X_{tt}$  by

$$\phi_v = 1 + 2.85X_{tt}^{0.523} \quad (18)$$

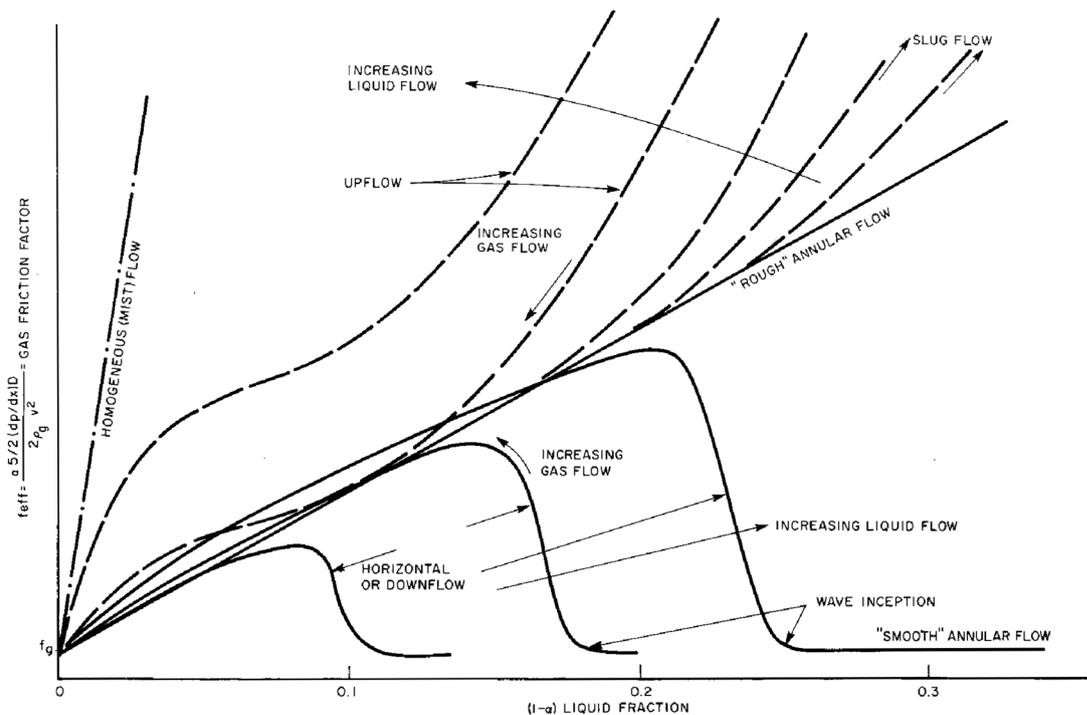

Fig. 12 Qualitative Pressure Drop Characteristics of Two-Phase Flow Regime

In the correlation of Dukler et al. (1964), the frictional pressure gradient is given by

$$\left(\frac{dp}{dz}\right)_f = -\frac{2G^2 f_o \alpha(\lambda) \beta}{D_i \rho_{NS}} \quad (19)$$

where

$f_o$  = single-phase friction coefficient evaluated at two-phase Reynolds number

$$= 0.0014 + 0.125 \left( \frac{4\dot{m}_t \beta}{\pi D_i \mu_{NS}} \right)^{-0.32} \quad (20)$$

$$\alpha(\lambda) = 1 - (\ln \lambda) / [1.281 + 0.478 \ln \lambda + 0.444 (\ln \lambda)^2 + 0.094 (\ln \lambda)^3 + 0.00843 (\ln \lambda)^4] \quad (21)$$

$$\beta = \left( \frac{\rho_l}{\rho_{NS}} \right) \frac{\lambda^2}{(1-\psi)} + \left( \frac{\rho_v}{\rho_{NS}} \right) \frac{(1-\lambda)^2}{\psi} \quad (22)$$

$$\rho_{NS} = \rho_l \lambda + \rho_v (1-\lambda) \quad (23)$$

$$\mu_{NS} = \mu_l \lambda + \mu_v (1-\lambda) \quad (24)$$

$$\lambda = 1 / \left( 1 + \frac{x}{(1-x)} \frac{\rho_v}{\rho_e} \right) \quad (25)$$

Because the correlations mentioned here were originally developed for adiabatic two-phase flow, Luu and Bergles (1980) modified the friction coefficients in Equations (16) and (19), using the modifier suggested by Silver and Wallis (1965-66). The modification replaced the friction coefficient  $f_o$  with the friction coefficient  $f_{co}$ . These terms are related by

$$\left(\frac{f_{co}}{f_o}\right) = \exp\left(\frac{\xi}{2f_o}\right) - \left(\frac{\xi}{f_o}\right) \quad (26)$$

where

$$\xi = \left(\frac{D_i \Psi}{2x}\right) \frac{dx}{dz} \quad (27)$$

Because the Lockhart-Martinelli and Dukler correlations for the frictional pressure gradient were based on the separated flow model, the momentum pressure gradient should be as well. Thus,

$$\left(\frac{dp}{dz}\right)_m = -G^2 \left(\frac{dx}{dz}\right) \left\{ \frac{2x}{\rho_v \psi} - \frac{2(1-x)}{\rho_l (1-\psi)} + q_l \left[ \frac{\psi(1-x)}{x(1-\psi)\rho_l} - \frac{x(1-\psi)}{\psi(1-x)\rho_v} \right] \right\} \quad (28)$$

To determine  $(dp/dz)_m$ , the void fraction  $\psi$  and the quality gradient must be known. A generalized expression for  $\psi$  was suggested by Butterworth (1975):

$$\psi = \frac{1}{1 + A_l [(1-x)/x]^{q_l} (\rho_v/\rho_l)^{r_l} (\mu_l/\mu_v)^{S_l}} \quad (29)$$

**Table 5 Constants in Equation (29) for Different Void Fraction Correlations**

Model	$A_l$	$q_l$	$r_l$	$S_l$
Homogeneous (Collier 1972)	1.0	1.0	1.0	0
Lockhart-Martinelli (1949)	0.28	0.64	0.36	0.07
Baroczy (1963)	1.0	0.74	0.65	0.13
Thom (1964)	1.0	1.0	0.89	0.18
Zivi (1964)	1.0	1.0	0.67	0
Turner-Wallis (1965)	1.0	0.72	0.40	0.08

where  $A_l$ ,  $q_l$ ,  $r_l$ , and  $S_l$  are constants and are listed for the various correlations in Table 5.

The quality gradient  $dx/dz$  in Equation (28) can be estimated by assuming a constant rate of cooling. In the case of complete condensation, its value is  $-1/L$ , where  $L$  is the length of the condenser tube.

Evaporators and condensers often have valves, tees, bends, and other fittings that contribute to the overall pressure drop of the heat exchanger. Collier and Thome (1996) summarize methods predicting the two-phase pressure drop in these fittings.

## ENHANCED SURFACES

Enhanced heat transfer surfaces are used in heat exchangers to improve performance and decrease cost. Condensing heat transfer is often enhanced with circular fins attached to the external surfaces of tubes to increase the heat transfer area. Other enhancement methods, such as porous coatings, integral fins, and reentrant cavities, are used to augment boiling heat transfer on the external surfaces of evaporator tubes. Webb (1981) surveys external boiling surfaces and compares the performances of several enhanced surfaces with the performance of smooth tubes. For heat exchangers, the heat transfer coefficient for the refrigerant side is often smaller than the coefficient for the water side. Thus, enhancing the refrigerant-side surface can reduce the size of the heat exchanger and improve its performance.

Internal fins increase the heat transfer coefficients during evaporation or condensation in tubes. However, internal fins increase the refrigerant pressure drop and reduce the heat transfer rate by decreasing the available temperature difference between hot and cold fluids. Designers should carefully determine the number of parallel refrigerant passes that give optimum loading for best overall heat transfer.

For additional information on enhancement methods in two-phase flow, consult Bergles (1976, 1985), Thome (1990), and Webb (1994).

## SYMBOLS

- $A$  = area
- $A_{eff}$  = total effective area [Equation (7) in Table 3]
- $a$  = local acceleration [Equation (19) in Table 1]; void fraction [Equations (9) and (10)]
- $a_f$  = area of one side of one film
- $B_o$  = boiling number [Equations (3) and (7) in Table 2]
- $b$  = breadth of a condensing surface. For vertical tube,  $b = \pi d$ ; for horizontal tube,  $b = 2L$
- $C$  = a coefficient or constant
- $C_o$  = convection number
- $C_1 \dots C_5$  = special constants (see Table 2)
- $c_p$  = specific heat at constant pressure
- $c_v$  = specific heat at constant volume
- $D$  = diameter
- $D_d$  = bubble departure diameter [Equation (5) in Table 1]
- $D_i$  = inside tube diameter
- $D_o$  = outside tube diameter
- $d$  = diameter; or prefix meaning differential
- $(dp/dz)$  = pressure gradient

$(dp/dz)_f$  = frictional pressure gradient  
 $(dp/dz)_l$  = frictional pressure gradient, assuming that liquid alone is flowing in pipe  
 $(dp/dz)_m$  = momentum pressure gradient  
 $(dp/dz)_v$  = frictional pressure gradient, assuming that gas (or vapor) alone is flowing in pipe  
 $E$  = special coefficient (Table 2)  
 $F_c$  = Reynolds number factor [Equation (12) in Table 2 and Figure 7]  
 $F_{PF}$  = special coefficient [Equation (7) in Table 1]  
 $Fr$  = Froude number  
 $F_1, F_2$  = condensing coefficient factors (Table 4)  
 $f$  = friction factor for single-phase flow  
 $f'$  = friction factor for gas flow inside pipes with wetted walls (Figure 10)  
 $f_{co}$  = friction factor in presence of condensation [Equation (26)]  
 $f_o$  = friction factor [Equations (17) and (19)]  
 $G$  = mass velocity  
 $Gr$  = Grashof number  
 $g$  = gravitational acceleration  
 $g_c$  = gravitational constant  
 $h$  = heat transfer coefficient  
 $h_f$  = special coefficient [Equation (7) in Table 1]  
 $h_{fg}$  = latent heat of vaporization or of condensation  
 $j$  = Colburn  $j$ -factor  
 $K_D$  = mass transfer coefficient  
 $k$  = thermal conductivity  
 $L$  = length  
 $L_{mf}$  = mean length of fin [Equation (7) in Table 3]  
 $\ln$  = natural logarithm  
 $M$  = mass; or molecular mass  
 $M_m$  = mean relative molecular mass of vapor-gas mixture  
 $M_v$  = relative molecular mass of condensing vapor  
 $m$  = general exponent [Equations (1) and (6) in Table 1]  
 $\dot{m}$  = mass rate of flow  
 $N$  = number of tubes in vertical tier  
 $Nu$  = Nusselt number  
 $n$  = general exponent [Equations (1) and (6) in Table 1]  
 $Pr$  = Prandtl number  
 $p$  = pressure  
 $p_c$  = critical thermodynamic pressure for coolant  
 $p_r$  = reduced pressure  
 $Q$  = total heat transfer  
 $q$  = rate of heat transfer  
 $r$  = radius  
 $Ra$  = Rayleigh number  
 $Re$  = Reynolds number  
 $R_p$  = surface roughness,  $\mu\text{m}$   
 $S$  = distance along flow direction  
 $S_c$  = suppression factor (Table 2 and Figure 8)  
 $t$  = temperature  
 $U$  = overall heat transfer coefficient  
 $V$  = linear velocity  
 $x$  = quality (i.e., vapor fraction =  $M_v/M$ ); or distance in  $dt/dx$   
 $X_n$  = Martinelli parameter [Figure 7, Table 2, and Equation (14)]  
 $x, y, z$  = lengths along principal coordinate axes  
 $Y_g$  = mole fraction of gas [Equations (2) and (3)]  
 $Y_v$  = mole fraction of vapor [Equation (3)]  
 $\alpha$  = thermal diffusivity =  $k/\rho c_p$   
 $\alpha(\lambda)$  = ratio of two-phase friction factor to single-phase friction factor at two-phase Reynolds number [Equation (21)]  
 $\beta$  = ratio of two-phase density to no-slip density [Equation (22)]  
 $\Gamma$  = mass rate of flow of condensate per unit of breadth (see section on Condensing)  
 $\Delta$  = difference between values  
 $\varepsilon$  = roughness of interface  
 $\Lambda$  = special coefficient [Equations (16) through (19) in Table 1]  
 $\lambda$  = ratio of liquid volumetric flow rate to total volumetric flow rate [Equation (25)]  
 $\mu$  = absolute (dynamic) viscosity  
 $\mu_l$  = dynamic viscosity of saturated liquid  
 $\mu_{NS}$  = dynamic viscosity of two-phase homogeneous mixture [Equation (24)]  
 $\mu_v$  = dynamic viscosity of saturated vapor  
 $\nu$  = kinematic viscosity

$\rho$  = density  
 $\rho_l$  = density of saturated liquid  
 $\rho_{NS}$  = density of two-phase homogeneous mixture [Equation (23)]  
 $\rho_v$  = density of saturated vapor phase  
 $\sigma$  = surface tension  
 $\phi_g$  = fin efficiency, Martinelli factor [Equation (11)]  
 $\phi_v$  = Lockhart-Martinelli parameter [Equation (15)]  
 $\psi$  = void fraction

#### Subscripts and Superscripts

$a$  = exponent in Equation (1)  
 $b$  = bubble  
 $c$  = critical or cold (fluid)  
 $cg$  = condensing  
 $e$  = equivalent  
 $eff$  = effective  
 $f$  = film or fin  
 $g$  = gas  
 $h$  = horizontal or hot (fluid) or hydraulic  
 $i$  = inlet or inside  
 $if$  = interface  
 $L$  = liquid  
 $l$  = liquid  
 $m$  = mean  
 $mac$  = convective mechanism [Equations (11) through (13) in Table 2]  
 $max$  = maximum

## CHAPTER 5

# MASS TRANSFER

<i>Molecular Diffusion</i> .....	5.1
<i>Convection of Mass</i> .....	5.5
<i>Simultaneous Heat and Mass Transfer Between Water-Wetted Surfaces and Air</i> .....	5.9
<i>Symbols</i> .....	5.13

**M**ASS transfer by either molecular diffusion or convection is the transport of one component of a mixture relative to the motion of the mixture and is the result of a **concentration gradient**. In an air-conditioning process, water vapor is added or removed from the air by a simultaneous transfer of heat and mass (water vapor) between the airstream and a wetted surface. The wetted surface can be water droplets in an air washer, wetted slats of a cooling tower, condensate on the surface of a dehumidifying coil, surface presented by a spray of liquid absorbent, or wetted surfaces of an evaporative condenser. The performance of equipment with these phenomena must be calculated carefully because of the simultaneous heat and mass transfer.

This chapter addresses the principles of mass transfer and provides methods of solving a simultaneous heat and mass transfer problem involving air and water vapor. Emphasis is on air-conditioning processes involving mass transfer. The formulations presented can help in analyzing the performance of specific equipment. For a discussion on the performance of air washers, cooling coils, evaporative condensers, and cooling towers, see Chapters 19, 21, 35, and 36, respectively, of the 2000 *ASHRAE Handbook—Systems and Equipment*.

This chapter is divided into (1) the principles of molecular diffusion, (2) a discussion on the convection of mass, and (3) simultaneous heat and mass transfer and its application to specific equipment.

### MOLECULAR DIFFUSION

Most mass transfer problems can be analyzed by considering the diffusion of a gas into a second gas, a liquid, or a solid. In this chapter, the diffusing or dilute component is designated as component B, and the other component as component A. For example, when water vapor diffuses into air, the water vapor is component B and dry air is component A. Properties with subscripts *A* or *B* are local properties of that component. Properties without subscripts are local properties of the mixture.

The primary mechanism of mass diffusion at ordinary temperature and pressure conditions is **molecular diffusion**, a result of density gradient. In a binary gas mixture, the presence of a concentration gradient causes transport of matter by molecular diffusion; that is, because of random molecular motion, gas B diffuses through the mixture of gases A and B in a direction that reduces the concentration gradient.

#### Fick's Law

The basic equation for molecular diffusion is Fick's law. Expressing the concentration of component B of a binary mixture of components A and B in terms of the mass fraction  $\rho_B/\rho$  or mole fraction  $C_B/C$ , Fick's law is

$$J_B = -\rho D_v \frac{d(\rho_B/\rho)}{di} = -J_A \quad (1a)$$

The preparation of this chapter is assigned to TC 1.3, Heat Transfer and Fluid Flow.

$$J_B^* = -CD_v \frac{d(C_B/C)}{di} = -J_A^* \quad (1b)$$

where  $\rho = \rho_A + \rho_B$  and  $C = C_A + C_B$ .

The minus sign indicates that the concentration gradient is negative in the direction of diffusion. The proportionality factor  $D_v$  is the **mass diffusivity** or the **diffusion coefficient**. The total mass flux  $\dot{m}_B$  and molar flux  $\dot{m}_B^{**}$  are due to the average velocity of the mixture plus the diffusive flux:

$$\dot{m}_B'' = \rho_B v - \rho D_v \frac{d(\rho_B/\rho)}{dy} \quad (2a)$$

$$\dot{m}_B^{**} = C_B v^* - CD_v \frac{d(C_B/C)}{dy} \quad (2b)$$

where  $v$  is the mass average velocity of the mixture and  $v^*$  is the molar average velocity.

Bird et al. (1960) present an analysis of Equations (1a) and (1b). Equations (1a) and (1b) are equivalent forms of Fick's law. The equation used depends on the problem and individual preference. This chapter emphasizes mass analysis rather than molar analysis. However, all results can be converted to the molar form using the relation  $C_B \equiv \rho_B/M_B$ .

#### Fick's Law for Dilute Mixtures

In many mass diffusion problems, component B is dilute; the density of component B is small compared to the density of the mixture. In this case, Equation (1a) can be written as

$$J_B = -D_v \frac{d\rho_B}{dy} \quad (3)$$

when  $\rho_B \ll \rho$  and  $\rho_A \approx \rho$ .

Equation (3) can be used without significant error for water vapor diffusing through air at atmospheric pressure and a temperature less than 27°C. In this case,  $\rho_B < 0.02\rho$ , where  $\rho_B$  is the density of water vapor and  $\rho$  is the density of moist air (air and water vapor mixture). The error in  $J_B$  caused by replacing  $\rho[d(\rho_B/\rho)/dy]$  with  $d\rho_B/dy$  is less than 2%. At temperatures below 60°C where  $\rho_B < 0.10\rho$ , Equation (3) can still be used if errors in  $J_B$  as great as 10% are tolerable.

#### Fick's Law for Mass Diffusion Through Solids or Stagnant Fluids (Stationary Media)

Fick's law can be simplified for cases of dilute mass diffusion in solids, stagnant liquids, or stagnant gases. In these cases,  $\rho_B \ll \rho$  and  $v \approx 0$ , which yields the following approximate result:

$$\dot{m}_B'' = J_B = -D_v \frac{d\rho_B}{dy} \quad (4)$$

**Fick’s Law for Ideal Gases with Negligible Temperature Gradient**

For cases of dilute mass diffusion, Fick’s law can be written in terms of partial pressure gradient instead of concentration gradient. When gas B can be approximated as ideal,

$$p_B = \frac{\rho_B R_u T}{M_B} = C_B R_u T \tag{5}$$

and when the gradient in  $T$  is small, Equation (3) can be written as

$$J_B = -\left(\frac{M_B D_v}{R_u T}\right) \frac{dp_B}{dy} \tag{6a}$$

or

$$J_B^* = -\left(\frac{D_v}{R_u T}\right) \frac{dp_B}{dy} \tag{6b}$$

If  $v \approx 0$ , Equation (4) may be written as

$$\dot{m}_B'' = J_B = -\left(\frac{M_B D_v}{R_u T}\right) \frac{dp_B}{dy} \tag{7a}$$

or

$$\dot{m}_B''^* = J_B^* = -\left(\frac{D_v}{R_u T}\right) \frac{dp_B}{dy} \tag{7b}$$

The partial pressure gradient formulation for mass transfer analysis has been used extensively; this is unfortunate because the pressure formulation [Equations (6) and (7)] applies only to cases where one component is dilute, the fluid closely approximates an ideal gas, and the temperature gradient has a negligible effect. The density (or concentration) gradient formulation expressed in Equations (1) through (4) is more general and can be applied to a wider range of mass transfer problems, including cases where neither component is dilute [Equation (1)]. The gases need not be ideal, nor the temperature gradient negligible. Consequently, this chapter emphasizes the density formulation.

**Diffusion Coefficient**

For a binary mixture, the diffusion coefficient  $D_v$  is a function of temperature, pressure, and composition. Experimental measurements of  $D_v$  for most binary mixtures are limited in range and accuracy. Table 1 gives a few experimental values for diffusion of some gases in air. For more detailed tables, see the section on Bibliography at the end of this chapter.

In the absence of data, use equations developed from (1) theory or (2) theory with constants adjusted from limited experimental data. For binary gas mixtures at low pressure,  $D_v$  is inversely proportional to pressure, increases with increasing temperature, and is almost independent of composition for a given gas pair. Bird et al. (1960) present the following equation, developed from kinetic theory and corresponding states arguments, for estimating  $D_v$  at pressures less than  $0.1 p_{c \min}$ :

**Table 1 Mass Diffusivities for Gases in Air<sup>a</sup>**

Gas	$D_v, \text{mm}^2/\text{s}$
Ammonia	27.9
Benzene	8.8
Carbon dioxide	16.5
Ethanol	11.9
Hydrogen	41.3
Oxygen	20.6
Water vapor	25.5

<sup>a</sup>Gases at 25°C and 101.325 kPa.

$$D_v = a \left( \frac{T}{\sqrt{T_{cA} + T_{cB}}} \right)^b \sqrt{\frac{1}{M_A} + \frac{1}{M_B}} \times \frac{(p_{cA} p_{cB})^{1/3} (T_{cA} T_{cB})^{5/12}}{p} \tag{8}$$

where

- $D_v$  = diffusion coefficient,  $\text{mm}^2/\text{s}$
- $a$  = constant, dimensionless
- $b$  = constant, dimensionless
- $T$  = absolute temperature, K
- $p$  = pressure, kPa
- $M$  = relative molecular mass,  $\text{kg}/\text{kg mol}$

The subscripts  $cA$  and  $cB$  refer to the critical states of the two gases. Analysis of experimental data gives the following values of the constants  $a$  and  $b$ :

For nonpolar gas pairs,

$$a = 0.1280 \text{ and } b = 1.823$$

For water vapor with a nonpolar gas,

$$a = 0.1697 \text{ and } b = 2.334$$

A **nonpolar gas** is one for which the intermolecular forces are independent of the relative orientation of molecules, depending only on the separation distance from each other. Air, composed of nonpolar gases  $\text{O}_2$  and  $\text{N}_2$ , is nonpolar.

Equation (8) is stated to agree with experimental data at atmospheric pressure to within about 8% (Bird et al. 1960).

The mass diffusivity  $D_v$  for binary mixtures at low pressure is predictable within about 10% by kinetic theory (Reid et al. 1987).

$$D_v = 0.5320 \frac{T^{1.5}}{p(\sigma_{AB})^2 \Omega_{D, AB}} \sqrt{\frac{1}{M_A} + \frac{1}{M_B}} \tag{9}$$

where

- $\sigma_{AB}$  = characteristic molecular diameter, nm
- $\Omega_{D, AB}$  = temperature function, dimensionless

$D_v$  is in  $\text{mm}^2/\text{s}$ ,  $p$  in kPa, and  $T$  in kelvins. If the gas molecules of A and B are considered rigid spheres having diameters  $\sigma_A$  and  $\sigma_B$  [and  $\sigma_{AB} = (\sigma_A/2) + (\sigma_B/2)$ ], all expressed in nanometres, the dimensionless function  $\Omega_{D, AB}$  equals unity. More realistic models for the molecules having intermolecular forces of attraction and repulsion lead to values of  $\Omega_{D, AB}$  that are functions of temperature. Reid et al. (1987) present tabulations of this quantity. These results show that  $D_v$  increases as the 2.0 power of  $T$  at low temperatures and as the 1.65 power of  $T$  at very high temperatures.

The diffusion coefficient of moist air has been calculated for Equation (8) using a simplified intermolecular potential field function for water vapor and air (Mason and Monchick 1965).

The following is an empirical equation for mass diffusivity of water vapor in air up to 1100°C (Sherwood and Pigford 1952):

$$D_v = \frac{0.926}{p} \left( \frac{T^{2.5}}{T + 245} \right) \tag{10}$$

where  $D_v$  is in  $\text{mm}^2/\text{s}$ ,  $p$  in kPa, and  $T$  in kelvins.

**Diffusion of One Gas Through a Second Stagnant Gas**

Figure 1 shows diffusion of one gas through a second stagnant gas. Water vapor diffuses from the liquid surface into surrounding stationary air. It is assumed that local equilibrium exists through the gas mixture, that the gases are ideal, and that the Gibbs-Dalton law is valid, which implies that the temperature gradient has a negligible effect. Diffusion of water vapor is due to concentration gradient and is given by Equation (6a). There is a continuous gas phase, so the mixture pressure  $p$  is constant, and the Gibbs-Dalton law yields

$$p_A + p_B = p = \text{constant} \quad (11a)$$

or 
$$\frac{p_A}{M_A} + \frac{p_B}{M_B} = \frac{p}{R_u T} = \text{constant} \quad (11b)$$

The partial pressure gradient of the water vapor causes a partial pressure gradient of the air such that

$$\frac{dp_A}{dy} = - \frac{dp_B}{dy}$$

or 
$$\left(\frac{1}{M_A}\right) \frac{dp_A}{dy} = - \left(\frac{1}{M_B}\right) \frac{dp_B}{dy} \quad (12)$$

Air, then, diffuses toward the liquid water interface. Because it cannot be absorbed there, a bulk velocity  $v$  of the gas mixture is established in a direction away from the liquid surface, so that the net transport of air is zero (i.e., the air is stagnant):

$$\dot{m}_A'' = -D_v \frac{d\rho_A}{dy} + \rho_A v = 0 \quad (13)$$

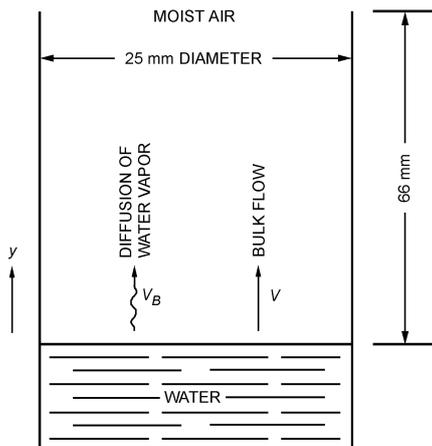

The bulk velocity  $v$  transports not only air but also water vapor away from the interface. Therefore, the total rate of water vapor diffusion is

$$\dot{m}_B'' = -D_v \frac{d\rho_B}{dy} + \rho_B v \quad (14)$$

Substituting for the velocity  $v$  from Equation (13) and using Equations (11b) and (12) gives

$$\dot{m}_B'' = \left(\frac{D_v M_B p}{\rho_A R_u T}\right) \frac{d\rho_A}{dy} \quad (15)$$

Integration yields

**Fig. 1 Diffusion of Water Vapor Through Stagnant Air**

$$\dot{m}_B'' = \frac{D_v M_B p}{R_u T} \left[ \frac{\ln(\rho_{AL}/\rho_{A0})}{y_L - y_0} \right] \quad (16a)$$

or 
$$\dot{m}_B'' = -D_v P_{Am} \left( \frac{\rho_{BL} - \rho_{B0}}{y_L - y_0} \right) \quad (16b)$$

where 
$$P_{Am} \equiv \frac{p}{\rho_{AL}} \rho_{AL} \left[ \frac{\ln(\rho_{AL}/\rho_{A0})}{\rho_{AL} - \rho_{A0}} \right] \quad (17)$$

$P_{Am}$  is the logarithmic mean density factor of the stagnant air. The pressure distribution for this type of diffusion is illustrated in Figure 2. **Stagnant** refers to the net behavior of the air; it does not move because the bulk flow exactly offsets diffusion. The term  $P_{Am}$  in Equation (16b) approximately equals unity for dilute mixtures such as water vapor in air at near atmospheric conditions. This condition makes it possible to simplify Equations (16) and implies that in the case of dilute mixtures, the partial pressure distribution curves in Figure 2 are straight lines.

**Example 1.** A vertical tube of 25 mm diameter is partially filled with water so that the distance from the water surface to the open end of the tube is 60 mm, as shown in Figure 1. Perfectly dried air is blown over the open tube end, and the complete system is at a constant temperature of 15°C. In 200 h of steady operation, 2.15 g of water evaporates from the tube. The total pressure of the system is 101.325 kPa. Using these data, (a) calculate the mass diffusivity of water vapor in air, and (b) compare this experimental result with that from Equation (10).

**Solution:**

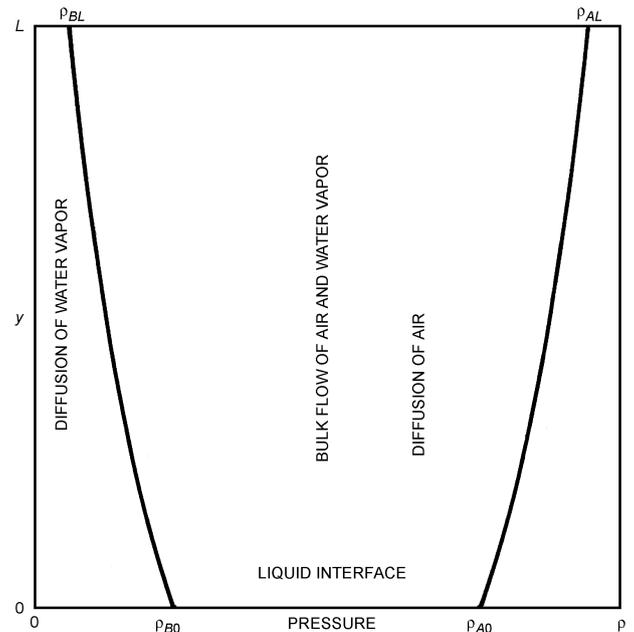

(a) The mass diffusion flux of water vapor from the water surface is

$$\dot{m}_B = 2.15/200 = 0.01075 \text{ g/h}$$

The cross-sectional area of a 25 mm diameter tube is  $\pi(12.5)^2 = 491 \text{ mm}^2$ . Therefore,  $\dot{m}_B'' = 0.00608 \text{ g/(m}^2\cdot\text{s)}$ . The partial densities are determined with the aid of the psychrometric tables.

$$\rho_{BL} = 0; \quad \rho_{B0} = 12.8 \text{ g/m}^3$$

$$\rho_{AL} = 1.225 \text{ kg/m}^3; \quad \rho_{A0} = 1.204 \text{ kg/m}^3$$

**Fig. 2 Pressure Profiles for Diffusion of Water Vapor Through Stagnant Air**

Because  $p = p_{AL} = 101.325$  kPa, the logarithmic mean density factor [Equation (17)] is

$$P_{Am} = 1.225 \left[ \frac{\ln(1.225/1.204)}{1.225 - 1.204} \right] = 1.009$$

The mass diffusivity is now computed from Equation (16b) as

$$D_v = \frac{-\dot{m}_B''(y_L - y_0)}{P_{Am}(p_{BL} - p_{B0})} = \frac{-(0.00608)(0.060)(10^6)}{(1.009)(0 - 12.8)} = 28.2 \text{ mm}^2/\text{s}$$

(b) By Equation (10), with  $p = 101.325$  kPa and  $T = 15 + 273 = 288$  K,

$$D_v = \frac{0.926}{101.325} \left( \frac{288^{2.5}}{288 + 245} \right) = 24.1 \text{ mm}^2/\text{s}$$

Neglecting the correction factor  $P_{Am}$  for this example gives a difference of less than 1% between the calculated experimental and empirically predicted values of  $D_v$ .

**Equimolar Counterdiffusion**

Figure 3 shows two large chambers, both containing an ideal gas mixture of two components A and B (e.g., air and water vapor) at the same total pressure  $p$  and temperature  $T$ . The two chambers are connected by a duct of length  $L$  and cross-sectional area  $A_{cs}$ . Partial pressure  $p_B$  is higher in the left chamber, and partial pressure  $p_A$  is higher in the right chamber. The partial pressure differences cause component B to migrate to the right and component A to migrate to the left.

At steady state, the molar flows of A and B must be equal, but in the opposite direction, or

$$\dot{m}_A'' + \dot{m}_B'' = 0 \tag{18}$$

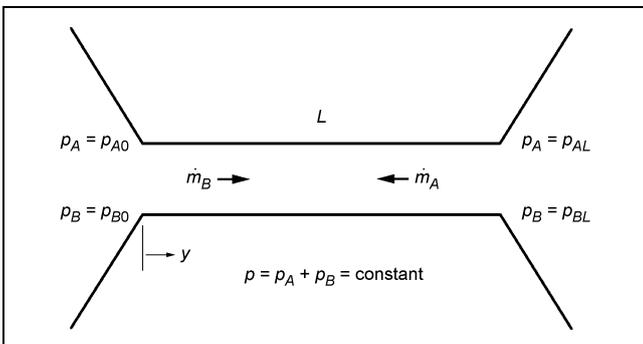

because the total molar concentration  $C$  must stay the same in both chambers if  $p$  and  $T$  remain constant. Since the molar fluxes are the same in both directions, the molar average velocity  $v^* = 0$ . Thus, Equation (7b) can be used to calculate the molar flux of B (or A):

$$\dot{m}_B'' = \frac{-D_v}{R_u T} \frac{dp_B}{dy} \tag{19}$$

or

$$\dot{m}_B'' = \frac{A_{cs} D_v}{R_u T} \frac{p_{B0} - p_{BL}}{L} \tag{20}$$

or

**Fig. 3 Equimolar Counterdiffusion**

$$\dot{m}_B = \frac{M_B A_{cs} D_v}{R_u T} \frac{p_{B0} - p_{BL}}{L} \tag{21}$$

**Example 2.** One large room is maintained at 22°C (295 K), 101.3 kPa, 80% rh. A 20 m long duct with cross-sectional area of 0.15 m<sup>2</sup> connects the room to another large room at 22°C, 101.3 kPa, 10% rh. What is the rate of water vapor diffusion between the two rooms?

**Solution:** Let air be component A and water vapor be component B. Equation (21) can be used to calculate the mass flow of water vapor B. Equation (10) can be used to calculate the diffusivity.

$$D_v = \frac{0.926}{101.3} \left( \frac{295^{2.5}}{295 + 245} \right) = 25.3 \text{ mm}^2/\text{s}$$

From a psychrometric table (Table 3, Chapter 6), the saturated vapor pressure at 22°C is 2.645 kPa. The vapor pressure difference  $p_{B0} - p_{BL}$  is

$$p_{B0} - p_{BL} = (0.8 - 0.1)2.645 \text{ kPa} = 1.85 \text{ kPa}$$

Then, Equation (21) gives

$$\dot{m}_b = \frac{18 \times 0.15(25.3/10^6)1.85}{8.314 \times 295} \frac{1}{20} = 2.58 \times 10^{-9} \text{ kg/s}$$

**Molecular Diffusion in Liquids and Solids**

Because of the greater density, diffusion is slower in liquids than in gases. No satisfactory molecular theories have been developed for calculating diffusion coefficients. The limited measured values of  $D_v$  show that, unlike for gas mixtures at low pressures, the diffusion coefficient for liquids varies appreciably with concentration.

Reasoning largely from analogy to the case of one-dimensional diffusion in gases and employing Fick's law as expressed by Equation (4) gives

$$\dot{m}_B'' = D_v \left( \frac{p_{B1} - p_{B2}}{y_2 - y_1} \right) \tag{22}$$

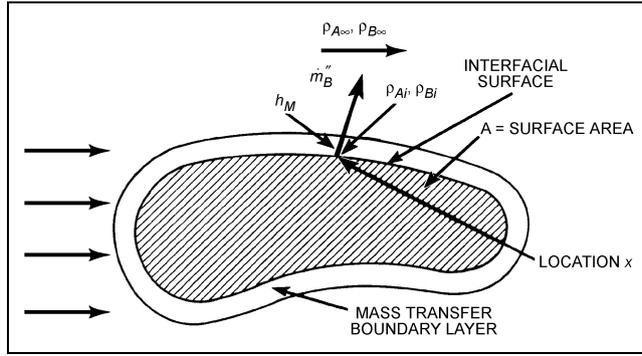

Equation (22) expresses the steady-state diffusion of the solute B through the solvent A in terms of the molal concentration difference of the solute at two locations separated by the distance  $\Delta y = y_2 - y_1$ . Bird et al. (1960), Hirschfelder et al. (1954), Sherwood and Pigford (1952), Reid and Sherwood (1966), Treybal (1980), and Eckert and Drake (1972) provide equations and tables for evaluating  $D_v$ . Hirschfelder et al. (1954) provide comprehensive treatment of the molecular developments.

Diffusion through a solid when the solute is dissolved to form a homogeneous solid solution is known as **structure-insensitive diffusion** (Treybal 1980). This solid diffusion closely parallels diffusion through fluids, and Equation (22) can be applied to one-dimensional steady-state problems. Values of mass diffusivity are generally lower than they are for liquids and vary with temperature.

The diffusion of a gas mixture through a porous medium is common (e.g., the diffusion of an air-vapor mixture through porous insulation). The vapor diffuses through the air along the tortuous narrow passages within the porous medium. The mass flux is a function of the vapor pressure gradient and diffusivity as indicated in Equation (7a). It is also a function of the structure of the pathways within the porous medium and is therefore called **structure-sensitive diffusion**. All of these factors are taken into account in the following version of Equation (7a):

$$\dot{m}_B'' = -\bar{\mu} \frac{dp_B}{dy} \tag{23}$$

where  $\bar{\mu}$  is called the permeability of the porous medium. Chapter 23 presents this topic in more depth.

**Fig. 4** Nomenclature for Convective Mass Transfer from External Surface at Location  $x$  Where Surface is Impermeable to Gas A

**CONVECTION OF MASS**

Convection of mass involves the mass transfer mechanisms of molecular diffusion and bulk fluid motion. Fluid motion in the region adjacent to a mass transfer surface may be laminar or turbulent, depending on geometry and flow conditions.

**Mass Transfer Coefficient**

Convective mass transfer is analogous to convective heat transfer where geometry and boundary conditions are similar. The analogy holds for both laminar and turbulent flows and applies to both external and internal flow problems.

**Mass Transfer Coefficients for External Flows.** Most external convective mass transfer problems can be solved with an appropriate formulation that relates the mass transfer flux (to or from an interfacial surface) to the concentration difference across the boundary layer illustrated in Figure 4. This formulation gives rise to the convective mass transfer coefficient, defined as

$$h_M \equiv \frac{\dot{m}_B''}{\rho_{Bi} - \rho_{B\infty}} \quad (24)$$

where

- $h_M$  = local external mass transfer coefficient, m/s
- $\dot{m}_B''$  = mass flux of gas B from surface, kg/(m<sup>2</sup>·s)
- $\rho_{Bi}$  = density of gas B at interface (saturation density), kg/m<sup>3</sup>
- $\rho_{B\infty}$  = density of component B outside boundary layer, kg/m<sup>3</sup>

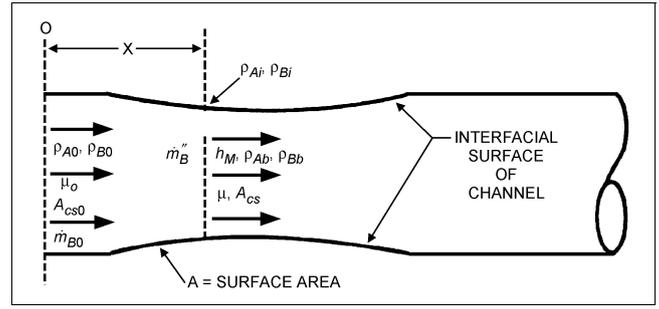

If  $\rho_{Bi}$  and  $\rho_{B\infty}$  are constant over the entire interfacial surface, the mass transfer rate from the surface can be expressed as

$$\dot{m}_B'' = \bar{h}_M(\rho_{Bi} - \rho_{B\infty}) \quad (25)$$

where  $\bar{h}_M$  is the average mass transfer coefficient, defined as

$$\bar{h}_M \equiv \frac{1}{A} \int_A h_m dA \quad (26)$$

**Mass Transfer Coefficients for Internal Flows.** Most internal convective mass transfer problems, such as those that occur in channels or in the cores of dehumidification coils, can be solved if an appropriate expression is available to relate the mass transfer flux (to or from the interfacial surface) to the difference between the concentration at the surface and the bulk concentration in the channel, as illustrated in Figure 5. This formulation leads to the definition of the mass transfer coefficient for internal flows:

**Fig. 5** Nomenclature for Convective Mass Transfer from Internal Surface Impermeable to Gas A

$$h_M \equiv \frac{\dot{m}_B''}{\rho_{Bi} - \rho_{Bb}} \quad (27)$$

where

- $h_M$  = internal mass transfer coefficient, m/s
- $\dot{m}_B''$  = mass flux of gas B at interfacial surface, kg/(m<sup>2</sup>·s)
- $\rho_{Bi}$  = density of gas B at interfacial surface, kg/m<sup>3</sup>
- $\rho_{Bb} \equiv (1/\bar{u}_B A_{cs}) \int_{A_{cs}} u_B \rho_B dA_{cs}$  = bulk density of gas B at location  $x$
- $\bar{u}_B \equiv (1/A_{cs}) \int_A u_B dA_{cs}$  = average velocity of gas B at location  $x$ , m/s
- $A_{cs}$  = cross-sectional area of channel at station  $x$ , m<sup>2</sup>
- $u_B$  = velocity of component B in  $x$  direction, m/s
- $\rho_B$  = density distribution of component B at station  $x$ , kg/m<sup>3</sup>

Often, it is easier to obtain the bulk density of gas B from

$$\rho_{Bb} = \frac{\dot{m}_{B0} + \int_A \dot{m}_B'' dA}{\bar{u}_B A_{cs}} \quad (28)$$

where

- $\dot{m}_{B0}$  = mass flow rate of component B at station  $x = 0$ , kg/s
- $A$  = interfacial area of channel between station  $x = 0$  and station  $x = x$ , m<sup>2</sup>

Equation (28) can be derived from the preceding definitions. The major problem is the determination of  $\bar{u}_B$ . If, however, the analysis is restricted to cases where B is dilute and concentration gradients of B in the  $x$  direction are negligibly small,  $\bar{u}_B \approx \bar{u}$ . Component B is swept along in the  $x$  direction with an average velocity equal to the average velocity of the dilute mixture.

**Analogy Between Convective Heat and Mass Transfer**

Most expressions for the convective mass transfer coefficient  $h_M$  are determined from expressions for the convective heat transfer coefficient  $h$ .

For problems in internal and external flow where mass transfer occurs at the convective surface and where component B is dilute, it is shown by Bird et al. (1960) and Incropera and DeWitt (1996) that the Nusselt and Sherwood numbers are defined as follows:

$$Nu = f(X, Y, Z, Pr, Re) \quad (29)$$

$$Sh = f(X, Y, Z, Sc, Re) \quad (30)$$

and 
$$\bar{Nu} = g(Pr, Re) \quad (31)$$

$$\bar{Sh} = g(Sc, Re) \quad (32)$$

where the function  $f$  is the same in Equations (29) and (30), and the function  $g$  is the same in Equations (31) and (32). The quantities  $Pr$  and  $Sc$  are dimensionless Prandtl and Schmidt numbers, respectively, as defined in the section on Symbols. The primary restrictions on the analogy are that the surface shapes are the same and that the temperature boundary conditions are analogous to the density distribution boundary conditions for component B when cast in dimensionless form. Several primary factors prevent the analogy from being perfect. In some cases, the Nusselt number was derived for smooth surfaces. Many mass transfer problems involve wavy, droplet-like, or roughened surfaces. Many Nusselt number relations are obtained for constant temperature surfaces. Sometimes  $\rho_{B1}$  is not constant over the entire surface because of varying saturation conditions and the possibility of surface dryout.

In all mass transfer problems, there is some blowing or suction at the surface because of the condensation, evaporation, or transpiration of component B. In most cases, this blowing/suction phenomenon has little effect on the Sherwood number, but the analogy should be examined closely if  $v_i/u_\infty > 0.01$  or  $v_i/\bar{u} > 0.01$ , especially if the Reynolds number is large.

**Example 3.** Use the analogy expressed in Equations (31) and (32) to solve the following problem. An expression for heat transfer from a constant temperature flat plate in laminar flow is

$$\bar{Nu}_L = 0.664 Pr^{1/3} Re_L^{1/2} \tag{33}$$

$Sc = 0.35$ ,  $D_v = 3.6 \times 10^{-5} \text{ m}^2/\text{s}$ , and  $Pr = 0.708$  for the given conditions; determine the mass transfer rate and temperature of the water-wetted flat plate in Figure 6 using the heat/mass transfer analogy.

**Solution:** To solve the problem, properties should be evaluated at film conditions. However, since the plate temperature and the interfacial water vapor density are not known, a first estimate will be obtained assuming the plate  $t_{i1}$  to be at  $25^\circ\text{C}$ . The plate Reynolds number is

$$Re_{L1} = \frac{\rho u_\infty L}{\mu} = \frac{(1.166 \text{ kg/m}^3)(10 \text{ m/s})(0.1 \text{ m})}{[1.965 \times 10^{-5} \text{ kg/(m}\cdot\text{s)}]} = 59\,340$$

The plate is entirely in laminar flow, since the transitional Reynolds number is about  $5 \times 10^5$ . Using the mass transfer analogy given by Equations (31) and (32), Equation (33) yields

$$\begin{aligned} \bar{Sh}_{L1} &= 0.664 Sc^{1/3} Re_L^{1/2} \\ &= 0.664(0.35)^{1/3}(59\,340)^{1/2} = 114 \end{aligned}$$

From the definition of the Sherwood number,

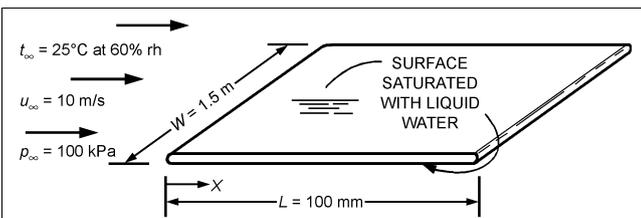

$$\bar{h}_{M1} = \bar{Sh}_{L1} D_v / L = (114)(3.6 \times 10^{-5} \text{ m}^2/\text{s}) / (0.1 \text{ m}) = 0.04104 \text{ m/s}$$

The psychrometric tables give a humidity ratio  $W$  of 0.0121 at  $25^\circ\text{C}$  and 60% rh. Therefore,

$$\rho_{B\infty} = 0.0121 \rho_{A\infty} = (0.0121)(1.166 \text{ kg/m}^3) = 0.01411 \text{ kg/m}^3$$

From steam tables, the saturation density for water at  $25^\circ\text{C}$  is

$$\rho_{B11} = 0.02352 \text{ kg/m}^3$$

**Fig. 6** Water-Saturated Flat Plate in Flowing Airstream

Therefore, the mass transfer rate from the double-sided plate is

$$\begin{aligned} \dot{m}_{B1} &= \bar{h}_{M1} A (\rho_{B1} - \rho_{B\infty}) \\ &= (0.04104 \text{ m/s})(0.1 \text{ m} \times 1.5 \text{ m} \times 2) \\ &\quad \times (0.02352 \text{ kg/m}^3 - 0.01411 \text{ kg/m}^3) \\ &= 1.159 \times 10^{-4} \text{ kg/s} = 0.1159 \text{ g/s} \end{aligned}$$

This mass rate, transformed from the liquid state to the vapor state, requires the following heat rate to the plate to maintain the evaporation:

$$q_{i1} = \dot{m}_{B1} h_{fg} = (0.1159 \text{ g/s})(2443 \text{ kJ/kg}) = 283.1 \text{ W}$$

To obtain a second estimate of the wetted plate temperature in this type of problem, the following criteria are used. Calculate the  $t_i$  necessary to provide a heat rate of  $q_{i1}$ . If this temperature  $t_{iq1}$  is above the dew-point temperature  $t_{id}$ , set the second estimate at  $t_{i2} = (t_{iq1} + t_{i1})/2$ . If  $t_{iq1}$  is below the dew-point temperature, set  $t_{i2} = (t_{id} + t_{i1})/2$ . For this problem, the dew point is  $t_{id} = 14^\circ\text{C}$ .

Obtaining the second estimate of the plate temperature requires an approximate value of the heat transfer coefficient.

$$\begin{aligned} \bar{Nu}_{L1} &= 0.664 Pr^{1/3} Re_L^{1/2} = 0.664(0.708)^{1/3}(59\,340)^{1/2} \\ &= 144.2 \end{aligned}$$

From the definition of the Nusselt number,

$$\begin{aligned} \bar{h}_1 &= \bar{Nu}_{L1} k / L = (144.2)[0.0261 \text{ W/(m}\cdot\text{K)}] / 0.1 \text{ m} \\ &= 37.6 \text{ W/(m}^2\cdot\text{K)} \end{aligned}$$

Therefore, the second estimate for the plate temperature is

$$\begin{aligned} t_{iq1} &= t_\infty - q_{i1} / (\bar{h}_1 A) \\ &= 25^\circ\text{C} - \{283.1 \text{ W} / [37.6 \text{ W/(m}^2\cdot\text{K)} \times (2 \times 0.1 \text{ m} \times 1.5 \text{ m})]\} \\ &= 25^\circ\text{C} - 25^\circ\text{C} = 0^\circ\text{C} \end{aligned}$$

This temperature is below the dew-point temperature; therefore,

$$t_{i2} = (14^\circ\text{C} + 25^\circ\text{C}) / 2 = 19.5^\circ\text{C}$$

The second estimate of the film temperature is

$$t_{f2} = (t_{i2} + t_\infty) / 2 = (19.5^\circ\text{C} + 25^\circ\text{C}) / 2 = 22.25^\circ\text{C}$$

The next iteration on the solution is as follows:

$$Re_{L2} = 61\,010$$

$$\bar{Sh}_{L2} = 0.664(0.393)^{1/3}(61\,010)^{1/2} = 120$$

$$\bar{h}_{M2} = (120)(3.38 \times 10^{-5}) / 0.1 = 0.04056 \text{ m/s}$$

The free stream density of the water vapor has been evaluated. The density of the water vapor at the plate surface is the saturation density at  $19.5^\circ\text{C}$ .

$$\rho_{B12} = (0.01374)(1.183 \text{ kg/m}^3) = 0.01625 \text{ kg/m}^3$$

$$A = 2 \times 0.1 \times 1.5 = 0.3 \text{ m}^2$$

$$\dot{m}_{B2} = (0.04056 \text{ m/s})(0.3 \text{ m}^2)(0.01625 \text{ kg/m}^3 - 0.01411 \text{ kg/m}^3)$$

$$= 2.604 \times 10^{-5} \text{ kg/s} = 0.02604 \text{ g/s}$$

$$q_{i2} = (0.02604 \text{ g/s})(2458 \text{ J/kg}) = 64.01 \text{ W}$$

$$\bar{Nu}_{L2} = 0.664(0.709)^{1/3}(61\,010)^{1/2} = 146$$

$$\bar{h}_2 = (146)(0.02584) / 0.1 = 37.73 \text{ W/(m}^2\cdot\text{K)}$$

$$t_{iq2} = 25^\circ\text{C} - [(64.01 \text{ W}) / (37.73 \times 0.3)] = 19.34^\circ\text{C}$$

This temperature is above the dew-point temperature; therefore,

$$t_{i3} = (t_{i2} + t_{iq2}) / 2 = (19.5 + 19.34) / 2 = 19.42^\circ\text{C}$$

This is approximately the same result as that obtained in the previous iteration. Therefore, the problem solution is

$$t_i = 19.5^\circ\text{C}$$

$$\dot{m}_B = 0.0260 \text{ g/s}$$

The kind of similarity between heat and mass transfer that results in Equation (29) through Equation (32) can also be shown to exist between heat and momentum transfer. Chilton and Colburn (1934) used this similarity to relate Nusselt number to friction factor by the analogy

$$j_H = \frac{\text{Nu}}{\text{Re Pr}^{(1-n)}} = \text{St Pr}^n = \frac{f}{2} \quad (34)$$

where  $n = 2/3$ ,  $\text{St} = \text{Nu}/(\text{Re Pr})$  is the Stanton number, and  $j_H$  is the Chilton-Colburn  $j$ -factor for heat transfer. Substituting  $\text{Sh}$  for  $\text{Nu}$  and  $\text{Sc}$  for  $\text{Pr}$  in Equations (31) and (32) gives the Chilton-Colburn  $j$ -factor for mass transfer,  $j_D$ :

$$j_D = \frac{\text{Sh}}{\text{Re Sc}^{(1-n)}} = \text{St}_m \text{Sc}^n = \frac{f}{2} \quad (35)$$

where  $\text{St}_m = \text{Sh}P_{AM}/(\text{Re Sc})$  is the Stanton number for mass transfer. Equations (34) and (35) are called the **Chilton-Colburn  $j$ -factor analogy**.

The power of the Chilton-Colburn  $j$ -factor analogy is represented in Figures 7 through 10. Figure 7 plots various experimental values of  $j_D$  from a flat plate with flow parallel to the plate surface. The solid line, which represents the data to near perfection, is actually  $f/2$  from Blasius' solution of laminar flow on a flat plate (left-hand portion of the solid line) and Goldstein's solution for a turbulent boundary layer (right-hand portion). The right-hand portion of the solid line also represents McAdams' (1954) correlation of turbulent flow heat transfer coefficient for a flat plate.

A **wetted-wall column** is a vertical tube in which a thin liquid film adheres to the tube surface and exchanges mass by evaporation or absorption with a gas flowing through the tube. Figure 8 illustrates typical data on vaporization in wetted-wall columns, plotted as  $j_D$  versus  $\text{Re}$ . The spread of the points with variation in  $\mu/\rho D_v$  results from Gilliland's finding of an exponent of 0.56, not  $2/3$ ,

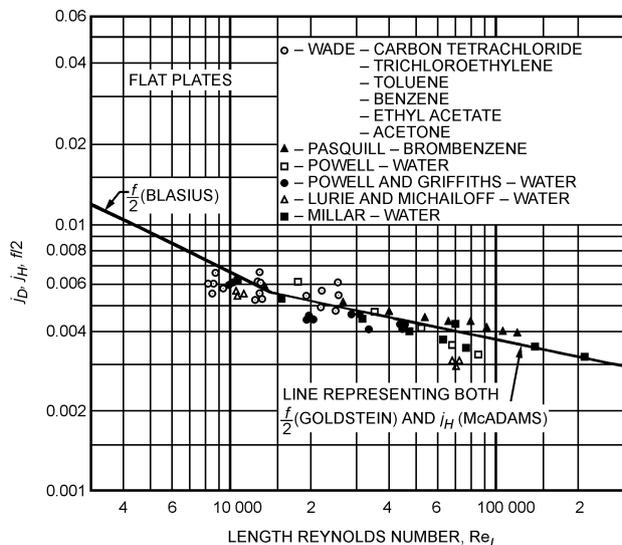

Fig. 7 Mass Transfer from Flat Plate

representing the effect of the Schmidt number. Gilliland's equation can be written as follows:

$$j_D = 0.023 \text{Re}^{-0.17} \left( \frac{\mu}{\rho D_v} \right)^{-0.56} \quad (36)$$

Similarly, McAdams' (1954) equation for heat transfer in pipes can be expressed as

$$j_H = 0.023 \text{Re}^{-0.20} \left( \frac{c_p \mu}{k} \right)^{-0.7} \quad (37)$$

This is represented by the dash-dot curve in Figure 8, which falls below the mass transfer data. The curve  $f/2$  representing friction in smooth tubes is the upper, solid curve.

Data for the evaporation of liquids from single cylinders into gas streams flowing transversely to the cylinders' axes are shown in Figure 9. Although the dash-dot line on Figure 9 represents the data, it is actually taken from McAdams (1954) as representative of a large collection of data on heat transfer to single cylinders placed transverse to airstreams. To compare these data with friction, it is necessary to distinguish between total drag and skin friction. Since the analogies are based on skin friction, the normal pressure drag must be subtracted from the measured total drag. At  $\text{Re} = 1000$ , the skin friction is 12.6% of the total drag; at  $\text{Re} = 31\,600$ , it is only 1.9%. Consequently, the values of  $f/2$  at a high Reynolds number, obtained by the difference, are subject to considerable error.

In Figure 10, data on the evaporation of water into air for single spheres are presented. The solid line, which best represents these data, agrees with the dashed line representing McAdams' correlation for heat transfer to spheres. These results cannot be compared with friction or momentum transfer because total drag has not been allocated to skin friction and normal pressure drag. Application of these data to air-water contacting devices such as air washers and spray cooling towers is well substantiated.

When the temperature of the heat exchanger surface in contact with moist air is below the dew-point temperature of the air, vapor condensation occurs. Typically, the air dry-bulb temperature and

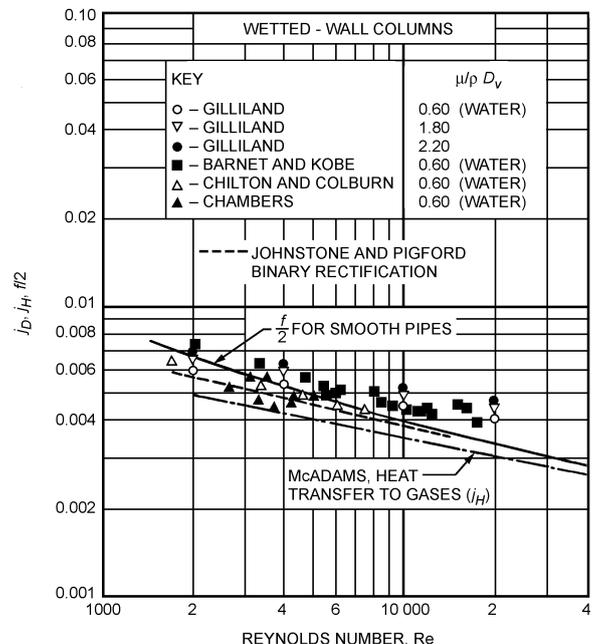

Fig. 8 Vaporization and Absorption in Wetted-Wall Column

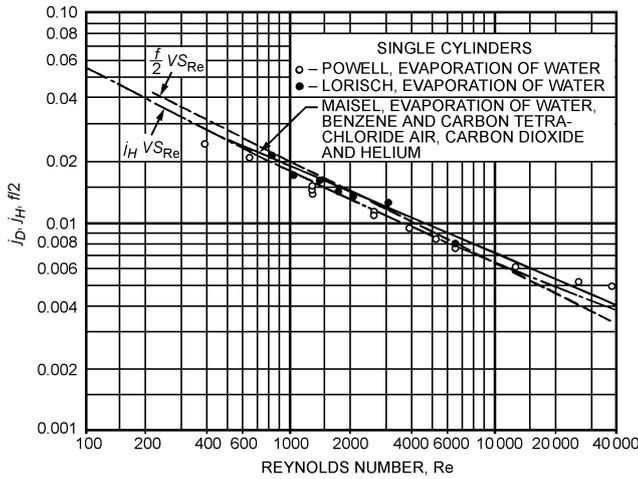

Fig. 9 Mass Transfer from Single Cylinders in Crossflow

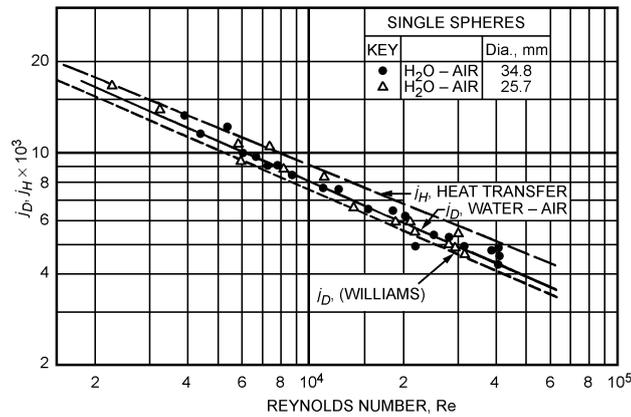

Fig. 10 Mass Transfer from Single Spheres

humidity ratio both decrease as the air flows through the exchanger. Therefore, sensible and latent heat transfer occur simultaneously. This process is similar to one that occurs in a spray dehumidifier and can be analyzed using the same procedure; however, this is not generally done.

Cooling coil analysis and design are complicated by the problem of determining transport coefficients  $h$ ,  $h_M$ , and  $f$ . It would be convenient if heat transfer and friction data for dry heating coils could be used with the Colburn analogy to obtain the mass transfer coefficients. However, this approach is not always reliable, and work by Guillory and McQuiston (1973) and Helmer (1974) shows that the analogy is not consistently true. Figure 11 shows  $j$ -factors for a simple parallel plate exchanger for different surface conditions with sensible heat transfer. Mass transfer  $j$ -factors and the friction factors exhibit the same behavior. Dry surface  $j$ -factors fall below those obtained under dehumidifying conditions with the surface wet. At low Reynolds numbers, the boundary layer grows quickly; the droplets are soon covered and have little effect on the flow field. As the Reynolds number is increased, the boundary layer becomes thin and more of the total flow field is exposed to the droplets. The roughness caused by the droplets induces mixing and larger  $j$ -factors. The data in Figure 11 cannot be applied to all surfaces because the length of the flow channel is also an important variable. However, the water collecting on the surface is mainly responsible for breakdown of the  $j$ -factor analogy. The  $j$ -factor analogy is approximately true when the surface conditions are identical. Under some conditions, it is possible to obtain a film of condensate on the surface instead of droplets.

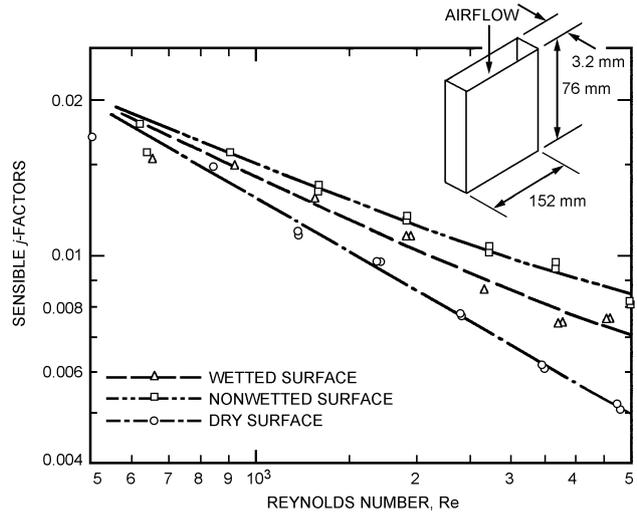

Fig. 11 Sensible Heat Transfer  $j$ -Factors for Parallel Plate Exchanger

Guillory and McQuiston (1973) and Helmer (1974) related dry sensible  $j$ - and  $f$ -factors to those for wetted dehumidifying surfaces.

The equality of  $j_H \cdot j_D$ , and  $f/2$  for certain streamline shapes at low mass transfer rates has experimental verification. For flow past bluff objects,  $j_H$  and  $j_D$  are much smaller than  $f/2$ , based on total pressure drag. The heat and mass transfer, however, still relate in a useful way by equating  $j_H$  and  $j_D$ .

**Example 4.** Using solid cylinders of volatile solids (e.g., naphthalene, camphor, dichlorobenzene) with airflow normal to these cylinders, Bedingfield and Drew (1950) found that the ratio between the heat and mass transfer coefficients could be closely correlated by the following relation:

$$\frac{h}{\rho h_M} = [1230 \text{ J}/(\text{kg} \cdot \text{K})] \left( \frac{\mu}{\rho D_v} \right)^{0.56}$$

For completely dry air at 21°C flowing at a velocity of 9.5 m/s over a wet-bulb thermometer of diameter  $d = 7.5$  mm, determine the heat and mass transfer coefficients from Figure 9 and compare their ratio with the Bedingfield-Drew relation.

**Solution:** For dry air at 21°C and standard pressure,  $\rho = 1.198 \text{ kg/m}^3$ ,  $\mu = 1.82 \times 10^{-5} \text{ kg/(s} \cdot \text{m)}$ ,  $k = 0.02581 \text{ W/(m} \cdot \text{K)}$ , and  $c_p = 1.006 \text{ kJ/(kg} \cdot \text{K)}$ . From Equation (10),  $D_v = 25.13 \text{ mm}^2/\text{s}$ . Therefore,

$$\begin{aligned} Re_{da} &= \rho u_{\infty} d / \mu = 1.198 \times 9.5 \times 7.5 / (1000 \times 1.82 \times 10^{-5}) = 4690 \\ Pr &= c_p \mu / k = 1.006 \times 1.82 \times 10^{-5} \times 1000 / (0.02581) = 0.709 \\ Sc &= \mu / \rho D_v = 1.82 \times 10^{-5} \times 10^6 / (1.198 \times 25.13) = 0.605 \end{aligned}$$

From Figure 9 at  $Re_{da} = 4700$ , read  $j_H = 0.0089$ ,  $j_D = 0.010$ . From Equations (34) and (35),

$$\begin{aligned} h &= j_H \rho c_p u_{\infty} / (Pr)^{2/3} \\ &= 0.0089 \times 1.198 \times 1.006 \times 9.5 \times 1000 / (0.709)^{2/3} \\ &= 128 \text{ W/(m}^2 \cdot \text{K)} \\ h_M &= j_D u_{\infty} / (Sc)^{2/3} = 0.010 \times 9.5 / (0.605)^{2/3} \\ &= 0.133 \text{ m/s} \\ h / \rho h_M &= 128 / (1.198 \times 0.133) = 803 \text{ J/(kg} \cdot \text{K)} \end{aligned}$$

From the Bedingfield-Drew relation,

$$h/\rho h_M = 1230(0.605)^{0.56} = 928 \text{ J}/(\text{kg} \cdot \text{K})$$

Equations (34) and (35) are call the Reynolds analogy when  $\text{Pr} = \text{Sc} = 1$ . This suggests that  $h/\rho h_M = c_p = 1006 \text{ J}/(\text{kg} \cdot \text{K})$ . This close agreement is because the ratio  $\text{Sc}/\text{Pr}$  is  $0.605/0.709$  or  $0.85$ , so that the exponent of these numbers has little effect on the ratio of the transfer coefficients.

The extensive developments for calculating heat transfer coefficients can be applied to calculate mass transfer coefficients under similar geometrical and flow conditions using the  $j$ -factor analogy. For example, Table 6 of Chapter 3 lists equations for calculating heat transfer coefficients for flow inside and normal to pipes. Each equation can be used for mass transfer coefficient calculations by equating  $j_H$  and  $j_D$  and imposing the same restriction to each stated in Table 6 of Chapter 3. Similarly, mass transfer experiments often replace corresponding heat transfer experiments with complex geometries where exact boundary conditions are difficult to model (Sparrow and Ohadi 1987a, 1987b).

The  $j$ -factor analogy is useful only at low mass transfer rates. As the rate of mass transfer increases, the movement of matter normal to the transfer surface increases the convective velocity. For example, if a gas is blown from many small holes in a flat plate placed parallel to an airstream, the boundary layer thickens, and resistance to both mass and heat transfer increases with increasing blowing rate. Heat transfer data are usually collected at zero or, at least, insignificant mass transfer rates. Therefore, if such data are to be valid for a mass transfer process, the mass transfer rate (i.e., the blowing) must be low.

The  $j$ -factor relationship  $j_H = j_D$  can still be valid at high mass transfer rates, but neither  $j_H$  nor  $j_D$  can be represented by data at zero mass transfer conditions. Eckert and Drake (1972) and Chapter 24 of Bird et al. (1960) have detailed information on high mass transfer rates.

### Lewis Relation

Heat and mass transfer coefficients are satisfactorily related at the same Reynolds number by equating the Chilton-Colburn  $j$ -factors. Comparing Equations (34) and (35) gives

$$\text{St Pr}^n = \frac{f}{2} = \text{St}_m \text{Sc}^n$$

Inserting the definitions of  $\text{St}$ ,  $\text{Pr}$ ,  $\text{St}_m$ , and  $\text{Sc}$  gives

$$\frac{h}{\rho c_p \bar{u}} \left( \frac{c_p \mu}{k} \right)^{2/3} = \frac{h_M P_{Am}}{\bar{u}} \left( \frac{\mu}{\rho D_v} \right)^{2/3}$$

or

$$\begin{aligned} \frac{h}{h_M \rho c_p} &= P_{Am} \left[ \frac{(\mu/\rho D_v)}{(c_p \mu/k)} \right]^{2/3} \\ &= P_{Am} (\alpha/D_v)^{2/3} \end{aligned} \quad (38)$$

The quantity  $\alpha/D_v$  is the **Lewis number**  $\text{Le}$ . Its magnitude expresses relative rates of propagation of energy and mass within a system. It is fairly insensitive to temperature variation. For air and water vapor mixtures, the ratio is  $(0.60/0.71)$  or  $0.845$ , and  $(0.845)^{2/3}$  is  $0.894$ . At low diffusion rates, where the heat-mass transfer analogy is valid,  $P_{Am}$  is essentially unity. Therefore, for air and water vapor mixtures,

$$\frac{h}{h_M \rho c_p} \approx 1 \quad (39)$$

The ratio of the heat transfer coefficient to the mass transfer coefficient is equal to the specific heat per unit volume of the mixture at constant pressure. This relation [Equation (39)] is usually called the Lewis relation and is nearly true for air and water vapor at low mass transfer rates. It is generally not true for other gas mixtures because the ratio  $\text{Le}$  of thermal to vapor diffusivity can differ from unity. The agreement between wet-bulb temperature and adiabatic saturation temperature is a direct result of the nearness of the Lewis number to unity for air and water vapor.

The Lewis relation is valid in turbulent flow whether or not  $\alpha/D_v$  equals 1 because eddy diffusion in turbulent flow involves the same mixing action for heat exchange as for mass exchange, and this action overwhelms any molecular diffusion. Deviations from the Lewis relation are, therefore, due to a laminar boundary layer or a laminar sublayer and buffer zone where molecular transport phenomena are the controlling factors.

## SIMULTANEOUS HEAT AND MASS TRANSFER BETWEEN WATER-WETTED SURFACES AND AIR

A simplified method used to solve simultaneous heat and mass transfer problems was developed using the Lewis relation, and it gives satisfactory results for most air-conditioning processes. Extrapolation to very high mass transfer rates, where the simple heat-mass transfer analogy is not valid, will lead to erroneous results.

### Enthalpy Potential

The water vapor concentration in the air is the humidity ratio  $W$ , defined as

$$W \equiv \frac{\rho_B}{\rho_A} \quad (40)$$

A mass transfer coefficient is defined using  $W$  as the driving potential:

$$\dot{m}_B'' = K_M (W_i - W_\infty) \quad (41)$$

where the coefficient  $K_M$  is in  $\text{kg}/(\text{s} \cdot \text{m}^2)$ . For dilute mixtures,  $\rho_{Ai} \equiv \rho_{A\infty}$ ; that is, the partial mass density of dry air changes by only a small percentage between interface and free stream conditions. Therefore,

$$\dot{m}_B'' = \frac{K_M}{\rho_{Am}} (\rho_{Bi} - \rho_\infty) \quad (42)$$

where  $\rho_{Am}$  = mean density of dry air,  $\text{kg}/\text{m}^3$ . Comparing Equation (42) with Equation (24) shows that

$$h_M = \frac{K_M}{\rho_{Am}} \quad (43)$$

The **humid specific heat**  $c_{pm}$  of the airstream is, by definition (Mason and Monchick 1965),

$$c_{pm} = (1 + W_\infty) c_p \quad (44a)$$

or

$$c_{pm} = \left( \frac{\rho}{\rho_{A\infty}} \right) c_p \quad (44b)$$

where  $c_{pm}$  is in  $\text{kJ}/(\text{kg}_{\text{da}} \cdot \text{K})$ .

Substituting from Equations (43) and (44b) into Equation (39) gives

$$\frac{h\rho_{Am}}{K_M\rho_{A\infty}c_{pm}} = 1 \approx \frac{h}{K_Mc_{pm}} \quad (45)$$

since  $\rho_{Am} \approx \rho_{A\infty}$  because of the small change in dry-air density. Using a mass transfer coefficient with the humidity ratio as the driving force, the Lewis relation becomes ratio of heat to mass transfer coefficient equals humid specific heat.

For the plate humidifier illustrated in Figure 6, the total heat transfer from liquid to interface is

$$q'' = q_A'' + \dot{m}_B'' h_{fg} \quad (46)$$

Using the definitions of the heat and mass transfer coefficients gives

$$q'' = h(t_i - t_\infty) + K_M(W_i - W_\infty)h_{fg} \quad (47)$$

Assuming Equation (45) is valid gives

$$q'' = K_M [c_{pm}(t_i - t_\infty) + (W_i - W_\infty)h_{fg}] \quad (48)$$

The enthalpy of the air is approximately

$$h = c_{pa}t + Wh_s \quad (49)$$

The enthalpy  $h_s$  of the water vapor can be expressed by the ideal gas law as

$$h_s = c_{ps}(t - t_o) + h_{fgo} \quad (50)$$

where the base of enthalpy is taken as saturated water at temperature  $t_o$ . Choosing  $t_o = 0^\circ\text{C}$  to correspond with the base of the dry-air enthalpy gives

$$h = (c_{pa} + Wc_{ps})t + Wh_{fgo} = c_{pm}t + Wh_{fgo} \quad (51)$$

If small changes in the latent heat of vaporization of water with temperature are neglected when comparing Equations (49) and (51), the total heat transfer can be written as

$$q'' = K_M(h_i - h_\infty) \quad (52)$$

Where the driving potential for heat transfer is temperature difference and the driving potential for mass transfer is mass concentration or partial pressure, the driving potential for simultaneous transfer of heat and mass in an air water-vapor mixture is, to a close approximation, enthalpy.

### Basic Equations for Direct-Contact Equipment

Air-conditioning equipment can be classified as (1) having direct contact between air and water used as a cooling or heating fluid or (2) having the heating or cooling fluid separated from the airstream by a solid wall. Examples of the former are air washers and cooling towers; an example of the latter is a direct-expansion refrigerant (or water) cooling and dehumidifying coil. In both cases, the airstream is in contact with a water surface. Direct contact implies contact directly with the cooling (or heating) fluid. In the dehumidifying coil, the contact with the condensate removed from the airstream is direct, but it is indirect with the refrigerant flowing inside the tubes of the coil. These two cases are treated separately because the surface areas of direct-contact equipment cannot be evaluated.

For the direct-contact spray chamber air washer of cross-sectional area  $A_{cs}$  and length  $l$  (Figure 12), the steady mass flow rate of dry air per unit cross-sectional area is

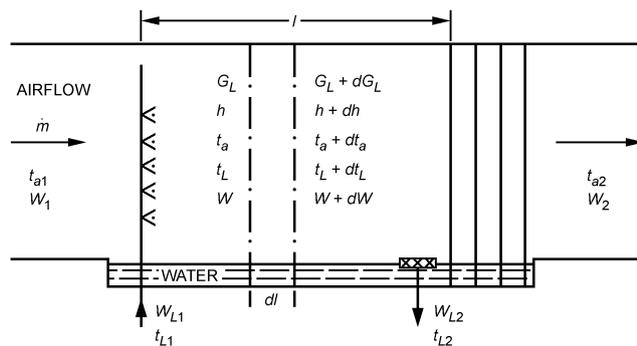

Fig. 12 Air Washer Spray Chamber

$$\dot{m}_a/A_{cs} = G_a \quad (53)$$

and the corresponding mass flux of water flowing parallel with the air is

$$\dot{m}_L/A_{cs} = G_L \quad (54)$$

where

$\dot{m}_a$  = mass flow rate of air, kg/s

$G_a$  = mass flux or flow rate per unit cross-sectional area for air,  $\text{kg}/(\text{s} \cdot \text{m}^2)$

$\dot{m}_L$  = mass flow rate of liquid, kg/s

$G_L$  = mass flux or flow rate per unit cross-sectional area for liquid,  $\text{kg}/(\text{s} \cdot \text{m}^2)$

Because water is evaporating or condensing,  $G_L$  changes by an amount  $dG_L$  in a differential length  $dl$  of the chamber. Similar changes occur in temperature, humidity ratio, enthalpy, and other properties.

Because evaluating the true surface area in direct-contact equipment is difficult, it is common to work on a unit volume basis. If  $a_H$  and  $a_M$  are the area of heat transfer and mass transfer surface per unit of chamber volume, respectively, the total surface areas for heat and mass transfer are

$$A_H = a_H A_{cs} l \quad \text{and} \quad A_M = a_M A_{cs} l \quad (55)$$

The basic equations for the process occurring in the differential length  $dl$  can be written for

#### 1. Mass transfer

$$-dG_L = G_a dW = K_M a_M (W_i - W) dl \quad (56)$$

That is, the water evaporated, the moisture increase of the air, and the mass transfer rate are all equal.

#### 2. Heat transfer to air

$$G_a c_{pm} dt_a = h_a a_H (t_i - t_a) dl \quad (57)$$

#### 3. Total energy transfer to air

$$\begin{aligned} G_a (c_{pm} dt_a + h_{fgo} dW) \\ = [K_M a_M (W_i - W) h_{fg} + h_a a_H (t_i - t_a)] dl \end{aligned} \quad (58)$$

Assuming  $a_H = a_M$  and  $Le = 1$ , and neglecting small variations in  $h_{fg}$ , Equation (58) reduces to

$$G_a dh = K_M a_M (h_i - h) dl \quad (59)$$

The heat and mass transfer areas of spray chambers are assumed to be identical ( $a_H = a_M$ ). Where packing materials, such as wood slats or Raschig rings, are used, the two areas may be considerably different because the packing may not be wet uniformly. The validity of the Lewis relation was discussed previously. It is not necessary to account for the small changes in latent heat  $h_{fg}$  after making the two previous assumptions.

4. Energy balance

$$G_a dh = \pm G_L c_L dt_L \quad (60)$$

A minus sign refers to parallel flow of air and water; a plus sign refers to counterflow (water flow in the opposite direction from airflow).

The water flow rate changes between inlet and outlet as a result of the mass transfer. For exact energy balance, the term  $(c_L t_L dG_L)$  should be added to the right side of Equation (60). The percentage change in  $G_L$  is quite small in usual applications of air-conditioning equipment and, therefore, can be ignored.

5. Heat transfer to water

$$\pm G_L c_L dt_L = h_L a_H (t_L - t_i) dl \quad (61)$$

Equations (56) to (61) are the basic relations for solution of simultaneous heat and mass transfer processes in direct-contact air-conditioning equipment.

To facilitate the use of these relations in equipment design or performance, three other equations can be extracted from the above set. Combining Equations (59), (60), and (61) gives

$$\frac{h - h_i}{t_L - t_i} = - \frac{h_L a_H}{K_M a_M} = - \frac{h_L}{K_M} \quad (62)$$

Equation (62) relates the enthalpy potential for the total heat transfer through the gas film to the temperature potential for this same transfer through the liquid film. Physical reasoning leads to the conclusion that this ratio is proportional to the ratio of gas film resistance ( $1/K_M$ ) to liquid film resistance ( $1/h_L$ ). Combining Equations (57), (59), and (45) gives

$$\frac{dh}{dt_a} = \frac{h - h_i}{t_a - t_i} \quad (63)$$

Similarly, combining Equations (56), (57), and (45) gives

$$\frac{dW}{dt_a} = \frac{W - W_i}{t_a - t_i} \quad (64)$$

Equation (64) indicates that at any cross section in the spray chamber, the instantaneous slope of the air path  $dW/dt_a$  on a psychrometric chart is determined by a straight line connecting the air state with the interface saturation state at that cross section. In Figure 13, state 1 represents the state of the air entering the parallel flow air washer chamber of Figure 12. The washer is operating as a heating and humidifying apparatus so that the interface saturation state of the water at air inlet is the state designated  $1_i$ . Therefore, the initial slope of the air path is along a line directed from state 1 to state  $1_i$ . As the air is heated, the water cools and the interface temperature drops. Corresponding air states and interface saturation states are indicated by the letters  $a, b, c,$  and  $d$  in Figure 13. In each instance, the air path is directed toward the associated interface state. The interface states are derived from Equations (60) and (62). Equation (60) describes how the air enthalpy changes with water temperature; Equation (62) describes how the interface saturation state

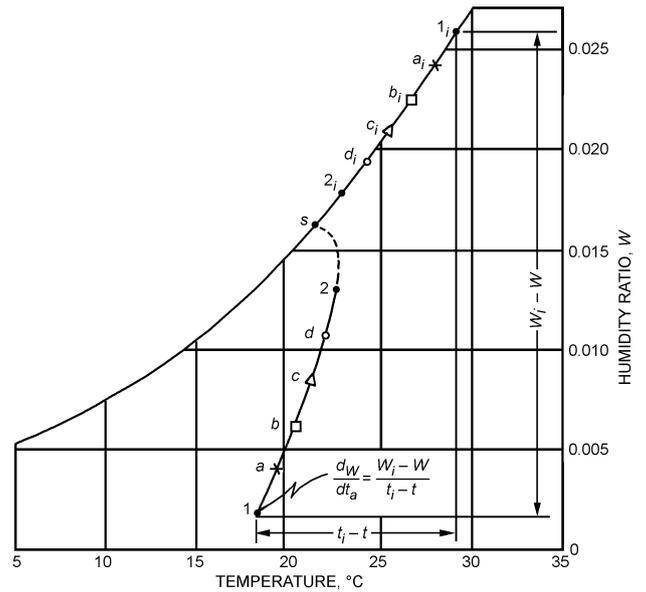

Fig. 13 Air Washer Humidification Process on Psychrometric Chart

changes to accommodate this change in air and water conditions. The solution for the interface state on the normal psychrometric chart of Figure 13 can be determined either by trial and error from Equations (60) and (62) or by a complex graphical procedure (Kusuda 1957).

Air Washers

Air washers are direct-contact apparatus used to (1) simultaneously change the temperature and humidity content of air passing through the chamber and (2) remove air contaminants such as dust and odors. Adiabatic spray washers, which have no external heating or chilling source, are used to cool and humidify air. Chilled spray air washers have an external chiller to cool and dehumidify air. Heated spray air washers, whose external heating source provides additional energy for evaporation of water, are used to humidify and possibly heat air.

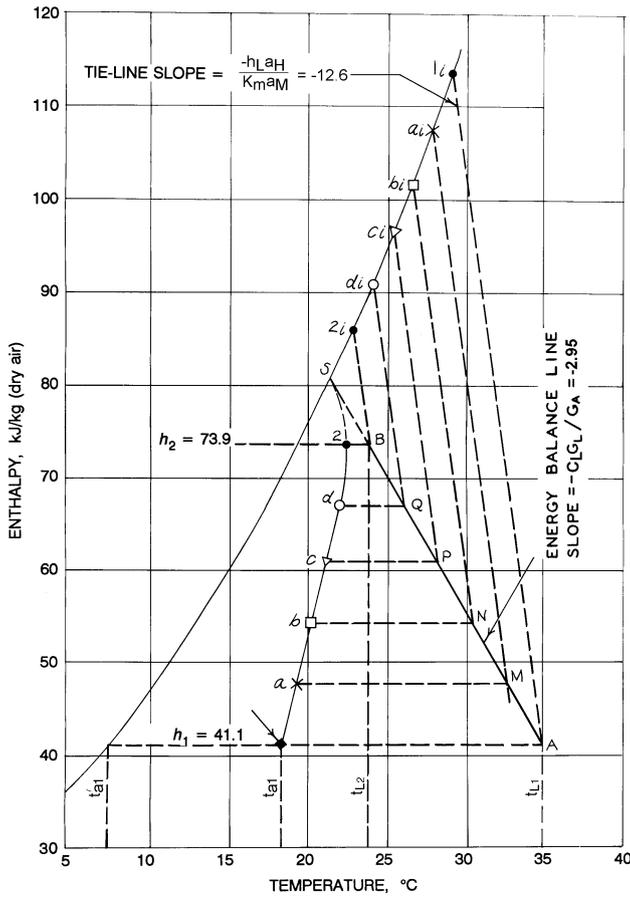

**Example 5.** A parallel flow air washer with the following design conditions is to be designed (see Figure 12).

- Water temperature at inlet  $t_{L1} = 35^\circ\text{C}$
- Water temperature at outlet  $t_{L2} = 23.9^\circ\text{C}$
- Air temperature at inlet  $t_{a1} = 18.3^\circ\text{C}$
- Air wet-bulb at inlet  $t'_{a1} = 7.2^\circ\text{C}$
- Air mass flow rate per unit area  $G_a = 1.628 \text{ kg}/(\text{s} \cdot \text{m}^2)$
- Spray ratio  $G_L/G_a = 0.70$
- Air heat transfer coefficient per cubic metre of chamber volume  $h_a a_H = 1.34 \text{ kW}/(\text{m}^3 \cdot \text{K})$
- Liquid heat transfer coefficient per cubic metre of chamber volume  $h_L a_H = 16.77 \text{ kW}/(\text{m}^3 \cdot \text{K})$
- Air volumetric flow rate  $Q = 3.07 \text{ m}^3/\text{s}$

**Solution:** The air mass flow rate  $\dot{m}_a = 3.07 \times 1.20 = 3.68 \text{ kg/s}$ ; the required spray chamber cross-sectional area is, then,  $A_{cs} = \dot{m}_a/G_a = 3.68/1.628 = 2.26 \text{ m}^2$ . The mass transfer coefficient is given by the Lewis relation [Equation (45)] as

$$K_M a_M = (h_a a_H)/c_{pm} = 1.34/1.005 = 1.33 \text{ kg}/(\text{m}^3 \cdot \text{s})$$

Figure 14 shows the enthalpy-temperature psychrometric chart with the graphical solution for the interface states and the air path through the washer spray chamber. The solution proceeds as follows:

**Fig. 14 Graphical Solution for Air-State Path in Parallel Flow Air Washer**

1. Enter bottom of chart with  $t'_{a1}$  of 7.2°C, and follow up to saturation curve to establish air enthalpy  $h_1$  of 41.1 kJ/kg. Extend this enthalpy line to intersect initial air temperature  $t_{a1}$  of 18.3°C (state 1 of air) and initial water temperature  $t_{L1}$  of 35°C at point A. (Note that the temperature scale is used for both air and water temperatures.)
2. Through point A, construct the energy balance line A-B with a slope of

$$\frac{dh}{dt_L} = -\frac{c_L G_L}{G_a} = -2.95$$

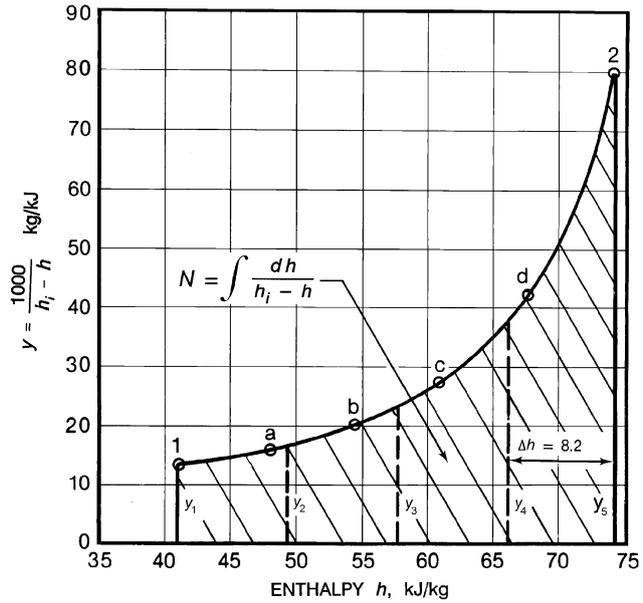

Point B is determined by intersection with the leaving water temperature  $t_{L2} = 23.9^\circ\text{C}$ . The negative slope here is a consequence of the parallel flow, which results in the air-water mixture's approaching, but not reaching, the common saturation state  $s$ . (The line A-B has no physical significance in representing any air state on the psychrometric chart. It is merely a construction line in the graphical solution.)

3. Through point A, construct the tie-line A- $1_i$  having a slope of

$$\frac{h - h_i}{t_L - t_i} = -\frac{h_L a_H}{K_M a_M} = -\frac{16.77}{1.33} = -12.6$$

The intersection of this line with the saturation curve gives the initial interface state  $1_i$  at the chamber inlet. (Note how the energy balance line and tie-line, representing Equations (60) and (62), combine for a simple graphical solution on Figure 14 for the interface state.)

4. The initial slope of the air path can now be constructed, according to Equation (63), drawing line 1- $a$  toward the initial interface state  $1_i$ . (The length of the line 1- $a$  will depend on the degree of accuracy required in the solution and the rate at which the slope of the air path is changing.)

**Fig. 15 Graphical Solution of  $\int dh/(h_i - h)$**

5. Construct the horizontal line a-M locating the point M on the energy-balance line. Draw a new tie-line (slope of -12.6 as before) from M to  $a_i$  locating interface state  $a_i$ . Continue the air path from a to b by directing it toward the new interface state  $a_i$ . (Note that the change in slope of the air path from 1-a to a-b is quite small, justifying the path incremental lengths used.)
6. Continue in the manner of step 5 until point 2, the final state of the air leaving the chamber, is reached. In this example, six steps are used in the graphical construction with the following results:

State	1	a	b	c	d	2
$t_L$	35	32.8	30.6	28.3	26.1	23.9
$h$	41.1	47.7	54.3	60.8	67.4	73.9
$t_i$	29.2	27.9	26.7	25.4	24.2	22.9
$h_i$	114.4	108.0	102.3	96.9	91.3	86.4
$t_a$	18.3	19.3	20.3	21.1	21.9	22.4

The final state of the air leaving the washer is  $t_{a2} = 22.4^\circ\text{C}$  and  $h_2 = 73.6$  kJ/kg (wet-bulb temperature  $t'_{a2} = 19.4^\circ\text{C}$ ).

7. The final step involves calculating the required length of the spray chamber. From Equation (59),

$$l = \frac{G_a}{K_M a_M} \int_1^2 \frac{dh}{(h_i - h)}$$

The integral is evaluated graphically by plotting  $1/(h_i - h)$  versus  $h$  as shown in Figure 15. Any satisfactory graphical method can be used to evaluate the area under the curve. Simpson's rule with four equal increments of  $\Delta h$  equal to 8.2 gives

$$N = \int_1^2 \frac{dh}{(h_i - h)} \approx (\Delta h/3)(y_1 + 4y_2 + 2y_3 + 4y_4 + y_5)$$

$$N = (8.2/3)[0.0136 + (4 \times 0.0167) + (2 \times 0.0238) + (4 \times 0.0372) + 0.0800] = 0.975$$

The design length is, therefore,  $l = (1.628/1.33)(0.975) = 1.19$  m.

The method used in Example 5 can also be used to predict the performance of existing direct-contact equipment and can determine the transfer coefficients when performance data from test runs are available. By knowing the water and air temperatures entering and leaving the chamber and the spray ratio, it is possible, by trial and error, to determine the proper slope of the tie-line necessary to achieve the measured final air state. The tie-line slope gives the ratio

$h_L a_H / K_M a_M$ ;  $K_M a_M$  is found from the integral relationship in Example 5 from the known chamber length  $l$ .

Additional descriptions of air spray washers and general performance criteria are given in Chapter 19 of the 2000 ASHRAE Handbook—Systems and Equipment.

**Cooling Towers**

A cooling tower is a direct-contact heat exchanger in which waste heat picked up by the cooling water from a refrigerator, air conditioner, or industrial process is transferred to atmospheric air by cooling the water. Cooling is achieved by breaking up the water flow to provide a large water surface for air, moving by natural or forced convection through the tower, to contact the water. Cooling towers may be counterflow, crossflow, or a combination of both.

The temperature of the water leaving the tower and the packing depth needed to achieve the desired leaving water temperature are of primary interest for design. Therefore, the mass and energy balance equations are based on an overall coefficient  $K$ , which is based on (1) the enthalpy driving force due to  $h$  at the bulk water temperature and (2) neglecting the film resistance. Combining Equations (59) and (60) and using the parameters described above yields

$$G_L c_L dt = K_M a_M (h_i - h) dl = G_a dh$$

$$= \frac{K_a dV (h' - h_a)}{A_{cs}} \quad (65)$$

or

$$\frac{K_a V}{\dot{m}_L} = \int_{t_1}^{t_2} \frac{c_L dt}{(h' - h_a)} \quad (66)$$

Chapter 36 of the 2000 ASHRAE Handbook—Systems and Equipment covers cooling tower design in detail.

**Cooling and Dehumidifying Coils**

When water vapor is condensed out of an airstream onto an extended surface (finned) cooling coil, the simultaneous heat and mass transfer problem can be solved by the same procedure set forth for direct-contact equipment. The basic equations are the same, except that the true surface area of the coil  $A$  is known and the problem does not have to be solved on a unit volume basis. Therefore, if in Equations (56), (57), and (59)  $a_M dl$  or  $a_H dl$  is replaced by  $dA/A_{cs}$ , these equations become the basic heat, mass, and total energy transfer equations for indirect-contact equipment such as dehumidifying coils. The energy balance shown by Equation (60) remains unchanged. The heat transfer from the interface to the refrigerant now encounters the combined resistances of the condensate film ( $R_L = 1/h_L$ ); the metal wall and fins, if any ( $R_m$ ); and the refrigerant film ( $R_r = A/h_r A_r$ ). If this combined resistance is designated as  $R_i = R_L + R_m + R_r = 1/U_i$ , Equation (61) becomes, for a coil dehumidifier,

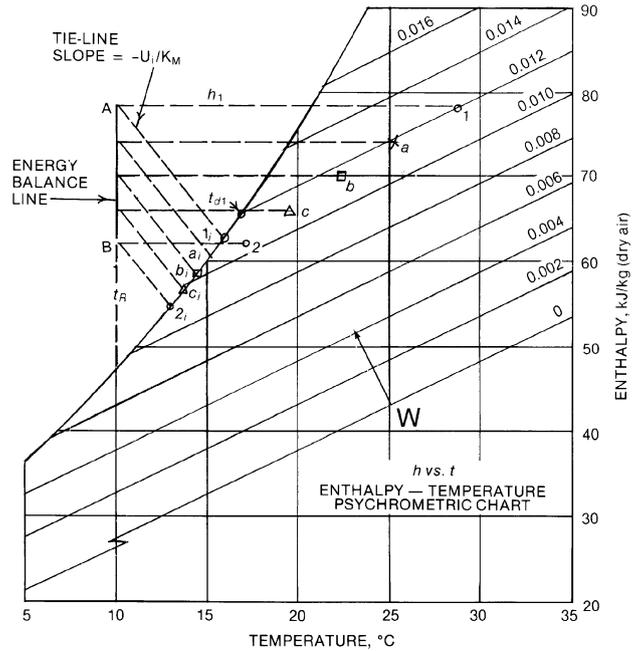

$$\pm \dot{m}_L c_L dt_L = U_i (t_L - t_i) dA \quad (67)$$

(plus sign for counterflow, minus sign for parallel flow).

The tie-line slope is then

$$\frac{h - h_i}{t_L - t_i} = \mp \frac{U_i}{K_M} \quad (68)$$

Figure 16 illustrates the graphical solution on a psychrometric chart for the air path through a dehumidifying coil with a constant refrigerant temperature. Because the tie-line slope is infinite in this case, the energy balance line is vertical. The corresponding inter-

**Fig. 16 Graphical Solution for Air-State Path in Dehumidifying Coil with Constant Refrigerant Temperature**

face states and air states are denoted by the same letter symbols, and the solution follows the same procedure as in Example 5.

If the problem is to determine the required coil surface area for a given performance, the area is computed by the following relation:

$$A = \frac{\dot{m}_a}{K_M} \int_1^2 \frac{dh}{(h_i - h)} \quad (69)$$

This graphical solution on the psychrometric chart automatically determines whether any part of the coil is dry. Thus, in the example illustrated in Figure 16, the entering air at state 1 initially encounters an interface saturation state  $i_1$ , clearly below its dew-point temperature  $t_{d1}$ , so the coil immediately becomes wet. Had the graphical technique resulted in an initial interface state above the dew-point temperature of the entering air, the coil would be initially dry. The air would then follow a constant humidity ratio line (the sloping  $W = \text{constant}$  lines on the chart) until the interface state reached the air dew-point temperature.

Mizushima et al. (1959) developed this method not only for water vapor and air, but also for other vapor-gas mixtures. Chapter 21 of the 2000 ASHRAE Handbook—Systems and Equipment shows another related method, based on ARI Standard 410, of determining air-cooling and dehumidifying coil performance.

**SYMBOLS**

- $a$  = constant, dimensionless; or surface area per unit volume,  $\text{m}^2/\text{m}^3$
- $A$  = surface area,  $\text{m}^2$
- $A_{cs}$  = cross-sectional area,  $\text{m}^2$
- $b$  = exponent, dimensionless
- $c_L$  = specific heat of liquid,  $\text{kJ}/(\text{kg} \cdot \text{K})$
- $c_p$  = specific heat at constant pressure,  $\text{kJ}/(\text{kg} \cdot \text{K})$
- $c_{pm}$  = specific heat of moist air at constant pressure,  $\text{kJ}/(\text{kg}_{\text{da}} \cdot \text{K})$
- $C$  = molal concentration of solute in solvent,  $\text{mol}/\text{m}^3$
- $d$  = diameter,  $\text{m}$
- $D_v$  = diffusion coefficient (mass diffusivity),  $\text{mm}^2/\text{s}$
- $f$  = Fanning friction factor, dimensionless
- $G$  = mass flux, flow rate per unit of cross-sectional area,  $\text{kg}/(\text{s} \cdot \text{m}^2)$
- $h$  = enthalpy,  $\text{kJ}/\text{kg}$ ; or heat transfer coefficient,  $\text{W}/(\text{m}^2 \cdot \text{K})$

$h_{fg}$  = enthalpy of vaporization, kJ/kg  
 $h_M$  = mass transfer coefficient, m/s  
 $J_D$  = Colburn mass transfer group =  $Sh/(Re \cdot Sc^{1/3})$ , dimensionless  
 $J_H$  = Colburn heat transfer group =  $Nu/(Re \cdot Pr^{1/3})$ , dimensionless  
 $J$  = diffusive mass flux, kg/(s·m<sup>2</sup>)  
 $J^*$  = diffusive molar flux, mol/(s·m<sup>2</sup>)  
 $k$  = thermal conductivity, W/(m·K)  
 $K_M$  = mass transfer coefficient, kg/(s·m<sup>2</sup>)  
 $l$  = length, m  
 $L$  = characteristic length, m  
 $L/G$  = liquid-to-air mass flow ratio  
 $Le$  = Lewis number =  $\alpha/D_v$ , dimensionless  
 $\dot{m}$  = rate of mass transfer, m/s  
 $\dot{m}''$  = mass flux, kg/(s·m<sup>2</sup>)  
 $\dot{m}''^*$  = molar flux, mol/(s·m<sup>2</sup>)  
 $M$  = relative molecular mass, kg/mol  
 $Nu$  = Nusselt number =  $hL/k$ , dimensionless  
 $p$  = pressure, kPa  
 $P_{Am}$  = logarithmic mean density factor  
 $Pr$  = Prandtl number =  $c_p \mu / k$ , dimensionless  
 $q$  = rate of heat transfer, W  
 $q''$  = heat flux per unit area, W/m<sup>2</sup>  
 $Q$  = volumetric flow rate, m<sup>3</sup>/s  
 $R_i$  = combined thermal resistance, m<sup>2</sup>·K/W  
 $R_L$  = thermal resistance of condensate film, m<sup>2</sup>·K/W  
 $R_m$  = thermal resistance across metal wall and fins, m<sup>2</sup>·K/W  
 $R_r$  = thermal resistance of refrigerant film, m<sup>2</sup>·K/W  
 $R_u$  = universal gas constant = 8.314 kJ/(mol·K)  
 $Re$  = Reynolds number =  $\rho u L / \mu$ , dimensionless  
 $Sc$  = Schmidt number =  $\mu / \rho D_v$ , dimensionless  
 $Sh$  = Sherwood number =  $h_M L / D_v$ , dimensionless  
 $St$  = Stanton number =  $h / \rho c_p \bar{u}$ , dimensionless  
 $St_m$  = mass transfer Stanton number =  $h_M P_{Am} / \bar{u}$ , dimensionless  
 $t$  = temperature, °C  
 $T$  = absolute temperature, K  
 $u$  = velocity in  $x$  direction, m/s  
 $U_i$  = overall conductance from refrigerant to air-water interface for dehumidifying coil, W/(m<sup>2</sup>·K)  
 $v$  = velocity in  $y$  direction, m/s  
 $v_i$  = velocity normal to mass transfer surface for component  $i$ , m/s  
 $V$  = fluid stream velocity, m/s  
 $W$  = humidity ratio, kg of water vapor per kg of dry air  
 $x, y, z$  = coordinate direction, m  
 $X, Y, Z$  = coordinate direction, dimensionless  
 $\alpha$  = thermal diffusivity =  $k / \rho c_p$ , m<sup>2</sup>/s  
 $\epsilon_D$  = eddy mass diffusivity, m<sup>2</sup>/s  
 $\theta$  = dimensionless time parameter  
 $\mu$  = absolute (dynamic) viscosity, kg/(m·s)  
 $\mu$  = permeability, mg/(s·m·Pa)  
 $\nu$  = kinematic viscosity, m<sup>2</sup>/s  
 $\rho$  = mass density or concentration, kg/m<sup>3</sup>  
 $\sigma$  = characteristic molecular diameter, nm  
 $\tau$  = time  
 $\tau_i$  = shear stress in the  $x$ - $y$  coordinate plane, N/m<sup>2</sup>  
 $\omega$  = mass fraction, kg/kg  
 $\Omega_{D,AB}$  = temperature function in Equation (9)

### Subscripts

$a$  = air property  
 $Am$  = logarithmic mean  
 $A$  = gas component of binary mixture  
 $B$  = the more dilute gas component of binary mixture  
 $c$  = critical state  
 $da$  = dry air property or air-side transfer quantity  
 $H$  = heat transfer quantity  
 $i$  = air-water interface value  
 $L$  = liquid  
 $m$  = mean value or metal  
 $M$  = mass transfer quantity  
 $o$  = property evaluated at 0°C

$s$  = water vapor property or transport quantity  
 $w$  = water vapor  
 $\infty$  = property of main fluid stream

### Superscripts

$*$  = on molar basis  
 $-$  = average value  
 $'$  = wet bulb

---	---

**P**SYCHROMETRICS deals with the thermodynamic properties of moist air and uses these properties to analyze conditions and processes involving moist air.

Hyland and Wexler (1983a,b) developed formulas for thermodynamic properties of moist air and water. However, perfect gas relations can be used instead of these formulas in most air-conditioning problems. Kuehn et al. (1998) showed that errors are less than 0.7% in calculating humidity ratio, enthalpy, and specific volume of saturated air at standard atmospheric pressure for a temperature range of  $-50$  to  $50^\circ\text{C}$ . Furthermore, these errors decrease with decreasing pressure.

This chapter discusses perfect gas relations and describes their use in common air-conditioning problems. The formulas developed by Hyland and Wexler (1983a) and discussed by Olivieri (1996) may be used where greater precision is required.

### COMPOSITION OF DRY AND MOIST AIR

**Atmospheric air** contains many gaseous components as well as water vapor and miscellaneous contaminants (e.g., smoke, pollen, and gaseous pollutants not normally present in free air far from pollution sources).

**Dry air** exists when all water vapor and contaminants have been removed from atmospheric air. The composition of dry air is relatively constant, but small variations in the amounts of individual components occur with time, geographic location, and altitude. Harrison (1965) lists the approximate percentage composition of dry air by volume as: nitrogen, 78.084; oxygen, 20.9476; argon, 0.934; carbon dioxide, 0.0314; neon, 0.001818; helium, 0.000524; methane, 0.00015; sulfur dioxide, 0 to 0.0001; hydrogen, 0.00005; and minor components such as krypton, xenon, and ozone, 0.0002. The relative molecular mass of all components for dry air is 28.9645, based on the carbon-12 scale (Harrison 1965). The gas constant for dry air, based on the carbon-12 scale, is

$$R_{da} = 8314.41/28.9645 = 287.055 \text{ J/(kg}\cdot\text{K)} \quad (1)$$

**Moist air** is a binary (two-component) mixture of dry air and water vapor. The amount of water vapor in moist air varies from zero (dry air) to a maximum that depends on temperature and pressure. The latter condition refers to **saturation**, a state of neutral equilibrium between moist air and the condensed water phase (liquid or solid). Unless otherwise stated, saturation refers to a flat interface surface between the moist air and the condensed phase. Saturation conditions will change when the interface radius is very

small such as with ultrafine water droplets. The relative molecular mass of water is 18.01528 on the carbon-12 scale. The gas constant for water vapor is

$$R_w = 8314.41/18.01528 = 461.520 \text{ J/(kg}\cdot\text{K)} \quad (2)$$

### UNITED STATES STANDARD ATMOSPHERE

The temperature and barometric pressure of atmospheric air vary considerably with altitude as well as with local geographic and weather conditions. The standard atmosphere gives a standard of reference for estimating properties at various altitudes. At sea level, standard temperature is  $15^\circ\text{C}$ ; standard barometric pressure is 101.325 kPa. The temperature is assumed to decrease linearly with increasing altitude throughout the troposphere (lower atmosphere), and to be constant in the lower reaches of the stratosphere. The lower atmosphere is assumed to consist of dry air that behaves as a perfect gas. Gravity is also assumed constant at the standard value,  $9.80665 \text{ m/s}^2$ . Table 1 summarizes property data for altitudes to 10 000 m.

**Table 1 Standard Atmospheric Data for Altitudes to 10 000 m**

Altitude, m	Temperature, $^\circ\text{C}$	Pressure, kPa
-500	18.2	107.478
0	15.0	101.325
500	11.8	95.461
1 000	8.5	89.875
1 500	5.2	84.556
2 000	2.0	79.495
2 500	-1.2	74.682
3 000	-4.5	70.108
4 000	-11.0	61.640
5 000	-17.5	54.020
6 000	-24.0	47.181
7 000	-30.5	41.061
8 000	-37.0	35.600
9 000	-43.5	30.742
10 000	-50	26.436
12 000	-63	19.284
14 000	-76	13.786
16 000	-89	9.632
18 000	-102	6.556
20 000	-115	4.328

The preparation of this chapter is assigned to TC 1.1, Thermodynamics and Psychrometrics.

The pressure values in Table 1 may be calculated from

$$p = 101.325(1 - 2.25577 \times 10^{-5}Z)^{5.2559} \quad (3)$$

The equation for temperature as a function of altitude is given as

$$t = 15 - 0.0065Z \quad (4)$$

where

$Z$  = altitude, m

$p$  = barometric pressure, kPa

$t$  = temperature, °C

Equations (3) and (4) are accurate from  $-5000$  m to  $11\,000$  m. For higher altitudes, comprehensive tables of barometric pressure and other physical properties of the standard atmosphere can be found in NASA (1976).

### THERMODYNAMIC PROPERTIES OF MOIST AIR

Table 2, developed from formulas by Hyland and Wexler (1983a,b), shows values of thermodynamic properties of **moist air** based on the **thermodynamic temperature scale**. This ideal scale differs slightly from practical temperature scales used for physical measurements. For example, the standard boiling point for water (at  $101.325$  kPa) occurs at  $99.97^\circ\text{C}$  on this scale rather than at the traditional value of  $100^\circ\text{C}$ . Most measurements are currently based on the International Temperature Scale of 1990 (ITS-90) (Preston-Thomas 1990).

The following paragraphs briefly describe each column of Table 2:

$t$  = Celsius temperature, based on thermodynamic temperature scale and expressed relative to absolute temperature  $T$  in kelvins (K) by the following relation:

$$T = t + 273.15$$

$W_s$  = humidity ratio at saturation, condition at which gaseous phase (moist air) exists in equilibrium with condensed phase (liquid or solid) at given temperature and pressure (standard atmospheric pressure). At given values of temperature and pressure, humidity ratio  $W$  can have any value from zero to  $W_s$ .

$v_{da}$  = specific volume of dry air,  $\text{m}^3/\text{kg}$  (dry air).

$v_{as}$  =  $v_s - v_{da}$ , difference between specific volume of moist air at saturation and that of dry air itself,  $\text{m}^3/\text{kg}$  (dry air), at same pressure and temperature.

$v_s$  = specific volume of moist air at saturation,  $\text{m}^3/\text{kg}$  (dry air).

$h_{da}$  = specific enthalpy of dry air,  $\text{kJ}/\text{kg}$  (dry air). In Table 2,  $h_{da}$  has been assigned a value of 0 at  $0^\circ\text{C}$  and standard atmospheric pressure.

$h_{as}$  =  $h_s - h_{da}$ , difference between specific enthalpy of moist air at saturation and that of dry air itself,  $\text{kJ}/\text{kg}$  (dry air), at same pressure and temperature.

$h_s$  = specific enthalpy of moist air at saturation,  $\text{kJ}/\text{kg}$  (dry air).

$s_{da}$  = specific entropy of dry air,  $\text{kJ}/(\text{kg}\cdot\text{K})$  (dry air). In Table 2,  $s_{da}$  has been assigned a value of 0 at  $0^\circ\text{C}$  and standard atmospheric pressure.

$s_{as}$  =  $s_s - s_{da}$ , difference between specific entropy of moist air at saturation and that of dry air itself,  $\text{kJ}/(\text{kg}\cdot\text{K})$  (dry air), at same pressure and temperature.

$s_s$  = specific entropy of moist air at saturation  $\text{kJ}/(\text{kg}\cdot\text{K})$  (dry air).

$h_w$  = specific enthalpy of condensed water (liquid or solid) in equilibrium with saturated moist air at specified temperature and pressure,  $\text{kJ}/\text{kg}$  (water). In Table 2,  $h_w$  is assigned a value of 0 at its triple point ( $0.01^\circ\text{C}$ ) and saturation pressure.

Note that  $h_w$  is greater than the steam-table enthalpy of saturated pure condensed phase by the amount of enthalpy increase governed by the pressure increase from saturation pressure to  $101.325$  kPa, plus influences from presence of air.

$s_w$  = specific entropy of condensed water (liquid or solid) in equilibrium with saturated air,  $\text{kJ}/(\text{kg}\cdot\text{K})$  (water);  $s_w$  differs from entropy of pure water at saturation pressure, similar to  $h_w$ .

$p_s$  = vapor pressure of water in saturated moist air, kPa. Pressure  $p_s$  differs negligibly from saturation vapor pressure of pure water  $p_{ws}$  for conditions shown. Consequently, values of  $p_s$  can be used at same pressure and temperature in equations where  $p_{ws}$  appears. Pressure  $p_s$  is defined as  $p_s = x_{ws}p$ , where  $x_{ws}$  is mole fraction of water vapor in moist air saturated with water at temperature  $t$  and pressure  $p$ , and where  $p$  is total barometric pressure of moist air.

### THERMODYNAMIC PROPERTIES OF WATER AT SATURATION

Table 3 shows thermodynamic properties of **water at saturation** for temperatures from  $-60$  to  $160^\circ\text{C}$ , calculated by the formulations described by Hyland and Wexler (1983b). Symbols in the table follow standard steam table nomenclature. These properties are based on the thermodynamic temperature scale. The enthalpy and entropy of saturated liquid water are both assigned the value zero at the triple point,  $0.01^\circ\text{C}$ . Between the triple-point and critical-point temperatures of water, two states—liquid and vapor—may coexist in equilibrium. These states are called **saturated liquid** and **saturated vapor**.

The **water vapor saturation pressure** is required to determine a number of moist air properties, principally the saturation humidity ratio. Values may be obtained from Table 3 or calculated from the following formulas (Hyland and Wexler 1983b).

The saturation pressure over **ice** for the temperature range of  $-100$  to  $0^\circ\text{C}$  is given by

$$\ln p_{ws} = C_1/T + C_2 + C_3T + C_4T^2 + C_5T^3 + C_6T^4 + C_7 \ln T \quad (5)$$

where

$$C_1 = -5.674\,535\,9\text{E}+03$$

$$C_2 = 6.392\,524\,7\text{E}+00$$

$$C_3 = -9.677\,843\,0\text{E}-03$$

$$C_4 = 6.221\,570\,1\text{E}-07$$

$$C_5 = 2.074\,782\,5\text{E}-09$$

$$C_6 = -9.484\,024\,0\text{E}-13$$

$$C_7 = 4.163\,501\,9\text{E}+00$$

The saturation pressure over **liquid water** for the temperature range of  $0$  to  $200^\circ\text{C}$  is given by

$$\ln p_{ws} = C_8/T + C_9 + C_{10}T + C_{11}T^2 + C_{12}T^3 + C_{13} \ln T \quad (6)$$

where

$$C_8 = -5.800\,220\,6\text{E}+03$$

$$C_9 = 1.391\,499\,3\text{E}+00$$

$$C_{10} = -4.864\,023\,9\text{E}-02$$

$$C_{11} = 4.176\,476\,8\text{E}-05$$

$$C_{12} = -1.445\,209\,3\text{E}-08$$

$$C_{13} = 6.545\,967\,3\text{E}+00$$

In both Equations (5) and (6),

$\ln$  = natural logarithm

$p_{ws}$  = saturation pressure, Pa

$T$  = absolute temperature,  $\text{K} = ^\circ\text{C} + 273.15$

The coefficients of Equations (5) and (6) have been derived from the Hyland-Wexler equations. Due to rounding errors in the derivations and in some computers' calculating precision, the results obtained from Equations (5) and (6) may not agree precisely with Table 3 values.

Table 2 Thermodynamic Properties of Moist Air at Standard Atmospheric Pressure, 101.325 kPa

## HUMIDITY PARAMETERS

### Basic Parameters

**Humidity ratio** (alternatively, the moisture content or mixing ratio)  $W$  of a given moist air sample is defined as the ratio of the mass of water vapor to the mass of dry air contained in the sample:

$$W = M_w/M_{da} \quad (7)$$

The humidity ratio  $W$  is equal to the mole fraction ratio  $x_w/x_{da}$  multiplied by the ratio of molecular masses, namely,  $18.01528/28.9645 = 0.62198$ :

$$W = 0.62198x_w/x_{da} \quad (8)$$

**Specific humidity**  $\gamma$  is the ratio of the mass of water vapor to the total mass of the moist air sample:

$$\gamma = M_w/(M_w + M_{da}) \quad (9a)$$

In terms of the humidity ratio,

$$\gamma = W/(1 + W) \quad (9b)$$

**Absolute humidity** (alternatively, water vapor density)  $d_v$  is the ratio of the mass of water vapor to the total volume of the sample:

$$d_v = M_w/V \quad (10)$$

The **density**  $\rho$  of a moist air mixture is the ratio of the total mass to the total volume:

$$\rho = (M_{da} + M_w)/V = (1/\nu)(1 + W) \quad (11)$$

where  $\nu$  is the moist air specific volume,  $\text{m}^3/\text{kg}$  (dry air), as defined by Equation (27).

### Humidity Parameters Involving Saturation

The following definitions of humidity parameters involve the concept of moist air saturation:

**Saturation humidity ratio**  $W_s(t, p)$  is the humidity ratio of moist air saturated with respect to water (or ice) at the same temperature  $t$  and pressure  $p$ .

**Degree of saturation**  $\mu$  is the ratio of the air humidity ratio  $W$  to the humidity ratio  $W_s$  of saturated moist air at the same temperature and pressure:

$$\mu = \frac{W}{W_s} \Big|_{t,p} \quad (12)$$

**Relative humidity**  $\phi$  is the ratio of the mole fraction of water vapor  $x_w$  in a given moist air sample to the mole fraction  $x_{ws}$  in an air sample saturated at the same temperature and pressure:

$$\phi = \frac{x_w}{x_{ws}} \Big|_{t,p} \quad (13)$$

Combining Equations (8), (12), and (13),

$$\mu = \frac{\phi}{1 + (1 - \phi)W_s/0.62198} \quad (14)$$

**Dew-point temperature**  $t_d$  is the temperature of moist air saturated at the same pressure  $p$ , with the same humidity ratio  $W$  as that of the given sample of moist air. It is defined as the solution  $t_d(p, W)$  of the following equation:

$$W_s(p, t_d) = W \quad (15)$$

**Thermodynamic wet-bulb temperature**  $t^*$  is the temperature at which water (liquid or solid), by evaporating into moist air at a given dry-bulb temperature  $t$  and humidity ratio  $W$ , can bring air to saturation adiabatically at the same temperature  $t^*$  while the total pressure  $p$  is maintained constant. This parameter is considered separately in the section on Thermodynamic Wet-Bulb Temperature and Dew-Point Temperature.

## PERFECT GAS RELATIONSHIPS FOR DRY AND MOIST AIR

When moist air is considered a mixture of independent perfect gases (i.e., dry air and water vapor), each is assumed to obey the perfect gas equation of state as follows:

$$\text{Dry air: } p_{da}V = n_{da}RT \quad (16)$$

$$\text{Water vapor: } p_wV = n_wRT \quad (17)$$

where

$p_{da}$  = partial pressure of dry air

$p_w$  = partial pressure of water vapor

$V$  = total mixture volume

$n_{da}$  = number of moles of dry air

$n_w$  = number of moles of water vapor

$R$  = universal gas constant,  $8314.41 \text{ J}/(\text{kg mol} \cdot \text{K})$

$T$  = absolute temperature, K

The mixture also obeys the perfect gas equation:

$$pV = nRT \quad (18)$$

or

$$(p_{da} + p_w)V = (n_{da} + n_w)RT \quad (19)$$

where  $p = p_{da} + p_w$  is the total mixture pressure and  $n = n_{da} + n_w$  is the total number of moles in the mixture. From Equations (16) through (19), the mole fractions of dry air and water vapor are, respectively,

$$x_{da} = p_{da}/(p_{da} + p_w) = p_{da}/p \quad (20)$$

and

$$x_w = p_w/(p_{da} + p_w) = p_w/p \quad (21)$$

From Equations (8), (20), and (21), the **humidity ratio**  $W$  is given by

$$W = 0.62198 \frac{p_w}{p - p_w} \quad (22)$$

The degree of saturation  $\mu$  is, by definition, Equation (12):

$$\mu = \frac{W}{W_s} \Big|_{t,p}$$

where

$$W_s = 0.62198 \frac{p_{ws}}{p - p_{ws}} \quad (23)$$

The term  $p_{ws}$  represents the saturation pressure of water vapor in the absence of air at the given temperature  $t$ . This pressure  $p_{ws}$  is a function only of temperature and differs slightly from the vapor pressure of water in saturated moist air.

The **relative humidity**  $\phi$  is, by definition, Equation (13):

$$\phi = \frac{x_w}{x_{ws}} \Big|_{t,p}$$

Substituting Equation (21) for  $x_w$  and  $x_{ws}$ ,

$$\phi = \frac{p_w}{p_{ws}} \Big|_{t,p} \quad (24)$$

Substituting Equation (21) for  $x_{ws}$  into Equation (14),

$$\phi = \frac{\mu}{1 - (1 - \mu)(p_{ws}/p)} \quad (25)$$

Both  $\phi$  and  $\mu$  are zero for dry air and unity for saturated moist air. At intermediate states their values differ, substantially so at higher temperatures.

The **specific volume**  $v$  of a moist air mixture is expressed in terms of a unit mass of dry air:

$$v = V/M_{da} = V/(28.9645n_{da}) \quad (26)$$

where  $V$  is the total volume of the mixture,  $M_{da}$  is the total mass of dry air, and  $n_{da}$  is the number of moles of dry air. By Equations (16) and (26), with the relation  $p = p_{da} + p_w$

$$v = \frac{RT}{28.9645(p - p_w)} = \frac{R_{da}T}{p - p_w} \quad (27)$$

Using Equation (22),

$$v = \frac{RT(1 + 1.6078W)}{28.964p} = \frac{R_{da}T(1 + 1.6078W)}{p} \quad (28)$$

In Equations (27) and (28),  $v$  is specific volume,  $T$  is absolute temperature,  $p$  is total pressure,  $p_w$  is the partial pressure of water vapor, and  $W$  is the humidity ratio.

In specific units, Equation (28) may be expressed as

$$v = 0.2871(t + 273.15)(1 + 1.6078W)/p$$

where

- $v$  = specific volume, m<sup>3</sup>/kg (dry air)
- $t$  = dry-bulb temperature, °C
- $W$  = humidity ratio, kg (water)/kg (dry air)
- $p$  = total pressure, kPa

The **enthalpy** of a mixture of perfect gases equals the sum of the individual partial enthalpies of the components. Therefore, the specific enthalpy of moist air can be written as follows:

$$h = h_{da} + Wh_g \quad (29)$$

where  $h_{da}$  is the specific enthalpy for dry air in kJ/kg (dry air) and  $h_g$  is the specific enthalpy for saturated water vapor in kJ/kg (water) at the temperature of the mixture. As an approximation,

$$h_{da} \approx 1.006t \quad (30)$$

$$h_g \approx 2501 + 1.805t \quad (31)$$

where  $t$  is the dry-bulb temperature in °C. The moist air specific enthalpy in kJ/kg (dry air) then becomes

$$h = 1.006t + W(2501 + 1.805t) \quad (32)$$

### THERMODYNAMIC WET-BULB TEMPERATURE AND DEW-POINT TEMPERATURE

For any state of moist air, a temperature  $t^*$  exists at which liquid (or solid) water evaporates into the air to bring it to saturation at exactly this same temperature and total pressure (Harrison 1965). During the adiabatic saturation process, the saturated air is expelled at a temperature equal to that of the injected water. In this constant pressure process,

- Humidity ratio is increased from a given initial value  $W$  to the value  $W_s^*$  corresponding to saturation at the temperature  $t^*$
- Enthalpy is increased from a given initial value  $h$  to the value  $h_s^*$  corresponding to saturation at the temperature  $t^*$
- Mass of water added per unit mass of dry air is  $(W_s^* - W)$ , which adds energy to the moist air of amount  $(W_s^* - W)h_w^*$ , where  $h_w^*$  denotes the specific enthalpy in kJ/kg (water) of the water added at the temperature  $t^*$

Therefore, if the process is strictly adiabatic, conservation of enthalpy at constant total pressure requires that

$$h + (W_s^* - W)h_w^* = h_s^* \quad (33)$$

The properties  $W_s^*$ ,  $h_w^*$ , and  $h_s^*$  are functions only of the temperature  $t^*$  for a fixed value of pressure. The value of  $t^*$ , which satisfies Equation (33) for given values of  $h$ ,  $W$ , and  $p$ , is the **thermodynamic wet-bulb temperature**.

The **psychrometer** consists of two thermometers; one thermometer's bulb is covered by a wick that has been thoroughly wetted with water. When the wet bulb is placed in an airstream, water evaporates from the wick, eventually reaching an equilibrium temperature called the **wet-bulb temperature**. This process is not one of adiabatic saturation, which defines the thermodynamic wet-bulb temperature, but one of simultaneous heat and mass transfer from the wet bulb. The fundamental mechanism of this process is described by the Lewis relation [Equation (39) in Chapter 5]. Fortunately, only small corrections must be applied to wet-bulb thermometer readings to obtain the thermodynamic wet-bulb temperature.

As defined, thermodynamic wet-bulb temperature is a unique property of a given moist air sample independent of measurement techniques.

Equation (33) is exact since it defines the thermodynamic wet-bulb temperature  $t^*$ . Substituting the approximate perfect gas relation [Equation (32)] for  $h$ , the corresponding expression for  $h_s^*$ , and the approximate relation

$$h_w^* \approx 4.186t^* \quad (34)$$

into Equation (33), and solving for the humidity ratio,

$$W = \frac{(2501 - 2.381t^*)W_s^* - 1.006(t - t^*)}{2501 + 1.805t - 4.186t^*} \quad (35)$$

where  $t$  and  $t^*$  are in °C.

The **dew-point temperature**  $t_d$  of moist air with humidity ratio  $W$  and pressure  $p$  was defined earlier as the solution  $t_d(p, w)$  of  $W_s(p, t_d)$ . For perfect gases, this reduces to

$$p_{ws}(t_d) = p_w = (pW)/(0.62198 + W) \quad (36)$$

where  $p_w$  is the water vapor partial pressure for the moist air sample and  $p_{ws}(t_d)$  is the saturation vapor pressure at temperature  $t_d$ . The saturation vapor pressure is derived from Table 3 or from Equation

(5) or (6). Alternatively, the dew-point temperature can be calculated directly by one of the following equations (Peppers 1988):

For the dew-point temperature range of 0 to 93°C,

$$t_d = C_{14} + C_{15}\alpha + C_{16}\alpha^2 + C_{17}\alpha^3 + C_{18}(p_w)^{0.1984} \quad (37)$$

For temperatures below 0°C,

$$t_d = 6.09 + 12.608\alpha + 0.4959\alpha^2 \quad (38)$$

where

- $t_d$  = dew-point temperature, °C
- $\alpha = \ln p_w$
- $p_w$  = water vapor partial pressure, kPa
- $C_{14} = 6.54$
- $C_{15} = 14.526$
- $C_{16} = 0.7389$
- $C_{17} = 0.09486$
- $C_{18} = 0.4569$

### NUMERICAL CALCULATION OF MOIST AIR PROPERTIES

The following are outlines, citing equations and tables already presented, for calculating moist air properties using perfect gas relations. These relations are sufficiently accurate for most engineering calculations in air-conditioning practice, and are readily adapted to either hand or computer calculating methods. For more details, refer to Tables 15 through 18 in Chapter 1 of Olivieri (1996). Graphical procedures are discussed in the section on Psychrometric Charts.

#### SITUATION 1.

Given: Dry-bulb temperature  $t$ , Wet-bulb temperature  $t^*$ , Pressure  $p$

To Obtain	Use	Comments
$p_{ws}(t^*)$	Table 3 or Equation (5) or (6)	Sat. press. for temp. $t^*$
$W_s^*$	Equation (23)	Using $p_{ws}(t^*)$
$W$	Equation (35)	
$p_{ws}(t)$	Table 3 or Equation (5) or (6)	Sat. press. for temp. $t$
$W_s$	Equation (23)	Using $p_{ws}(t)$
$\mu$	Equation (12)	Using $W_s$
$\phi$	Equation (25)	Using $p_{ws}(t)$
$v$	Equation (28)	
$h$	Equation (32)	
$p_w$	Equation (36)	
$t_d$	Table 3 with Equation (36), (37), or (38)	

#### SITUATION 2.

Given: Dry-bulb temperature  $t$ , Dew-point temperature  $t_d$ , Pressure  $p$

To Obtain	Use	Comments
$p_w = p_{ws}(t_d)$	Table 3 or Equation (5) or (6)	Sat. press. for temp. $t_d$
$W$	Equation (22)	
$p_{ws}(t)$	Table 3 or Equation (5) or (6)	Sat. press. for temp. $t_d$
$W_s$	Equation (23)	Using $p_{ws}(t)$
$\mu$	Equation (12)	Using $W_s$
$\phi$	Equation (25)	Using $p_{ws}(t)$

#### SITUATION 3.

Given: Dry-bulb temperature  $t$ , Relative humidity  $\phi$ , Pressure  $p$

To Obtain	Use	Comments
$p_{ws}(t)$	Table 3 or Equation (5) or (6)	Sat. press. for temp. $t$
$p_w$	Equation (24)	
$W$	Equation (22)	
$W_s$	Equation (23)	Using $p_{ws}(t)$
$\mu$	Equation (12)	Using $W_s$
$v$	Equation (28)	
$h$	Equation (32)	
$t_d$	Table 3 with Equation (36), (37), or (38)	
$t^*$	Equation (23) and (35) with Table 3 or with Equation (5) or (6)	Requires trial-and-error or numerical solution method

#### Exact Relations for Computing $W_s$ and $\phi$

Corrections that account for (1) the effect of dissolved gases on properties of condensed phase; (2) the effect of pressure on properties of condensed phase; and (3) the effect of intermolecular force on properties of moisture itself, can be applied to Equations (23) and (25):

$$W_s = 0.62198 \frac{f p_{ws}}{p - f p_{ws}} \quad (23a)$$

$$\phi = \frac{\mu}{1 - (1 - \mu)(f p_{ws}/p)} \quad (25a)$$

Table 4 lists  $f$  values for a number of pressure and temperature combinations. Hyland and Wexler (1983a) give additional values.

**Table 4 Values of  $f$  and Estimated Maximum Uncertainties (EMUs)**

$T, K$	0.1 MPa		0.5 MPa		1 MPa	
	$f$	EMU E+04	$f$	EMU E+04	$f$	EMU E+04
173.15	1.0105	134	1.0540	66	1.1130	136
273.15	1.0039	2	1.0177	10	1.0353	19
373.15	1.0039	0.1	1.0180	4	1.0284	11

#### Moist Air Property Tables for Standard Pressure

Table 2 shows values of thermodynamic properties for standard atmospheric pressure at temperatures from -60 to 90°C. The properties of intermediate moist air states can be calculated using the degree of saturation  $\mu$ :

$$\text{Volume} \quad v = v_{da} + \mu v_{as} \quad (39)$$

$$\text{Enthalpy} \quad h = h_{da} + \mu h_{as} \quad (40)$$

$$\text{Entropy} \quad s = s_{da} + \mu s_{as} \quad (41)$$

These equations are accurate to about 70°C. At higher temperatures, the errors can be significant. Hyland and Wexler (1983a) include charts that can be used to estimate errors for  $v$ ,  $h$ , and  $s$  for standard barometric pressure.

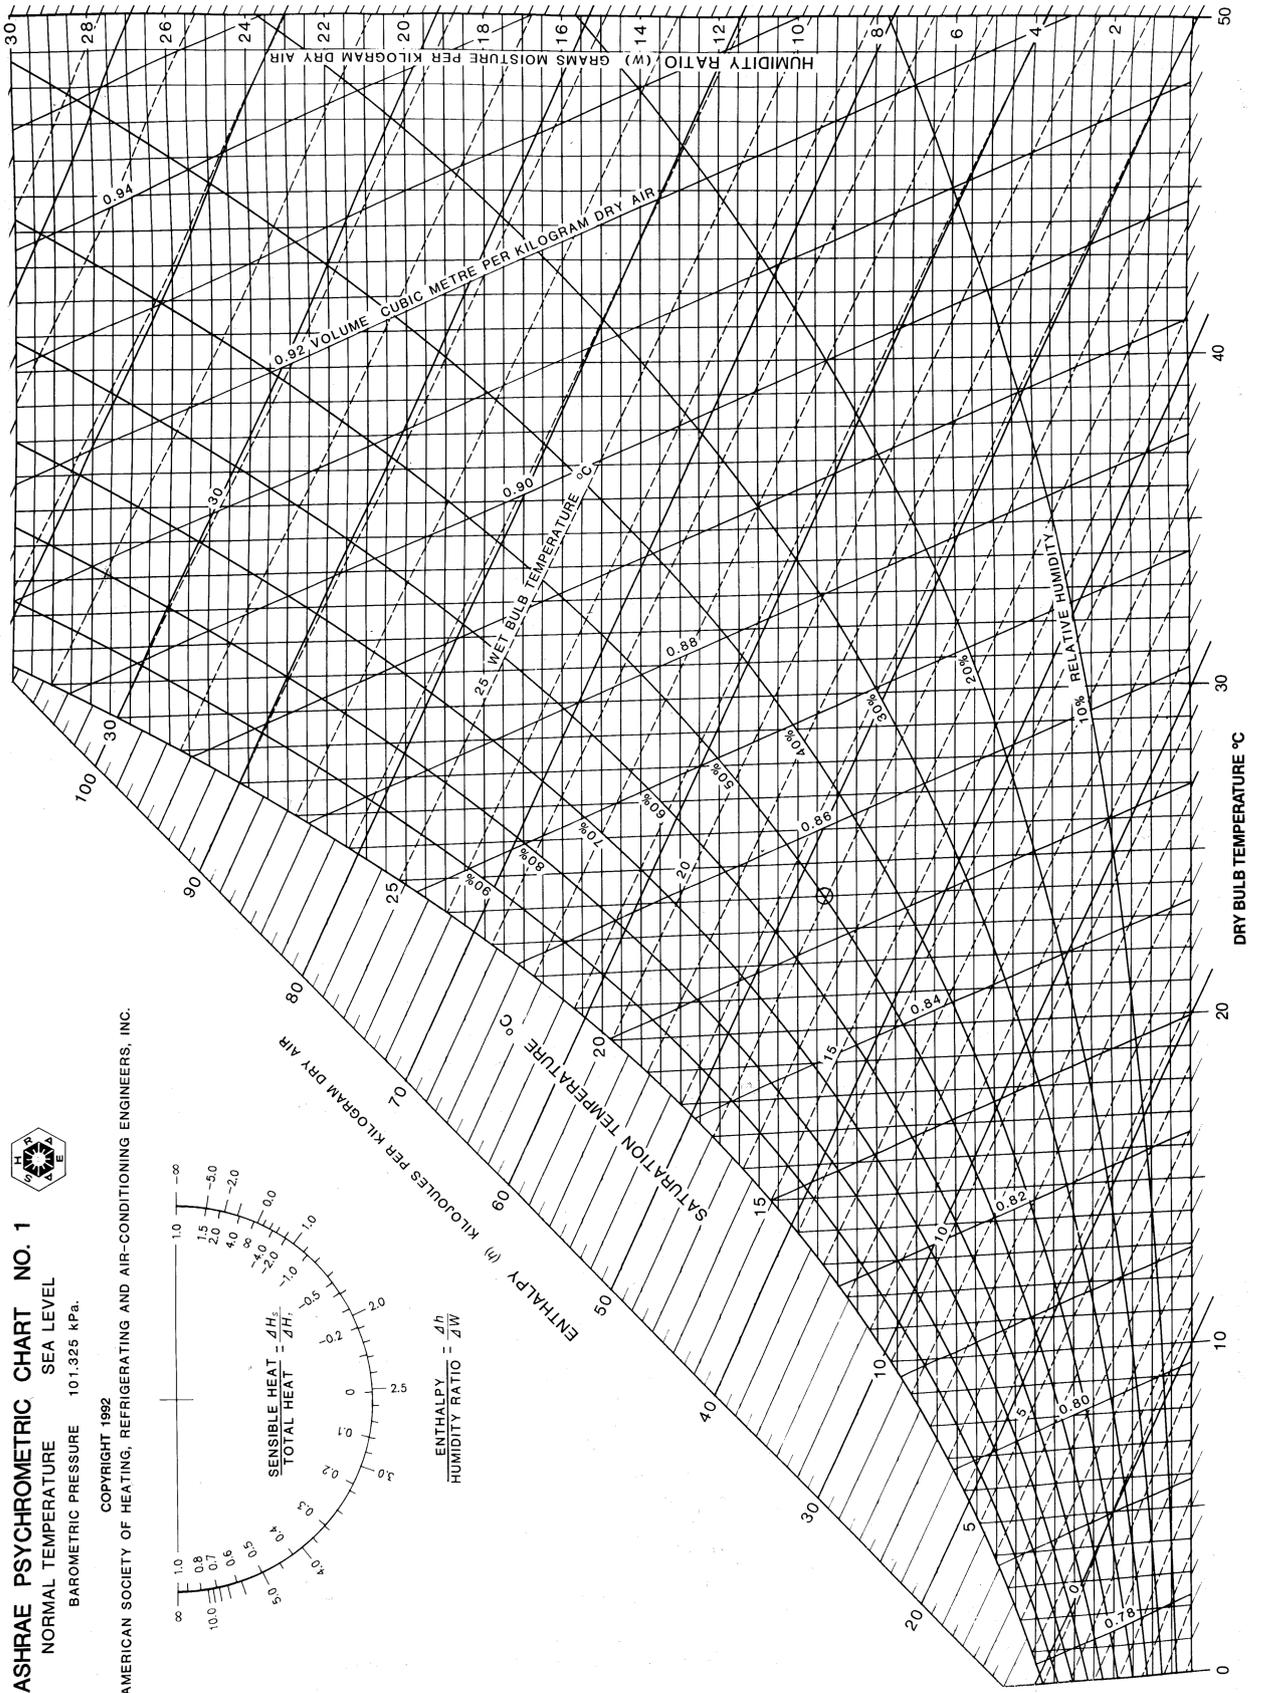

Fig. 1 ASHRAE Psychrometric Chart No. 1

## PSYCHROMETRIC CHARTS

A psychrometric chart graphically represents the thermodynamic properties of moist air.

The choice of coordinates for a psychrometric chart is arbitrary. A chart with coordinates of enthalpy and humidity ratio provides convenient graphical solutions of many moist air problems with a minimum of thermodynamic approximations. ASHRAE developed seven such psychrometric charts. Chart No. 1 is shown as Figure 1; the others may be obtained through ASHRAE.

Charts 1 through 4 are for sea level pressure (101.325 kPa). Chart 5 is for 750 m altitude (92.66 kPa), Chart 6 is for 1500 m altitude (84.54 kPa), and Chart 7 is for 2250 m altitude (77.04 kPa). All charts use oblique-angle coordinates of enthalpy and humidity ratio, and are consistent with the data of Table 2 and the properties computation methods of Goff and Gratch (1945), and Goff (1949) as well as Hyland and Wexler (1983a). Palmatier (1963) describes the geometry of chart construction applying specifically to Charts 1 and 4.

The dry-bulb temperature ranges covered by the charts are

Charts 1, 5, 6, 7	Normal temperature	0 to 50°C
Chart 2	Low temperature	-40 to 10°C
Chart 3	High temperature	10 to 120°C
Chart 4	Very high temperature	100 to 200°C

Psychrometric properties or charts for other barometric pressures can be derived by interpolation. Sufficiently exact values for most purposes can be derived by methods described in the section on Perfect Gas Relationships for Dry and Moist Air. The construction of charts for altitude conditions has been treated by Haines (1961), Rohsenow (1946), and Karig (1946).

Comparison of Charts 1 and 6 by overlay reveals the following:

1. The dry-bulb lines coincide.
2. Wet-bulb lines for a given temperature originate at the intersections of the corresponding dry-bulb line and the two saturation curves, and they have the same slope.
3. Humidity ratio and enthalpy for a given dry- and wet-bulb temperature increase with altitude, but there is little change in relative humidity.
4. Volume changes rapidly; for a given dry-bulb and humidity ratio, it is practically inversely proportional to barometric pressure.

The following table compares properties at sea level (Chart 1) and 1500 m (Chart 6):

Chart No.	db	wb	<i>h</i>	<i>W</i>	rh	<i>v</i>
1	40	30	99.5	23.0	49	0.920
6	40	30	114.1	28.6	50	1.111

Figure 1, which is ASHRAE Psychrometric Chart No. 1, shows humidity ratio lines (horizontal) for the range from 0 (dry air) to 30 g (water)/kg (dry air). Enthalpy lines are oblique lines drawn across the chart precisely parallel to each other.

Dry-bulb temperature lines are drawn straight, not precisely parallel to each other, and inclined slightly from the vertical position. Thermodynamic wet-bulb temperature lines are oblique lines that differ slightly in direction from that of enthalpy lines. They are straight but are not precisely parallel to each other.

Relative humidity lines are shown in intervals of 10%. The saturation curve is the line of 100% rh, while the horizontal line for  $W = 0$  (dry air) is the line for 0% rh.

Specific volume lines are straight but are not precisely parallel to each other.

A narrow region above the saturation curve has been developed for fog conditions of moist air. This two-phase region represents a mechanical mixture of saturated moist air and liquid water, with the two components in thermal equilibrium. Isothermal lines in the fog

region coincide with extensions of thermodynamic wet-bulb temperature lines. If required, the fog region can be further expanded by extension of humidity ratio, enthalpy, and thermodynamic wet-bulb temperature lines.

The protractor to the left of the chart shows two scales—one for sensible-total heat ratio, and one for the ratio of enthalpy difference to humidity ratio difference. The protractor is used to establish the direction of a condition line on the psychrometric chart.

Example 1 illustrates use of the ASHRAE Psychrometric Chart to determine moist air properties.

**Example 1.** Moist air exists at 40°C dry-bulb temperature, 20°C thermodynamic wet-bulb temperature, and 101.325 kPa pressure. Determine the humidity ratio, enthalpy, dew-point temperature, relative humidity, and specific volume.

**Solution:** Locate state point on Chart 1 (Figure 1) at the intersection of 40°C dry-bulb temperature and 20°C thermodynamic wet-bulb temperature lines. Read **humidity ratio**  $W = 6.5$  g (water)/kg (dry air).

The **enthalpy** can be found by using two triangles to draw a line parallel to the nearest enthalpy line [60 kJ/kg (dry air)] through the state point to the nearest edge scale. Read  $h = 56.7$  kJ/kg (dry air).

**Dew-point temperature** can be read at the intersection of  $W = 6.5$  g (water)/kg (dry air) with the saturation curve. Thus,  $t_d = 7^\circ\text{C}$ .

**Relative humidity**  $\phi$  can be estimated directly. Thus,  $\phi = 14\%$ .

**Specific volume** can be found by linear interpolation between the volume lines for 0.88 and 0.90 m<sup>3</sup>/kg (dry air). Thus,  $v = 0.896$  m<sup>3</sup>/kg (dry air).

## TYPICAL AIR-CONDITIONING PROCESSES

The ASHRAE psychrometric chart can be used to solve numerous process problems with moist air. Its use is best explained through illustrative examples. In each of the following examples, the process takes place at a constant total pressure of 101.325 kPa.

### Moist Air Sensible Heating or Cooling

The process of adding heat alone to or removing heat alone from moist air is represented by a horizontal line on the ASHRAE chart, since the humidity ratio remains unchanged.

Figure 2 shows a device that adds heat to a stream of moist air. For steady flow conditions, the required rate of heat addition is

$${}_1q_2 = \dot{m}_{da}(h_2 - h_1) \quad (42)$$

**Example 2.** Moist air, saturated at 2°C, enters a heating coil at a rate of 10 m<sup>3</sup>/s. Air leaves the coil at 40°C. Find the required rate of heat addition.

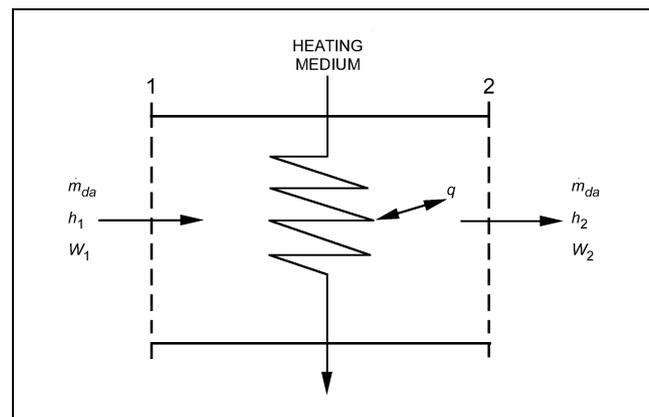

Fig. 2 Schematic of Device for Heating Moist Air

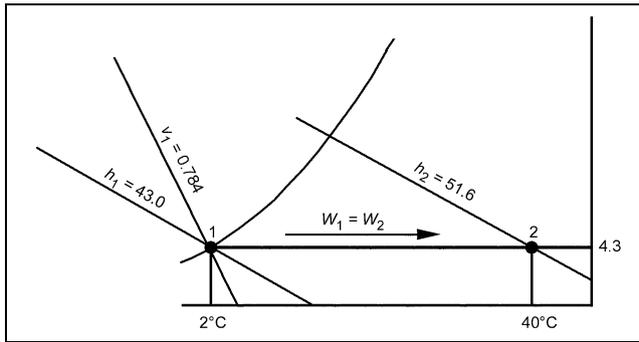

Fig. 3 Schematic Solution for Example 2

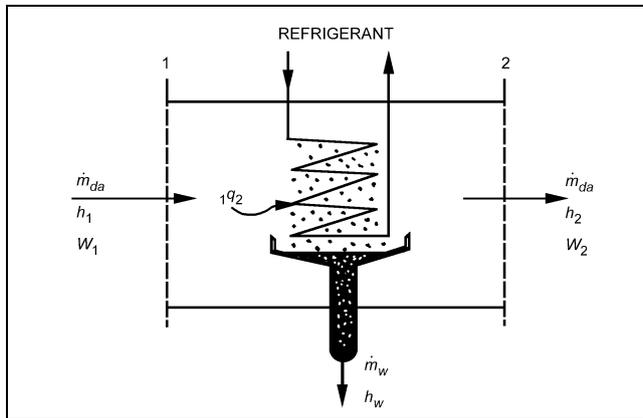

Fig. 4 Schematic of Device for Cooling Moist Air

**Solution:** Figure 3 schematically shows the solution. State 1 is located on the saturation curve at 2°C. Thus,  $h_1 = 13.0$  kJ/kg (dry air),  $W_1 = 4.3$  g (water)/kg (dry air), and  $v_1 = 0.784$  m<sup>3</sup>/kg (dry air). State 2 is located at the intersection of  $t = 40^\circ\text{C}$  and  $W_2 = W_1 = 4.3$  g (water)/kg (dry air). Thus,  $h_2 = 51.6$  kJ/kg (dry air). The mass flow of dry air is

$$\dot{m}_{da} = 10/0.784 = 12.76 \text{ kg/s (dry air)}$$

From Equation (42),

$${}_1q_2 = 12.76(51.6 - 13.0) = 492 \text{ kW}$$

**Moist Air Cooling and Dehumidification**

Moisture condensation occurs when moist air is cooled to a temperature below its initial dew point. Figure 4 shows a schematic cooling coil where moist air is assumed to be uniformly processed. Although water can be removed at various temperatures ranging from the initial dew point to the final saturation temperature, it is assumed that condensed water is cooled to the final air temperature  $t_2$  before it drains from the system.

For the system of Figure 4, the steady flow energy and material balance equations are

$$\dot{m}_{da}h_1 = \dot{m}_{da}h_2 + {}_1q_2 + \dot{m}_wh_w$$

$$\dot{m}_{da}W_1 = \dot{m}_{da}W_2 + \dot{m}_w$$

Thus,

$$\dot{m}_w = \dot{m}_{da}(W_1 - W_2) \tag{43}$$

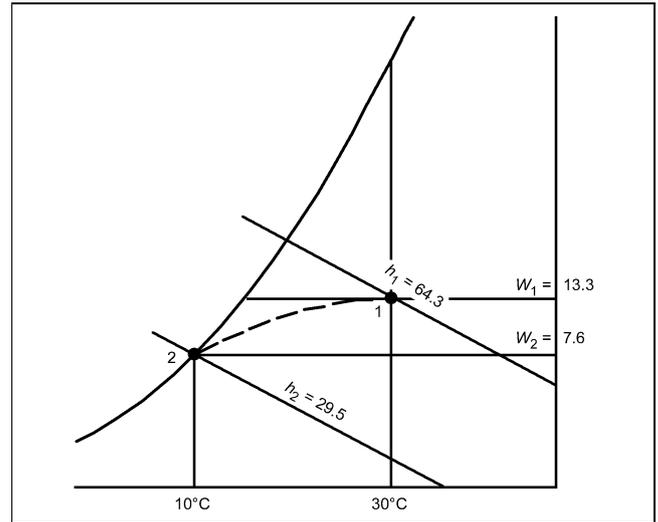

Fig. 5 Schematic Solution for Example 3

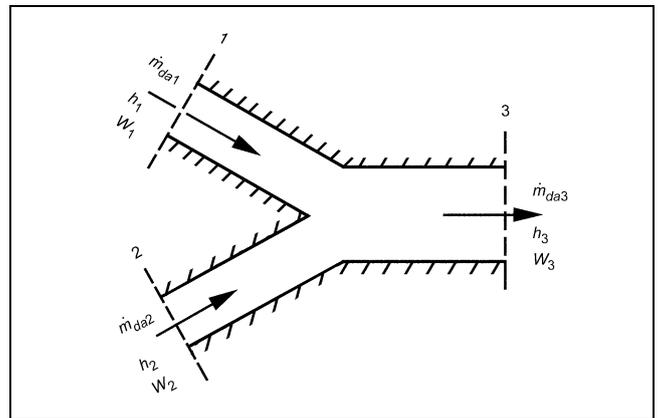

Fig. 6 Adiabatic Mixing of Two Moist Airstreams

$${}_1q_2 = \dot{m}_{da}[(h_1 - h_2) - (W_1 - W_2)h_{w2}] \tag{44}$$

**Example 3.** Moist air at 30°C dry-bulb temperature and 50% rh enters a cooling coil at 5 m<sup>3</sup>/s and is processed to a final saturation condition at 10°C. Find the kW of refrigeration required.

**Solution:** Figure 5 shows the schematic solution. State 1 is located at the intersection of  $t = 30^\circ\text{C}$  and  $\phi = 50\%$ . Thus,  $h_1 = 64.3$  kJ/kg (dry air),  $W_1 = 13.3$  g (water)/kg (dry air), and  $v_1 = 0.877$  m<sup>3</sup>/kg (dry air). State 2 is located on the saturation curve at 10°C. Thus,  $h_2 = 29.5$  kJ/kg (dry air) and  $W_2 = 7.66$  g (water)/kg (dry air). From Table 2,  $h_{w2} = 42.11$  kJ/kg (water). The mass flow of dry air is

$$\dot{m}_{da} = 5/0.877 = 5.70 \text{ kg/s (dry air)}$$

From Equation (44),

$$\begin{aligned} {}_1q_2 &= 5.70[(64.3 - 29.5) - (0.0133 - 0.00766)42.11] \\ &= 197 \text{ kW} \end{aligned}$$

**Adiabatic Mixing of Two Moist Airstreams**

A common process in air-conditioning systems is the adiabatic mixing of two moist airstreams. Figure 6 schematically shows the problem. Adiabatic mixing is governed by three equations:

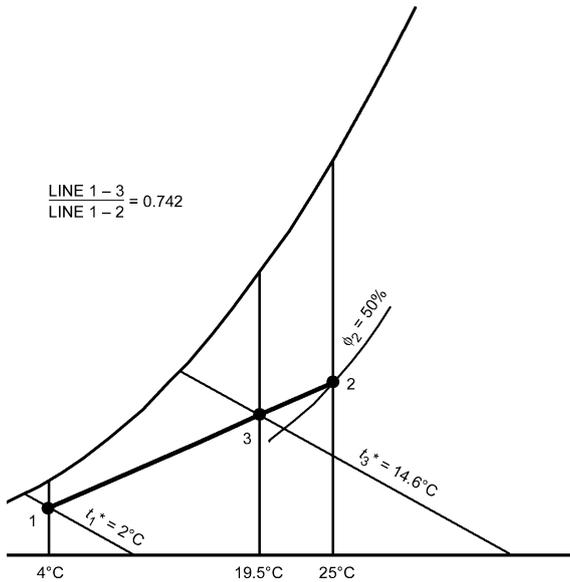

Fig. 7 Schematic Solution for Example 4

$$\begin{aligned} \dot{m}_{da1}h_1 + \dot{m}_{da2}h_2 &= \dot{m}_{da3}h_3 \\ \dot{m}_{da1} + \dot{m}_{da2} &= \dot{m}_{da3} \\ \dot{m}_{da1}W_1 + \dot{m}_{da2}W_2 &= \dot{m}_{da3}W_3 \end{aligned}$$

Eliminating  $\dot{m}_{da3}$  gives

$$\frac{h_2 - h_3}{h_3 - h_1} = \frac{W_2 - W_3}{W_3 - W_1} = \frac{\dot{m}_{da1}}{\dot{m}_{da2}} \quad (45)$$

according to which, on the ASHRAE chart, the state point of the resulting mixture lies on the straight line connecting the state points of the two streams being mixed, and divides the line into two segments, in the same ratio as the masses of dry air in the two streams.

**Example 4.** A stream of 2 m<sup>3</sup>/s of outdoor air at 4°C dry-bulb temperature and 2°C thermodynamic wet-bulb temperature is adiabatically mixed with 6.25 m<sup>3</sup>/s of recirculated air at 25°C dry-bulb temperature and 50% rh. Find the dry-bulb temperature and thermodynamic wet-bulb temperature of the resulting mixture.

**Solution:** Figure 7 shows the schematic solution. States 1 and 2 are located on the ASHRAE chart, revealing that  $v_1 = 0.789$  m<sup>3</sup>/kg (dry air), and  $v_2 = 0.858$  m<sup>3</sup>/kg (dry air). Therefore,

$$\begin{aligned} \dot{m}_{da1} &= 2/0.789 = 2.535 \text{ kg/s (dry air)} \\ \dot{m}_{da2} &= 6.25/0.858 = 7.284 \text{ kg/s (dry air)} \end{aligned}$$

According to Equation (45),

$$\frac{\text{Line } 3-2}{\text{Line } 1-3} = \frac{\dot{m}_{da1}}{\dot{m}_{da2}} \text{ or } \frac{\text{Line } 1-3}{\text{Line } 1-2} = \frac{\dot{m}_{da2}}{\dot{m}_{da3}} = \frac{7.284}{9.819} = 0.742$$

Consequently, the length of line segment 1-3 is 0.742 times the length of entire line 1-2. Using a ruler, State 3 is located, and the values  $t_3 = 19.5^\circ\text{C}$  and  $t_3^* = 14.6^\circ\text{C}$  found.

**Adiabatic Mixing of Water Injected into Moist Air**

Steam or liquid water can be injected into a moist airstream to raise its humidity. Figure 8 represents a diagram of this common air-conditioning process. If the mixing is adiabatic, the following equations apply:

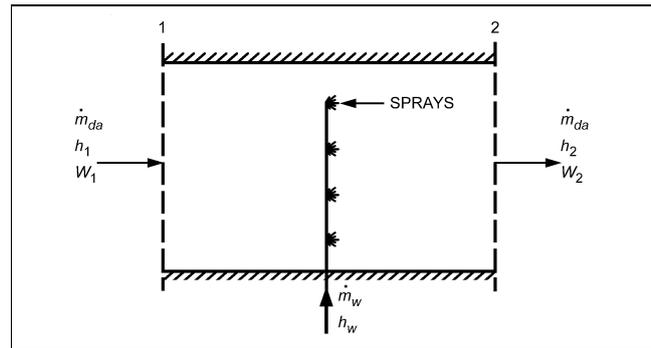

Fig. 8 Schematic Showing Injection of Water into Moist Air

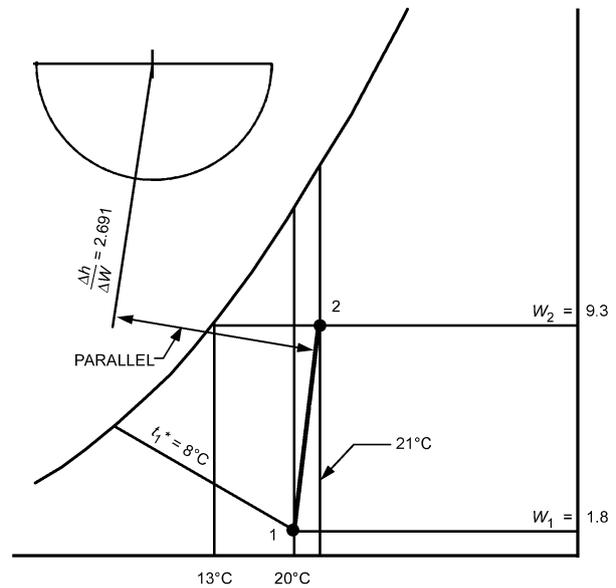

Fig. 9 Schematic Solution for Example 5

$$\begin{aligned} \dot{m}_{da}h_1 + \dot{m}_w h_w &= \dot{m}_{da}h_2 \\ \dot{m}_{da}W_1 + \dot{m}_w &= \dot{m}_{da}W_2 \end{aligned}$$

Therefore,

$$\frac{h_2 - h_1}{W_2 - W_1} = \frac{\Delta h}{\Delta W} = h_w \quad (46)$$

according to which, on the ASHRAE chart, the final state point of the moist air lies on a straight line whose direction is fixed by the specific enthalpy of the injected water, drawn through the initial state point of the moist air.

**Example 5.** Moist air at 20°C dry-bulb and 8°C thermodynamic wet-bulb temperature is to be processed to a final dew-point temperature of 13°C by adiabatic injection of saturated steam at 110°C. The rate of dry air-flow is 2 kg/s (dry air). Find the final dry-bulb temperature of the moist air and the rate of steam flow.

**Solution:** Figure 9 shows the schematic solution. By Table 3, the enthalpy of the steam  $h_g = 2691$  kJ/kg (water). Therefore, according to Equation (46), the condition line on the ASHRAE chart connecting States 1 and 2 must have a direction:

$$\Delta h / \Delta W = 2.691 \text{ kJ/g (water)}$$

The condition line can be drawn with the  $\Delta h/\Delta W$  protractor. First, establish the reference line on the protractor by connecting the origin with the value  $\Delta h/\Delta W = 2.691$  kJ/g (water). Draw a second line parallel to the reference line and through the initial state point of the moist air. This second line is the condition line. State 2 is established at the intersection of the condition line with the horizontal line extended from the saturation curve at 13°C ( $t_{d2} = 13^\circ\text{C}$ ). Thus,  $t_2 = 21^\circ\text{C}$ .

Values of  $W_2$  and  $W_1$  can be read from the chart. The required steam flow is,

$$\begin{aligned} \dot{m}_w &= \dot{m}_{da}(W_2 - W_1) = 2 \times 1000(0.0093 - 0.0018) \\ &= 15.0 \text{ kg/s (steam)} \end{aligned}$$

**Space Heat Absorption and Moist Air Moisture Gains**

Air conditioning a space is usually determined by (1) the quantity of moist air to be supplied, and (2) the supply air condition necessary to remove given amounts of energy and water from the space at the exhaust condition specified.

Figure 10 schematically shows a space with incident rates of energy and moisture gains. The quantity  $q_s$  denotes the net sum of all rates of heat gain in the space, arising from transfers through boundaries and from sources within the space. This heat gain involves addition of energy alone and does not include energy contributions due to addition of water (or water vapor). It is usually called the **sensible heat gain**. The quantity  $\Sigma \dot{m}_w$  denotes the net sum of all rates of moisture gain on the space arising from transfers through boundaries and from sources within the space. Each kilogram of water vapor added to the space adds an amount of energy equal to its specific enthalpy.

Assuming steady-state conditions, governing equations are

$$\begin{aligned} \dot{m}_{da}h_1 + q_s + \Sigma(\dot{m}_wh_w) &= \dot{m}_{da}h_2 \\ \dot{m}_{da}W_1 + \Sigma \dot{m}_w &= \dot{m}_{da}W_2 \end{aligned}$$

or

$$q_s + \Sigma(\dot{m}_wh_w) = \dot{m}_{da}(h_2 - h_1) \tag{47}$$

$$\Sigma \dot{m}_w = \dot{m}_{da}(W_2 - W_1) \tag{48}$$

The left side of Equation (47) represents the total rate of energy addition to the space from all sources. By Equations (47) and (48),

$$\frac{h_2 - h_1}{W_2 - W_1} = \frac{\Delta h}{\Delta W} = \frac{q_s + \Sigma(\dot{m}_wh_w)}{\Sigma \dot{m}_w} \tag{49}$$

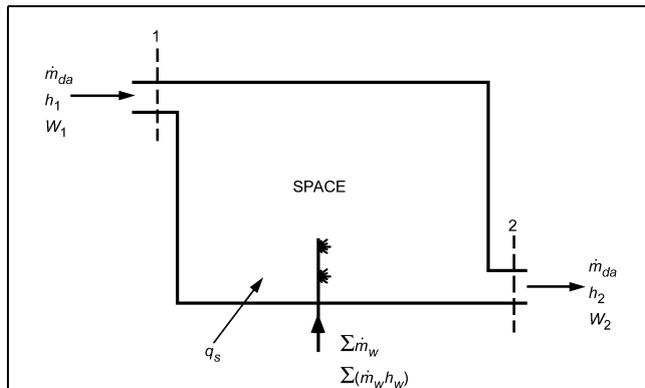

Fig. 10 Schematic of Air Conditioned Space

according to which, on the ASHRAE chart and for a given state of the withdrawn air, all possible states (conditions) for the supply air must lie on a straight line drawn through the state point of the withdrawn air, that has a direction specified by the numerical value of  $[q_s + \Sigma(\dot{m}_wh_w)]/\Sigma \dot{m}_w$ . This line is the condition line for the given problem.

**Example 6.** Moist air is withdrawn from a room at 25°C dry-bulb temperature and 19°C thermodynamic wet-bulb temperature. The sensible rate of heat gain for the space is 9 kW. A rate of moisture gain of 0.0015 kg/s (water) occurs from the space occupants. This moisture is assumed as saturated water vapor at 30°C. Moist air is introduced into the room at a dry-bulb temperature of 15°C. Find the required thermodynamic wet-bulb temperature and volume flow rate of the supply air.

**Solution:** Figure 11 shows the schematic solution. State 2 is located on the ASHRAE chart. From Table 3, the specific enthalpy of the added water vapor is  $h_g = 2555.52$  kJ/kg (water). From Equation (49),

$$\frac{\Delta h}{\Delta W} = \frac{9 + (0.0015 \times 2555.52)}{0.0015} = 8555 \text{ kJ/kg (water)}$$

With the  $\Delta h/\Delta W$  protractor, establish a reference line of direction  $\Delta h/\Delta W = 8.555$  kJ/g (water). Parallel to this reference line, draw a straight line on the chart through State 2. The intersection of this line with the 15°C dry-bulb temperature line is State 1. Thus,  $t_1^* = 13.8^\circ\text{C}$ .

An alternate (and approximately correct) procedure in establishing the condition line is to use the protractor's sensible-total heat ratio scale instead of the  $\Delta h/\Delta W$  scale. The quantity  $\Delta H_s/\Delta H_t$  is the ratio of the rate of sensible heat gain for the space to the rate of total energy gain for the space. Therefore,

$$\frac{\Delta H_s}{\Delta H_t} = \frac{q_s}{q_s + \Sigma(\dot{m}_wh_w)} = \frac{9}{9 + (0.0015 \times 2555.52)} = 0.701$$

Note that  $\Delta H_s/\Delta H_t = 0.701$  on the protractor coincides closely with  $\Delta h/\Delta W = 8.555$  kJ/g (water).

The flow of dry air can be calculated from either Equation (47) or (48). From Equation (47),

$$\begin{aligned} \dot{m}_{da} &= \frac{q_s + \Sigma(\dot{m}_wh_w)}{h_2 - h_1} = \frac{9 + (0.0015 \times 2555.52)}{54.0 - 39.0} \\ &= 0.856 \text{ kg/s (dry air)} \end{aligned}$$

At State 1,  $v_1 = 0.859$  m<sup>3</sup>/kg (dry air)

Therefore, supply volume =  $\dot{m}_{da}v_1 = 0.856 \times 0.859 = 0.735$  m<sup>3</sup>/s

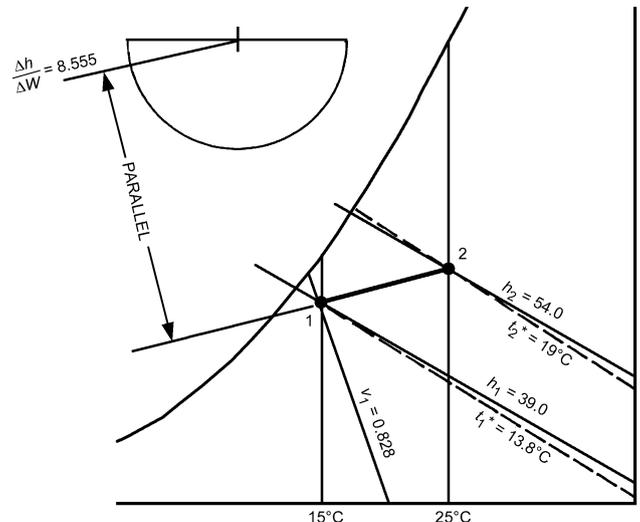

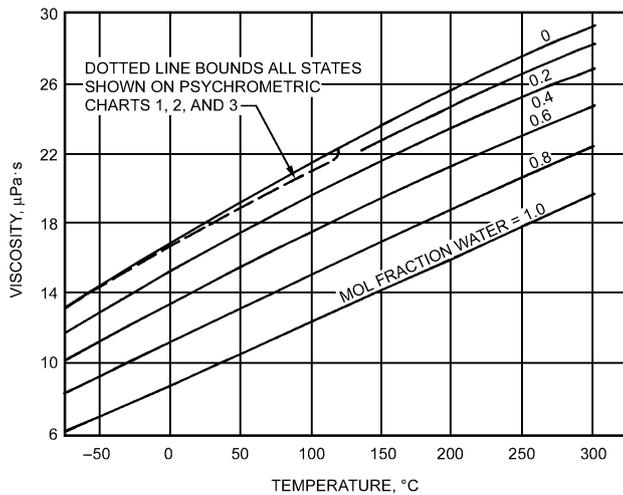

Fig. 11 Schematic Solution for Example 6

### TRANSPORT PROPERTIES OF MOIST AIR

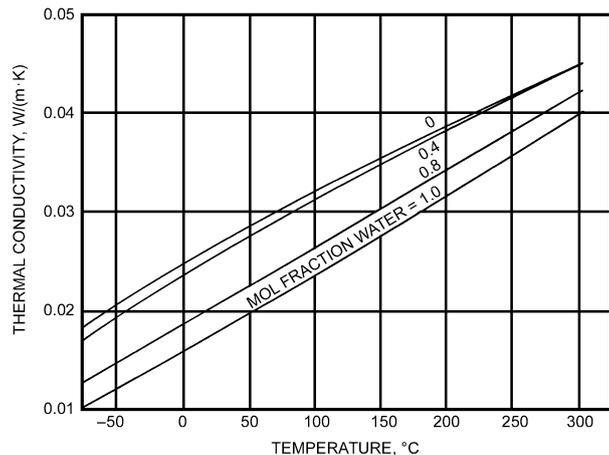

For certain scientific and experimental work, particularly in the heat transfer field, many other moist air properties are important. Generally classified as transport properties, these include diffusion coefficient, viscosity, thermal conductivity, and thermal diffusion factor. Mason and Monchick (1965) derive these properties by calculation. Table 5 and Figures 12 and 13 summarize the authors' results on the first three properties listed. Note that, within the boundaries of ASHRAE Psychrometric Charts 1, 2, and 3, the viscosity varies little from that of dry air at normal atmospheric pres-

**Table 5** Calculated Diffusion Coefficients for Water–Air at 101.325 kPa

Temp., °C	mm <sup>2</sup> /s	Temp., °C	mm <sup>2</sup> /s	Temp., °C	mm <sup>2</sup> /s
-70	13.2	0	22.2	50	29.5
-50	15.6	5	22.9	55	30.3

## SYMBOLS

- $C_1$  to  $C_{18}$  = constants in Equations (5), (6), and (37)  
 $d_v$  = absolute humidity of moist air, mass of water per unit volume of mixture  
 $f$  = enhancement factor, used in Equations (23a) and (25a)  
 $h$  = specific enthalpy of moist air  
 $h_s^*$  = specific enthalpy of saturated moist air at thermodynamic wet-bulb temperature  
 $h_w^*$  = specific enthalpy of condensed water (liquid or solid) at thermodynamic wet-bulb temperature and pressure of 101.325 kPa  
 $H_s$  = rate of sensible heat gain for space  
 $H_t$  = rate of total energy gain for space  
 $\dot{m}_{da}$  = mass flow of dry air, per unit time  
 $\dot{m}_w$  = mass flow of water (any phase), per unit time  
 $M_{da}$  = mass of dry air in moist air sample  
 $M_w$  = mass of water vapor in moist air sample  
 $n = n_{da} + n_w$ , total number of moles in moist air sample  
 $n_{da}$  = moles of dry air  
 $n_w$  = moles of water vapor  
 $p$  = total pressure of moist air  
 $p_{da}$  = partial pressure of dry air  
 $p_s$  = vapor pressure of water in moist air at saturation. Differs from saturation pressure of pure water because of presence of air.  
 $p_w$  = partial pressure of water vapor in moist air  
 $p_{ws}$  = pressure of saturated pure water  
 $q_s$  = rate of addition (or withdrawal) of sensible heat  
 $R$  = universal gas constant, 8314.41 J/(kg mole · K)  
 $R_{da}$  = gas constant for dry air  
 $R_w$  = gas constant for water vapor  
 $s$  = specific entropy  
 $t$  = dry-bulb temperature of moist air  
 $t_d$  = dew-point temperature of moist air  
 $t^*$  = thermodynamic wet-bulb temperature of moist air  
 $T$  = absolute temperature  
 $v$  = specific volume  
 $v_T$  = total gas volume  
 $V$  = total volume of moist air sample  
 $W$  = humidity ratio of moist air, mass of water per unit mass of dry air  
 $W_s^*$  = humidity ratio of moist air at saturation at thermodynamic wet-bulb temperature  
 $x_{da}$  = mole-fraction of dry air, moles of dry air per mole of mixture  
 $x_w$  = mole-fraction of water, moles of water per mole of mixture  
 $x_{ws}$  = mole-fraction of water vapor under saturated conditions, moles of vapor per mole of saturated mixture  
 $Z$  = altitude  
 $\alpha = \ln(p_w)$ , parameter used in Equations (37) and (38)  
 $\gamma$  = specific humidity of moist air, mass of water per unit mass of mixture  
 $\mu$  = degree of saturation  $W/W_s$   
 $\rho$  = moist air density  
 $\phi$  = relative humidity, dimensionless

## Subscripts

- $as$  = difference between saturated moist air and dry air  
 $da$  = dry air  
 $f$  = saturated liquid water  
 $fg$  = difference between saturated liquid water and saturated water vapor  
 $g$  = saturated water vapor  
 $i$  = saturated ice  
 $ig$  = difference between saturated ice and saturated water vapor  
 $s$  = saturated moist air  
 $t$  = total  
 $w$  = water in any phase

<i>Controlling Sound</i> .....	7.7	<i>Vibration Measurement Basics</i> .....	7.17

**I**F FUNDAMENTAL PRINCIPLES of sound and vibration control are applied in the design, installation, and use of HVAC and refrigeration systems, unacceptably high noise and vibration levels and the consequent complaints can be avoided. This chapter introduces these fundamental principles, including characteristics of sound, basic definitions and terminology, human response to sound, acoustical design goals, and vibration isolation fundamentals. Chapter 46 of the 1999 *ASHRAE Handbook—Applications* and the references listed at the end of this chapter contain technical discussions, tables, and design examples helpful to HVAC designers.

### ACOUSTICAL DESIGN OBJECTIVE

The primary objective for the acoustical design of HVAC systems and equipment is to ensure that the acoustical environment in a given space is not degraded. Sound and vibration are created by a **source**, are transmitted along one or more **paths**, and reach a **receiver**. Treatments and modifications can be applied to any or all of these elements to achieve an acceptable acoustical environment, although it is usually most effective and least expensive to reduce noise at the source.

### CHARACTERISTICS OF SOUND

Sound is a propagating disturbance in a fluid (gas or liquid) or in a solid. In fluid media, the disturbance travels as a longitudinal compression wave. Sound in air is called **airborne sound** or simply sound. It is generated by a vibrating surface or a turbulent fluid stream. In solids, sound can travel as bending waves, compressional waves, torsional waves, shear waves and others. Sound in solids is generally called **structureborne sound**. In HVAC system design, **both** airborne and structureborne sound propagation are important.

#### Speed

The speed of a longitudinal wave in a fluid is a function of the fluid's density and bulk modulus of elasticity. In air, at room temperature, the speed of sound is about 340 m/s; in water, it is about 1500 m/s. In solids, there are several different types of waves, each with a different speed and some that depend on frequency. In solids, the speed of sound is usually higher than that in air.

#### Sound Pressure and Sound Pressure Level

Sound waves in air are variations in pressure above and below atmospheric pressure. **Sound pressure** is measured in pascals. The human ear responds across a broad range of sound pressures; the threshold of hearing to the threshold of pain covers a range of approximately  $10^{14}$ :1. Table 1 gives approximate values of sound pressure for various sources.

The preparation of this chapter is assigned to TC 2.6, Sound and Vibration Control.

**Table 1 Typical Sound Pressures and Sound Pressure Levels**

Source	Sound Pressure, Pa	Sound Pressure Level, dB re 20 μPa	Subjective Reaction
Military jet takeoff at 30 m	200	140	Extreme danger
Artillery fire at 3 m	63.2	130	
Passenger jet takeoff at 30 m	20	120	Threshold of pain
Loud rock band	6.3	110	Threshold of discomfort
Platform of subway station (steel wheels)	2	100	
Unmuffled large diesel engine at 40 m	0.6	90	Very loud
Computer printout room	0.2	80	
Freight train at 30 m	0.06	70	
Conversational speech at 1 m	0.02	60	
Window air conditioner at 1 m	0.006	50	Moderate
Quiet residential area	0.002	40	
Whispered conversation at 2 m	0.0006	30	
Buzzing insect at 1 m	0.0002	20	Perceptible
Threshold of good hearing	0.00006	10	Faint
Threshold of excellent youthful hearing	0.00002	0	Threshold of hearing

The range of sound pressure in Table 1 is so large that it is more convenient to use a scale that is proportional to the logarithm of this quantity. The **decibel** (dB) scale is such a scale and is the preferred method of presenting quantities in acoustics. The term **level**, when used in relation to sound power, sound intensity, or sound pressure, indicates that dB notation is being used. Numerically, the decibel is ten times the base 10 logarithm of the ratio of two like quantities proportional to acoustical power or energy. Thus, the **sound pressure level**  $L_p$  (in dB) corresponding to a sound pressure is given by

$$L_p = 10 \log(p/p_{ref})^2 \quad (1)$$

where  $p$  is the root mean square (rms) value of acoustic pressure in pascals. The ratio  $p/p_{ref}$  is squared to give quantities proportional to intensity or energy. The reference quantity  $p_{ref}$  is 20 μPa, which corresponds to the approximate threshold of hearing.

The decibel scale is used for many different descriptors relating to sound: source strength, sound level, and sound attenuation, among others; each has a different reference quantity. For this reason, it is important to be aware of the context in which the term decibel or level is used. For most acoustical quantities, there is an

internationally accepted reference value. A reference quantity is always implied even if it does not appear.

Sound pressure level is relatively easy to measure and for this reason most noise codes and criteria use sound pressure level. (The human ear and microphones are pressure-sensitive devices.) Sound pressure levels for each source are also given in Table 1.

### Frequency

Frequency is the number of oscillations (or cycles) completed per second by a vibrating object. The international unit for frequency is hertz (Hz) with dimension  $s^{-1}$ . When the motion of vibrating air particles is simple harmonic, the sound is said to be a **pure tone** and the sound pressure  $p$  as a function of time and frequency can be described by

$$p(\theta, f) = p_0 \sin 2\pi f \theta \quad (2)$$

where  $f$  is frequency in hertz and  $\theta$  is time in seconds.

The **audible frequency range** for humans extends from about 20 Hz to 20 kHz. In some cases, infrasound (< 20 Hz) or ultrasound (> 20 kHz) are important, but methods and instrumentation for these frequency regions are specialized and are not considered here.

### Wavelength

The wavelength of sound in a medium is the distance between successive maxima or minima of a simple harmonic disturbance propagating in that medium. Wavelength, speed, and frequency are related by

$$\lambda = c/f \quad (3)$$

where

- $\lambda$  = wavelength, m
- $c$  = speed of sound, m/s
- $f$  = frequency, Hz

### Sound Power and Sound Power Level

The **sound power** of a source is its rate of emission of acoustical energy and is expressed in watts. The sound power of a source depends on the operating conditions. Approximate sound power outputs for common sources are shown in Table 2 together with the corresponding sound power levels. For **sound power level**  $L_w$ , the power reference is  $10^{-12}$  W. The definition of sound power level is therefore

$$L_w = 10 \log (w/10^{-12}) \quad (4)$$

where  $w$  is the acoustic power emitted by the source in watts. The acoustic power emitted by a source is not the same as the power consumed by the source. Only a small fraction of the consumed power is converted into sound. For example, a loudspeaker rated at 100 W may be only 1% to 5% efficient, generating only 1 to 5 W (acoustic).

Most mechanical equipment is rated according to sound power so equipment can be compared according to a common reference independent of distance and acoustical conditions in the room. AMCA *Publication* 303 provides guidelines for the application of sound power level ratings. In addition, AMCA *Standard* 301 provides standard methods for developing fan sound ratings from laboratory test data.

### Sound Intensity and Sound Intensity Level

The **sound intensity**  $I$  at a point in a specified direction is the rate of flow of sound energy through unit area at that point. The unit area is perpendicular to the specified direction, and the units

**Table 2 Typical Sound Power Outputs and Sound Power Levels**

Source	Sound Power, W	Sound Power Level, dB re $10^{-12}$ W
Saturn rocket	$10^8$	200
Turbojet engine <sup>a</sup>	$10^5$	170

<sup>c</sup> Four propeller engines

of intensity are  $W/m^2$ . **Sound intensity level**  $L_I$  is expressed in dB with a reference quantity of  $10^{-12}$   $W/m^2$ , thus

$$L_I = \log (I/10^{-12})$$

### Combining Sound Levels

Because the decibel is a logarithmic unit, two sound pressure levels cannot be added arithmetically. The levels must first be converted back to energy units, summed, and then converted to a level again. Thus, the combination of two levels,  $L_1$  and  $L_2$ , produces a level  $L_{sum}$  given by

$$L_{sum} = 10 \log (10^{L_1/10} + 10^{L_2/10}) \quad (5)$$

This process may be extended to as many levels as needed. A simpler and slightly less accurate method is outlined in Table 3. This method, although not exact, results in errors of 1 dB or less. The process with a series of levels may be shortened by combining the largest with the next largest. Then this sum is combined with the third largest, then the fourth largest, and so on until the next level added has little or no influence. The process may then be stopped.

The procedures outlined in Table 3 and in Equation (5) are valid if the individual sound levels are not highly correlated. This is true for most (but not all) sounds encountered in HVAC work. One notable exception is the pure tone. If two or more noise signals contain pure tones at the same frequency, the combined sound level is a function of not only the level of each tone, but also the phase difference between the tones. The combined sound levels from two tones of equal amplitude can range from zero (if the two tones are  $180^\circ$  out of phase) up to 6 dB greater than the level of either tone (if the two tones are exactly in phase). When two tones of similar amplitude are very close in frequency, but not exactly the same, the combined sound level oscillates as the tones move in and out of phase. This effect creates an audible "beating" with a period equal to the inverse of the difference in frequency between the two tones.

**Table 3 Combining Two Sound Levels**

Difference between two levels and to be combined, dB	10 and			
	0 to 1	2 to 4	5 to 9	More
Number of decibels to be added to highest level to obtain combined level	3	2	1	0

MEASURING SOUND

Instrumentation

The basic instrument for measuring sound is a **sound level meter**, which includes a microphone, electronic circuitry, and a display device. Sound pressure at a point is converted to sound pressure level and displayed by analog or digital meters. These devices are usually light, battery-operated, hand-held units with outputs that vary in complexity depending on cost and the level of current technology.

Time-Averaging

No sounds are constant; the pressure fluctuates from moment to moment and the level can vary quickly or slowly. Sound level meters can show the time fluctuations of the sound pressure level using specified time constants (slow, fast, impulse), or can hold the maximum or minimum level recorded during some specified interval. All sound level meters perform some kind of **time-averaging**. Some **integrating sound level meters** take an average of the sound pressure level over a user-definable time, then hold and display the result. As a result, an integrating meter is easier to read and more repeatable (especially if the measurement period is long). The quantity measured by the integrating sound level meter is the **equivalent continuous sound pressure level  $L_{eq}$** .

Spectra and Analysis Bandwidths

Real sounds are much more complex than simple pure tones. **Broadband sound** contains energy at many frequencies, usually covering most of the audible frequency range. All sounds, however, can be represented as a summation of pure tones with different amplitudes. This representation of a sound is called **frequency or spectral analysis** and is similar to spectral analysis in optics.

A **constant-bandwidth analysis** expresses the energy content of a sound as a spectrum where each data point represents the same spectral width, for example, 1 Hz. This kind of analysis is useful when an objectionable sound obviously contains strong tones and the frequencies need to be accurately identified before remedial action is taken. A constant-band spectrum usually contains too much information for typical noise control work.

Measurements for most HVAC noise control work are usually made with filters that extract the energy in either **octave bands** or **one-third octave bands**. An octave band is a frequency band with its upper frequency limit twice that of its lower frequency limit. Octave and 1/3 octave bands are identified by the mid-band frequency, which is the geometric mean of the upper and lower band limits (ANSI Standards S1.6, S1.11). Three 1/3 octave bands make up an octave band. Table 4 lists the preferred series of octave and one-third octave bands and the upper and lower band limit frequencies. For HVAC sound measurements, filters for the range of 16 Hz to 8000 Hz are usually adequate.

While analysis in octave bands is usually acceptable for rating acoustical environments in rooms, 1/3 octave band analysis is often useful in product development and for remedial investigations.

Some sound level meters have octave or 1/3 octave filters for determining the frequency content of the sound. Usually, standard broadband filters that simulate the response of the average human ear to sound are provided. The most commonly used filter is the **A-weighting** filter (Figure 1). This filter simulates the response of the human ear. It de-emphasizes the low-frequency portions of a sound spectrum, automatically compensating for the lower sensitivity of the human ear to low-frequency sound.

The **C-weighting** filter is sometimes used to estimate whether a particular sound has excessive low-frequency energy present when a spectrum analyzer is not available. If the difference between the C- and A-weighted levels for the sound exceeds about 30 dB, then the sound is likely to be annoying because of excessive

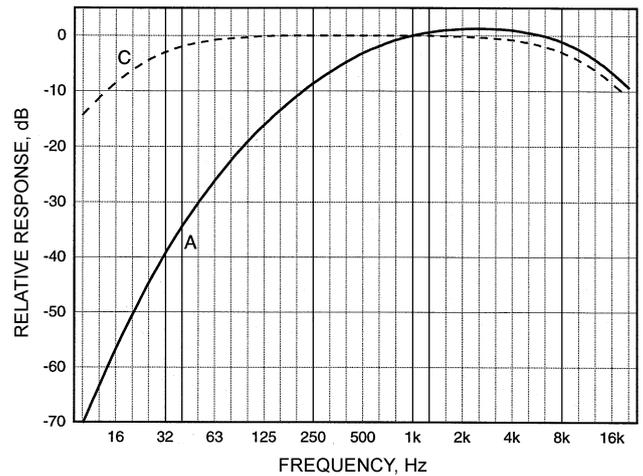

Fig. 1 Curves Showing A- and C-Weighting Responses for Sound Level Meters

Table 4 Mid-Band and Approximate Upper and Lower Cutoff Frequencies for Octave and 1/3 Octave Band Filters

Octave Bands, Hz			1/3 Octave Bands, Hz

			14 000	16 000	18 000
			18 000	20 000	22 400

low-frequency noise. Note (in Figure 1) that the C-weighting curve attenuates significantly at low and high frequencies; the instrument response is not flat when this filter is used.

Sound level meters are available in several accuracy grades (ANSI Standard S1.4). A Type 1 meter has a tolerance of about ±0.7 dB. The general-purpose meter, which is less expensive, is designated Type 2 with a tolerance of about ±1 dB, and is adequate for most HVAC sound measurements.

**Table 5 Combining Decibels to Determine Overall Sound Pressure Level**

Octave Band Frequency, Hz	Octave Band Level $L_p$ , dB	$10^{L_p/10}$	
63	85	$3.2 \times 10^8$	$= 0.32 \times 10^9$
125	90	$1.0 \times 10^9$	$= 1.0 \times 10^9$
250	92	$1.6 \times 10^9$	$= 1.6 \times 10^9$
500	87	$5.0 \times 10^8$	$= 0.5 \times 10^9$
1000	82	$1.6 \times 10^8$	$= 0.16 \times 10^9$
2000	78	$6.3 \times 10^7$	$= 0.06 \times 10^9$
4000	65	$3.2 \times 10^6$	$= 0.003 \times 10^9$
8000	54	$2.5 \times 10^5$	$= 0.0002 \times 10^9$
		$3.6432 \times 10^9$	
$10 \log (3.6 \times 10^9) = 96 \text{ dB}$			

**Table 6 Guidelines for Determining Equipment Sound Levels in the Presence of Contaminating Background Sound**

Measurement A minus Measurement B	Correction to Measurement A to Obtain Equipment Sound Level
10 dB or more	0 dB
6 to 9 dB	-1 dB
4 to 5 dB	-2 dB
Less than 4 dB	Equipment sound level is more than 2 dB below Measurement A

Measurement A = Tested equipment plus background sound  
Measurement B = Background sound alone

Manually selecting filters sequentially to cover the frequency range from 16 Hz to 8000 Hz is time-consuming. An instrument that gives all filtered levels simultaneously is called a **real-time analyzer** (RTA). It speeds up measurement significantly and, on most models, the information can be saved to an internal or external digital storage device.

The process described in the previous section on Combining Sound Levels can be applied to a set of octave or 1/3 octave bands to calculate the overall broadband level (see Table 5 for an example).

### Sound Measurement Basics

The sound pressure level in an occupied space can be measured directly with a sound level meter, or estimated from published sound power data after accounting for room volume, distance from the source, and other acoustical factors. Sound level meters measure the sound pressure at the microphone location. Estimation techniques calculate sound pressure at a specified point in an occupied space. Measured or estimated sound pressure levels in frequency bands can then be plotted, analyzed, and compared with established criteria for acceptance.

Measurements of HVAC sound must be done carefully to ensure repeatable and accurate results. The sound levels may not be steady, particularly at low frequencies (250 Hz and lower) and can vary significantly with time. In such cases, both the peak and average levels should be recorded.

Sophisticated sound measurements and their procedures should be carried out by experienced sound professionals. At present, only a few noise standards apply to measuring the interior noise from mechanical equipment (ASTM *Standard E 1574*, ASTM *Standard E 1573*). Most manuals for sound level meters include sections on how to measure sound.

Determining the sound spectrum in a room or investigating a noise complaint usually requires measuring the sound pressure levels in the octave bands from 16 Hz to 8000 Hz. In cases of tonal noise or rumble, narrow bands or 1/3 octave bands should be measured because their frequency resolution is higher. Whatever the measurement method, the sound pressure level is measured at a point. In a room, each measurement point often has a different

sound pressure level, so the precise location of the measurement must be detailed in the report. One might survey the room and record the location and level of the loudest position. Also, one could establish a few representative locations where occupants are normally situated. In general, the most appropriate height is 1.2 to 1.8 m above the floor. The exact geometric center of the room should be avoided, as should any location within 1 m of a wall.

Wherever the location, it must be defined and recorded. If the meter has an integrating-averaging function, one can use a rotating boom to sample a large area or walk slowly around the room to measure the average sound pressure level over that path. However, care must be taken that no extraneous sounds are generated by microphone movement or by walking. Also, locations where the sound levels are notably higher than average should be recorded. The section on Measurement of Room Sound Pressure Level has more details.

The contribution of other sources (plumbing noise, business machines, nearby traffic, etc.) to the sound pressure levels must also be determined. Sound from sources other than the source to be measured is designated background sound.

Sometimes the sound from a particular piece of HVAC equipment must be measured in the presence of background sound from other sources that cannot be turned off, such as automobile traffic or certain business machines. Two sets of measurements are required to determine the sound level due to selected equipment: one set with both the HVAC equipment sound and the background sound and another set with only the background sound (the HVAC equipment is turned off). This situation might also occur, for example, when determining whether the noise exposure at the property line due to a cooling tower meets a local noise ordinance. The guidelines in Table 6 will help in determining the sound level of a particular machine in the presence of background sound.

The uncertainty associated with correcting for background sound depends on the uncertainty of the measuring instrument and the steadiness of the sounds being measured. In favorable circumstances, it might be possible to extend Table 6. In particularly unfavorable circumstances, even values obtained from the table could be substantially in error.

Measuring sound emissions from a particular piece of equipment or group of equipment requires a measurement plan specific to the situation. The section on Standards lists several sound level measurement procedures for various laboratory and field sound measurement situations.

Outdoor measurements are somewhat easier to make than indoor because typically there are few or no boundary surfaces to affect sound build-up or absorption. Nevertheless, important issues such as the effect of large, nearby sound-reflecting surfaces and weather conditions such as wind, temperature, and precipitation must be considered. (In cases where measurements are made close to extended surfaces, sound pressure levels can be significantly increased.) These effects can be estimated through guidelines in many sources such as Harris (1991).

### Measurement of Room Sound Pressure Level

In the commissioning of HVAC systems in buildings, it often must be demonstrated that a specified room noise criterion has been met. Measurement procedures for obtaining the data to demonstrate compliance are often not specified. This can lead to confusion when different parties make measurements using different procedures, as the results often do not agree. The problem is that most rooms exhibit significant point-to-point variation in sound pressure level.

When a noise has no audible tonal components, the differences in measured sound pressure level at several locations in a room may be as high as 3 to 5 dB. However, when audible tonal components are present, especially at low frequencies, the variations due to standing waves may exceed 10 dB. These variations are generally noticeable to the average listener when moving through the room.

Although the commissioning procedures usually set precise limits for demonstrating compliance, the outcome can be controversial unless the measurement procedure has been specified in detail. At present, the industry has no general agreement regarding an acoustical measurement procedure for commissioning HVAC systems. However, ARI *Standard* 885 incorporates a “suggested procedure for field verification of NC/RC levels.”

## DETERMINING SOUND POWER

No instrument can measure the sound power of a source directly. Rather, sound power is calculated from several measurements of sound pressure or sound intensity created by a source in one of several test environments. The following four methods are commonly used.

### 1. Free-Field Method

A **free field** is a sound field where the effects of any boundaries are negligible over the frequency range of interest. In ideal conditions, there are no boundaries. Free-field conditions can be approximated in rooms having highly sound-absorbing walls, floor, and ceiling (**anechoic rooms**). In a free field the sound power of a sound source can be determined from a number of measurements of sound pressure level on an imaginary spherical surface centered on and surrounding the source. This method is based on the fact that, because absorption of sound in air can be practically neglected at small distances from the sound source, the sound power generated by a source must flow through an imagined sphere with the source at its center. The intensity of the sound is determined at each of the measuring points around the source and multiplied by the area of the imagined sphere associated with the measuring points. Total sound power is the sum of these products for each point.

ANSI *Standard* S12.35 describes various methods used to calculate the sound power level under free-field conditions. Measurement accuracy is limited at the lower frequencies because room surface treatments do not have high sound absorption coefficients at low frequencies. For example, a glass fiber wedge structure that gives significant absorption at 70 Hz must be at least 1.2 m long.

Using values for the speed of sound for air at 20°C and 100 kPa, the relationship between sound power level and sound pressure level for a nondirectional sound source is

$$L_w = L_p + 20 \log r + 11 \quad (6)$$

where

$$\begin{aligned} L_w &= \text{sound power level, dB re } 10^{-12} \text{ W} \\ L_p &= \text{sound pressure level dB re } 20 \text{ } \mu\text{Pa} \\ r &= \text{distance from nondirectional sound source, m} \end{aligned}$$

**Free-Field Over Reflecting Plane.** In many cases, a completely free field is not available, and measurements can only be made in a free field over a reflecting plane. That is, the sound source is placed on a hard floor (in an otherwise sound-absorbing room) or on pavement outdoors. Since the sound is then radiated into a hemisphere rather than a full sphere, the relationship for  $L_w$  and  $L_p$  for a nondirectional sound source becomes

$$L_w = L_p + 20 \log r + 8 \quad (7)$$

**Source Directivity.** A sound source may radiate different amounts of sound power in different directions because various areas of its surface do not vibrate at the same level or in phase. A directivity pattern can be established by measuring sound pressure under free-field conditions, either in an anechoic room or over a reflecting plane in a hemi-anechoic space at several points around the source. The **directivity factor**  $Q$  is defined as the ratio of sound pressure at a given angle from the sound source to the sound pressure that would be produced by the same source radiating uniformly

in all directions.  $Q$  is a function of both frequency and direction. Chapter 46 of the 1999 *ASHRAE Handbook—Applications* provides more detailed information on sound source directivity.

### 2. Reverberation Room Method

Another method to determine sound power places the sound source in a reverberation room. Standardized methods for determining the sound power of HVAC equipment in reverberation rooms are given in ANSI *Standard* S12.31, when the sound source contains mostly broadband sound; ANSI *Standard* S12.32, when tonal sound is prominent; and AMCA *Standard* 300 for testing fans.

Sound sources that can be measured by these methods include room air conditioners, refrigeration compressors, components of central HVAC systems, and air terminal devices. AMCA *Standard* 300, ASHRAE *Standard* 130, and ARI *Standard* 880 establish special measuring procedures for some of these units. Large equipment that can operate on a large paved area, such as a parking lot, can also be measured under free-field conditions above a reflecting plane. Determining the sound power of large equipment outdoors is difficult; however, data may be available from some manufacturers.

A **diffuse field** is a sound field in which the sound intensity is the same in all directions and at every point. The **reverberant field** in a reverberation room, because of its sound reflecting walls, floor, and ceiling, provides an approximation to a diffuse field.

**Direct Method.** With the source in a reverberation room, the sound pressure level is measured at some minimum distance from the source and the surfaces of the room. The sound power level is calculated from the sound pressure level, if the rate of decay of sound (in dB/s) and the volume of the reverberation room are known.

Using the direct method, the relationship between sound power level and sound pressure level in a reverberation room is given by

$$L_w = L_p + 10 \log V + 10 \log D - 31.8 \quad (\text{direct method}) \quad (8)$$

where

$$\begin{aligned} L_p &= \text{sound pressure level averaged over room, dB re } 20 \text{ } \mu\text{Pa} \\ V &= \text{volume of room, m}^3 \\ D &= \text{decay rate, dB/s} = 60/\theta \\ \theta &= \text{room reverberation time (time required for a 60 dB decay), s} \end{aligned}$$

**Substitution Method.** Most test standards use a calibrated **reference sound source** (RSS) to determine the sound power level of a device under test, such as a fan. The most common reference sound source is a small, direct-drive fan impeller that has no volute housing or scroll. The impeller is a forward-curved design, and a choke plate is installed on the inlet face of the impeller. The choke plate causes the fan to operate in a rotating-stall condition that is very noisy. The reference source is designed to have a stable sound power level output from 63 Hz to 8000 Hz and a relatively uniform frequency spectrum in each octave band.

To determine the sound power level of a given source, sound pressure level measurements are first made near the location of the given source with the reference sound source operating in the test room. Then the reference source is turned off and the measurements are repeated with the given source in operation. The differences in measured sound pressure levels between the reference source and unknown source represent differences in sound power level between the two. This procedure for sound power level determination is known as the **substitution method**.

Using this method, the relationship between sound power level and sound pressure level for the two sources is given by:

$$L_w = L_p + (L_w - L_p)_{ref} \quad (\text{substitution method}) \quad (9)$$

where

$$\begin{aligned} L_p &= \text{sound pressure level averaged over room, dB re } 20 \text{ } \mu\text{Pa} \\ (L_w - L_p)_{ref} &= \text{difference between sound power level and sound pressure level of reference sound source} \end{aligned}$$

### 3. Progressive Wave Method

By attaching a fan to one end of a duct, the sound energy is confined to a progressive wave field in the duct. Fan sound power can then be determined by measuring the sound pressure level inside the duct. The method is described in ASHRAE *Standard* 68 (AMCA *Standard* 330). This method is not commonly used because of difficulties in constructing the required duct termination.

### 4. Sound Intensity Method

Advances in acoustical instrumentation now permit the direct determination of sound intensity, defined as the sound power per unit area flowing through a small element of a surface surrounding a source. The average sound power radiated by the source can be determined by measuring the sound intensity over the sphere or hemisphere surrounding a sound source. One of the advantages of this method is that, with certain limitations, sound intensity (and, therefore, sound power) measurements can be made in the presence of steady background sound in ordinary rooms, thereby eliminating the need for a special testing environment. Another advantage is that by measuring sound intensity over restricted areas around a sound source, sound directivity can be determined. This procedure can be particularly useful in reducing noise of products during their development.

International and United States standards that prescribe methods for making sound power measurements with sound intensity probes have been issued (ISO *Standard* 9614-1, ISO *Standard* 9614-2, ANSI *Standard* S12.12). In some situations, the sound fields may be so complex that measurements become impractical. A particular concern is that small test rooms or those having somewhat flexible boundaries (sheet metal or thin drywall) can permit a reactive sound field to exist, one in which the room's acoustical characteristics cause it to affect the sound power output of the source.

### Measurement Bandwidths for Sound Power

Sound power is normally determined in octave or 1/3 octave bands. Occasionally, a more detailed determination of the sound source spectrum is required. In these cases, narrow band analysis, using either constant fractional bandwidth (1/12 or 1/24 octave) or constant absolute bandwidth (e.g., 1 Hz) can be applied. The digital filter analyzer is most frequently used for constant percent bandwidth measurements, and the fast Fourier transform (FFT) analyzer is used for constant bandwidth measurements. Narrow band analysis results are used to determine the exact frequencies of pure tones and their harmonics in a sound spectrum.

## CONVERTING FROM SOUND POWER TO SOUND PRESSURE

The designer is often required to use the sound power level information on a source to predict the sound pressure level at a given location. The sound pressure level at a given location in a room due to a source of known sound power level depends on: (1) room volume, (2) room furnishings and surface treatments, (3) magnitude of the sound source(s), and (4) distance from the sound source(s) to the point of observation.

The classic relationship between source sound power level and room sound pressure level at some frequency is

$$L_p = L_w + 10 \log \left( \frac{Q}{4\pi r^2} + \frac{4}{R} \right) + 0.5 \quad (10)$$

where

- $L_p$  = sound pressure level, dB re 20  $\mu$ Pa
- $L_w$  = sound power level, dB re  $10^{-12}$  W
- $Q$  = directivity of the sound source (dimensionless)
- $r$  = distance from the source, m
- $R$  = room constant,  $S\bar{\alpha}/(1 - \bar{\alpha})$
- $S$  = sum of all surface areas,  $m^2$

$\bar{\alpha}$  = average absorption coefficient of room surfaces at given frequency

If the source is outside, far from reflecting surfaces, this relationship simplifies to

$$L_p = L_w + 10 \log (Q/4\pi r^2) + 0.5 \quad (11)$$

This relationship does not account for atmospheric absorption, weather effects and barriers. Note that the  $r^2$  term is present because the sound pressure in a free field decreases as  $1/r^2$  (the **inverse-square law**). Each time the distance from the source is doubled, the sound pressure level decreases by 6 dB.

For a simple source centered in a large, flat, reflecting surface,  $Q$  may be taken as 2. At the junction of two large flat surfaces,  $Q$  is 4, and in a corner,  $Q$  is 8.

In most typical rooms, the presence of acoustically absorbent surfaces and sound-scattering elements, such as furniture, creates a relationship between sound power and sound pressure level that is almost independent of the absorptive properties of the space. For example, hospital rooms, which have only a small amount of absorption, and executive offices, which have substantial absorption, are similar when the comparison is based on the same room volume and distance between the source and point of observation.

Equation (12) can be used to estimate the sound pressure level at a chosen observation point in a normally furnished room. The estimate is accurate to  $\pm 2$  dB (Schultz 1985).

$$L_p = L_w - 5 \log V - 3 \log f - 10 \log r + 12 \quad (12)$$

where

- $L_p$  = room sound pressure level at chosen reference point, dB re 20  $\mu$ Pa
- $L_w$  = source sound power level, dB re  $10^{-12}$  W
- $V$  = room volume,  $m^3$
- $f$  = octave band center frequency, Hz
- $r$  = distance from source to observation point, m

Equation (12) applies to a single sound source in the room itself, not to sources above the ceiling. With more than one source, total sound pressure level at the observation point is obtained by adding the contribution from each source in energy or power-like units, not decibels, and then converting back to sound pressure level. Warnock (1998b), reporting on ASHRAE *Research Project* 755, indicated that sound sources above ceilings may not act as point sources, and Equation (12) may not apply. Chapter 46 of the 1999 ASHRAE *Handbook—Applications* provides more information on this topic.

## SOUND TRANSMISSION PATHS

Sound from a source is transmitted along one or more paths to a receiver. Airborne and structureborne transmission paths are of principal concern for the HVAC system designer. Sound transmission between rooms occurs along both airborne and structureborne transmission paths. Chapter 46 of the 1999 ASHRAE *Handbook—Applications* has additional information on transmission paths.

### Airborne Transmission

**Atmospheric transmission.** Sound transmits readily through air, both indoors and outdoors. Indoor sound transmission paths include the direct, line-of-sight path between the source and the receiver, as well as reflected paths introduced by the presence of a room's walls, floor, ceiling and furnishings, which cause multiple sound reflection paths.

Outdoors, the effects of the reflections are small, if the source is not located near large reflecting surfaces. However, sound outdoors can refract and change propagation direction, due to the presence of wind and temperature gradient effects. Sound propagation outdoors

follows the inverse square law. Therefore, Equations (6) and (7) can generally be used to calculate the relationship between sound power level and sound pressure level for fully free-field and hemispherical free-field conditions, respectively.

**Ductborne transmission.** Ductwork can provide an effective sound transmission path because the sound is primarily contained within the boundaries of the ductwork. Sound can transmit both upstream and downstream from the source. A special case of ductborne transmission is **crosstalk**, where sound is transmitted from one room to another via the duct path.

**Room-to-room transmission.** Room-to-room sound transmission generally involves both airborne and structureborne sound paths. The sound power incident on a room surface element undergoes three processes: (1) some of the sound energy is reflected from the surface element back into the room; (2) a portion of the sound energy is lost due to energy transfer into the material comprising the element, and (3) the remainder of the sound energy is transmitted through the element to the other room. Airborne sound is radiated as the element vibrates and structureborne sound can be transmitted via the studs of a partition or the floor and ceiling surfaces.

### Structureborne Transmission

Solid structures are efficient transmission paths for sound, which frequently originates as a vibration imposed on the transmitting structure. Typically, only a small amount of the input energy is radiated by the structure as airborne sound. A light structure with little inherent damping radiates more sound than a massive structure with greater damping.

### Flanking Transmission

Sound from the source room can bypass the primary separating element and get into the receiving room along other paths called **flanking paths**. Common sound flanking paths include return air plenums, doors, and windows. Less obvious paths are those along floor and adjoining wall structures. Such flanking paths can seriously reduce the sound isolation between rooms. Flanking can explain poor sound isolation between spaces when the partition between spaces is known to provide very good sound insulation. Flanking can also explain sounds being heard in one room at a great distance from another room. Determining whether flanking sound transmission is important and what paths are involved can be difficult. Experience with actual situations and the theoretical aspects of flanking transmission is helpful. Sound intensity methods may be useful in determining flanking paths.

## TYPICAL SOURCES OF SOUND

Whenever mechanical power is generated or transmitted, a fraction of the power is converted into sound power and is radiated into the air. Therefore, virtually any major component of an HVAC system could be considered a sound source (e.g., fans, pumps, ductwork, piping, motors, etc.). The component's sound source characteristics depend upon its construction, its form of mechanical power and its integration with associated system components. The most important sound source characteristics include total sound power output, frequency distribution, and radiation directivity. All of these characteristics vary with frequency.

Sound sources in HVAC systems are so numerous that it is impractical to provide a complete listing here. Typical sources of sound and vibration in HVAC systems include

- Rotating and reciprocating equipment such as fans, motors, pumps, and chillers.
- Air and fluid sounds, such as those associated with flow through ductwork, piping systems, grilles, diffusers, terminal boxes, manifolds, and pressure-reducing stations.

- Excitation of surfaces—for example, friction; movement of mechanical linkages; turbulent flow impacts on ducts, plenum panels, and pipes; and impacts within equipment, such as cams and valve slap.
- Magnetostriction (transformer hum), which becomes significant in motor laminations, transformers, switchgear, lighting ballasts, and dimmers. A characteristic of magnetostrictive oscillations is that their fundamental frequency is twice the line frequency (120 Hz in a 60 Hz system.)

## CONTROLLING SOUND

### Terminology

The following noninterchangeable terms are used to describe the acoustical performance of many system components. ASTM *Standard C 634* defines additional terms.

**Sound attenuation** is a general term describing the reduction of the level of sound as it travels from a source to a receiver.

**Insertion loss (IL)** of a silencer or other sound-attenuating element is expressed in dB and is defined as the decrease in sound pressure level or sound intensity level, measured at a fixed receiver location, when the sound-attenuating element is inserted into the path between the source and the receiver. For example, if a straight, unlined piece of ductwork were replaced with a duct silencer, the sound level difference at a fixed location would be considered the silencer's insertion loss. Measurements are typically made in either octave or 1/3 octave bands.

**Sound transmission loss (TL)** of a partition or other building element is equal to 10 times the logarithm (base 10) of the ratio of the airborne sound power incident on the partition to the sound power transmitted by the partition and radiated on the other side. The quantity so obtained is expressed in decibels. Measurements are typically made in octave or 1/3 octave bands. Chapter 46 of the 1999 ASHRAE *Handbook—Applications* defines the special case of breakout transmission loss through duct walls.

**Noise reduction (NR)** is the difference between the average sound pressure levels produced in two enclosed spaces or rooms—a receiving room and a source room—by one or more sound sources in the source room. An alternate, non-ASTM definition of NR is the difference in sound pressure levels measured upstream and downstream of a duct silencer or sound-attenuating element. Measurements are typically made in octave or 1/3 octave bands.

**Random incidence sound absorption coefficient  $\alpha$**  is the fraction of the incident sound energy that is absorbed by a surface exposed to randomly incident sound. It is measured in a reverberation room using 1/3 octave bands of broadband sound (ASTM C 423). The sound absorption coefficient of a material in a specific 1/3 octave band depends on the material's thickness, airflow resistivity, stiffness, and method of attachment to the supporting structure.

**Spherical spreading** is the process by which sound level decreases with distance from a point source. It occurs when the sound source is located in free space or an anechoic room. Sound propagation in an anechoic space follows the *inverse square law*—6 dB level reduction per doubling of distance from a reference position.

**Scattering** is the change in direction of sound propagation due to an obstacle or inhomogeneity in the transmission medium. It results in the incident sound energy being dispersed in many directions.

### Enclosures and Barriers

Enclosing a sound source is a common means of controlling airborne sound transmission. This may be done using single- or double-leaf partitions.

The term **single-leaf partition** refers to all types of solid homogeneous panels where both faces are rigidly connected. Examples are gypsum board, plywood, concrete block, brick, and poured

concrete. The transmission loss of a single-leaf partition depends mainly on its surface mass (mass per unit area) because the heavier the partition, the less it vibrates in response to sound waves and the less sound it radiates on the side opposite the sound source. Increased surface mass can be achieved either by an increase in the partition's thickness or its density.

The **mass law** is a semi-empirical expression that may be used to predict transmission loss for randomly incident sound for thin, homogeneous single-leaf panels. It is written as

$$TL = 20 \log (w_s f) - 42 \quad (13)$$

where

$$w_s = \text{surface mass of panel, kg/m}^2$$

$$f = \text{frequency, Hz}$$

The mass law predicts that transmission loss increases by 6 dB for each doubling of surface mass or frequency. If sound is incident only perpendicularly on the panel, the TL is about 5 dB greater than that predicted by the mass law.

Transmission loss also depends on material properties, such as stiffness and internal damping. The transmission losses of three single-leaf walls are illustrated in Figure 2. For the 16 mm gypsum board, TL depends mainly on the surface mass of the wall at frequencies below about 1 kHz; agreement with the mass law is good. At higher frequencies, there is a dip in the TL curve, called the **coincidence dip** because it occurs at the frequency where the wavelength of flexural vibrations in the wall coincides with the wavelength of sound in the air. The frequency where the minimum value of TL occurs in the coincidence dip is called the **critical frequency**, which depends on material stiffness and thickness. The stiffer or thicker the layer of material, the lower the critical frequency. For example, the 150 mm concrete slab has a surface mass of about 370 kg/m<sup>2</sup> and a coincidence frequency at 125 Hz. Thus, over most of the frequency range shown in Figure 2, the transmission loss for the 150 mm concrete slab is well below that predicted by mass law. The coincidence dip for the 25 gage (0.531 mm thick) steel sheet occurs at high frequencies not shown in the figure.

The **sound transmission class (STC) rating** of a partition or assembly is a single number rating often used in architecture to classify sound isolation for speech. (ASTM E 90, ASTM E 413) Because the STC rating system was developed to deal with sound sources in the speech frequency range (125 to 4000 Hz), the rating should not be used as an indicator of an assembly's ability to control sound of any source that is rich in low frequencies. Most fan sound spectra have dominant low-frequency sound; therefore, to control fan sound, walls and slabs should be selected only on the basis of 1/3

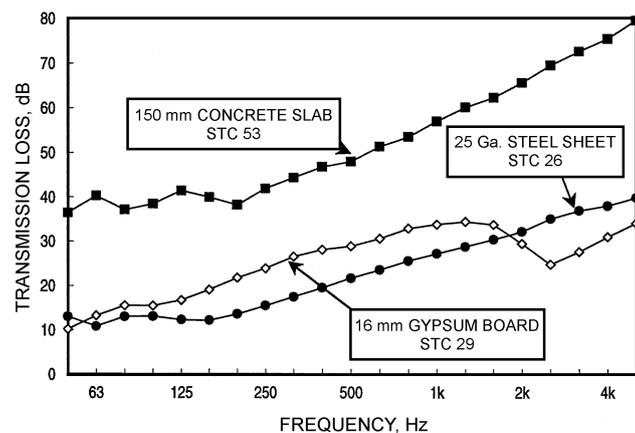

Fig. 2 Sound Transmission Loss Spectra for Single Layers of Some Common Materials

octave or octave band sound transmission loss values, particularly at low frequencies.

Sound transmission loss values for ceiling tile are also inappropriate for estimating the reduction of sound between a sound source located in a ceiling plenum and the room below. *ARI Standard 885* has guidance on this topic.

Walls with identical STC ratings may not provide identical sound insulation at all frequencies. Because of the limited frequency range of most single number rating systems, designers should select partitions and floors on the basis of their 1/3 octave or octave band sound transmission loss values rather than single number ratings, especially when frequencies below 125 Hz are important.

For a given total mass in a wall or floor, much higher values of TL can be obtained by forming a double-leaf construction where each layer is independently or resiliently supported so vibration transmission between them is minimized. As well as mass, TL for such walls depends on cavity depth. Adding sound-absorbing material in the cavity significantly increases the TL relative to the unfilled cavity case. For further information on such walls, see Chapter 46 of the 1999 ASHRAE *Handbook—Applications*.

If the sound fields in the rooms on each side of a panel are diffuse and the panel is the only significant path for sound between the rooms, the noise reduction NR is a function of the panel area  $S_p$  and the total sound absorption  $A_r$  in the receiving space, according to

$$NR = TL - 10 \log (S_p/A_r) \quad (14)$$

Because the total sound absorption in a room is expressed as the equivalent area of perfect sound absorption, both  $S_p$  and  $A_r$  are expressed in consistent units, usually square metres.

The sound reduction of an enclosure may be severely compromised by openings or leaks in the enclosure. Ducts that lead into or through a noisy space can carry sound to many areas of a building. Designers need to consider this factor when designing duct, piping, and electrical systems.

### Attenuation of Sound in Ducts and Plenums

Most ductwork, even a sheet metal duct without acoustical lining or silencers, attenuates sound to some degree. The natural attenuation of unlined ductwork is minimal, but can, especially for long runs of rectangular ductwork, significantly reduce ductborne sound. Acoustic lining of ductwork can greatly attenuate the propagation of sound through ducts, particularly at mid to high frequencies. Chapter 46 of the 1999 ASHRAE *Handbook—Applications* has a detailed discussion of lined and unlined ductwork attenuation.

If analysis shows that lined ductwork will not reduce sound propagation adequately, commercially available sound attenuators (also known as sound traps or duct silencers) can be used. There are three types: dissipative, reactive, and active. The first two are commonly known as **passive attenuators**.

- **Dissipative silencers** use absorptive media such as glass or rock fiber as the principal sound-absorption mechanism. Thick, perforated sheet metal baffles filled with low-density fiber insulation restrict the air passage width within the attenuator housing. The fiber is sometimes protected from the airstream by cloths or films. This type of attenuator is most effective in reducing mid- and high-frequency sound energy.
- **Reactive silencers** do not use any absorptive media to dissipate sound. This attenuator is typically used in HVAC systems serving hospitals, laboratories, or other areas with strict air quality standards. They are constructed only of metal, both solid and perforated. Chambers of specially designed shapes and sizes behind the perforated metal are tuned as resonators or expansion chambers to react with and reduce the sound power at selected frequencies. When designed for a broad frequency range, they are usually not as effective as dissipative attenuators and so are longer and

have a greater pressure drop. However, they can be highly effective and compact if designed for a limited frequency range such as for a pure tone.

- **Active silencer** systems use microphones, loudspeakers, and appropriate electronics to reduce in-duct sound by generating inverse-phase sound waves that destructively interfere with the incident sound energy. Microphones sample the sound field in the duct and loudspeakers generate signals with the opposite phase to the noise. Controlled laboratory experiments have shown that active attenuators reduce both broadband and tonal sound, but they are typically only effective in the 31.5 Hz through 250 Hz octave bands. Insertion losses of as much as 30 dB have been achieved under controlled conditions. The microphones and loudspeakers create a negligible pressure drop because they are mounted flush with the duct wall. Because active attenuators are not effective in the presence of excessively turbulent airflow, their use is limited to relatively long, straight duct sections with an air velocity less than about 7.5 m/s.

Silencers are available for fans, cooling towers, air-cooled condensers, compressors, gas turbines, and many other pieces of commercial and industrial equipment. Silencers are normally installed on the intake or the discharge side (or both) of a fan or air handling unit. Also, they may be used on the receiver side of other noise generators such as terminal boxes, valves, and dampers.

Self-noise can limit an attenuator's effective insertion loss for air velocities in excess of about 10 m/s. Use extreme caution when reviewing manufacturers' performance data for attenuators and duct liner materials to be sure that the test conditions are comparable to the specific design conditions. Short sections (1 to 1.5 m) of insulated flexible duct are often very effective as attenuators. (ARI *Standard* 885 and Chapter 46 of the 1999 *ASHRAE Handbook—Applications* have information on typical flexible duct attenuation factors).

**End Reflections.** End reflection losses due to abrupt area changes in duct cross-section are sometimes useful in controlling low frequencies. The end reflection effect can be maximized at the end of a duct run by designing the last metre or so of duct with the characteristic dimension of less than 400 mm. Low-frequency noise reduction is inversely proportional to the characteristic dimension of the duct. However, abrupt area changes can generate high frequency noise, especially at high flow rates.

**Lined Plenums.** Where space is available, a lined plenum can provide excellent attenuation across a broad frequency range. The combination of end reflection at the plenum's entrance and exit, a large distance between the entrance and exit, and sound-absorbing lining on the plenum walls can be as effective as a sound attenuator, but with less pressure drop.

Chapter 46 of the 1999 *ASHRAE Handbook—Applications* has additional information on the control of sound.

### Standards for Testing Duct Silencers

Attenuators and duct liner materials are tested according to ASTM *Standard* E 477 in North America and ISO 7235 elsewhere. These define acoustical and aerodynamic performance in terms of insertion loss, self-generated noise (or self-noise), and airflow pressure drop. While many similarities exist, the ASTM and ISO standards produce differing results because of variations in loudspeaker location, orientation, duct termination conditions, and computation methods. Currently, no standard test methods are available to measure the attenuation of active silencers, although it is easy to measure in the field simply by turning the system on and off.

Insertion loss is measured in the presence of both forward and reverse flows. Forward flow occurs when the air and sound move in the same direction, as in a supply air or fan discharge system; reverse flow occurs when the air and sound travel in opposite directions, as in the case of a return air or fan intake system.

## SYSTEM EFFECTS

The way the HVAC components are assembled into a **system** affects the sound level generated by the system. Many engineers believe that satisfactory noise levels in occupied spaces can be achieved solely by using a manufacturer's sound ratings as a design tool, without consideration of the system influence.

Sound data provided by most manufacturers is obtained under standard laboratory test conditions. If the equipment is installed in a manner that differs from the test configuration, different configurations of connected ductwork, and interactions with other components of the installation, often significantly increase the operating noise level. For example, aerodynamically clean fan inlet and outlet conditions are rarely found in typical field applications. Furthermore, components such as silencers are frequently installed too close to the fan to allow a uniform velocity profile to exist at the entrance to the silencer. This results in a significantly higher than anticipated pressure drop across that component. The combination of these two effects changes the operating point on the fan curve. As a result, airflow is reduced and must be compensated for by increasing the fan speed, which may increase noise.

## HUMAN RESPONSE TO SOUND

### Noise

Noise may be defined as any unwanted sound. Sound becomes noise when

- It is too loud—the sound is uncomfortable or makes speech difficult to understand
- It is unexpected (e.g., the sound of breaking glass)
- It is uncontrolled (e.g., a neighbor's lawn mower)
- it happens at the wrong time (e.g., a door slamming in the middle of the night)
- It contains pure tones (e.g., a whine, whistle, or hum)
- It contains unwanted information or is distracting (e.g., an adjacent telephone conversation or undesirable music)
- It is unpleasant (e.g., a dripping faucet)
- It connotes unpleasant experiences (e.g., a mosquito buzz or a siren wail)
- It is any combination of the above examples

To be noise, sound does not have to be loud, just unwanted. In addition to being annoying, loud noise can cause hearing loss, and, depending on other factors, it could affect stress level, sleep patterns and heart rate.

To increase privacy, broadband sound may be radiated into a room from a well-designed air-conditioning system to mask or hide low-level intrusive sounds from adjacent spaces. This controlled sound may be referred to as noise, but not in the context of unwanted sound; rather, it is a broadband, neutral sound that is frequently unobtrusive. Three types of broadband noise are frequently encountered in acoustics:

- **Random noise** is an oscillation, the instantaneous magnitude of which is not specified for any given instant. The instantaneous magnitudes of a random noise are specified only by probability distributions, giving the fraction of the total time that the magnitude, or some sequence of magnitudes, lies within a specified range (ANSI *Standard* S1.1).
- **White noise** is noise with a continuous frequency spectrum with equal energy per hertz over a specified frequency range. White noise is not necessarily random. Since octave bands double in width for each successive band, for white noise the energy also doubles in each successive octave band. Thus white noise displayed on a 1/3 octave or octave band chart increases by 3 dB per octave.
- **Pink noise** is noise with a continuous frequency spectrum but equal energy per constant-percentage bandwidth, such as per

octave or 1/3 octave band. Thus pink noise appears on a one-third octave or octave band chart as a horizontal line.

**Predicting Human Response to Sound**

Predicting the response of people to any given sound is, at best, only a statistical concept, and, at worst, very inaccurate. This is because response to sound is not only physiological but psychological and depends on the varying attitude of the listener. Hence, the effect of sound is often unpredictable. However, people’s response is adverse if the sound is considered too loud for the situation or if it sounds “wrong.” Therefore, most criteria are based on descriptors that account for level and spectrum shape.

**Sound Quality**

To determine the acoustic acceptability of a space to occupants, the sound pressure levels there must be known. This, however, is often not sufficient; the **sound quality** is important too. Factors influencing sound quality include (1) loudness, (2) tone perception, (3) frequency spectrum, (4) harshness, (5) time and frequency fluctuation, and (6) vibration.

People often perceive sounds with tones (like a whine or hum) as particularly annoying. A tone can cause a relatively low level sound to be perceived as noise. Studies have been done to characterize sounds with and without pure tones.

**Loudness**

The primary method used to determine a subjective estimate of loudness is to present sounds to a sample of human listeners under controlled conditions. To determine the loudness of a sound, listeners compare an unknown sound with a standard sound. (The accepted standard sound is a pure tone of 1000 Hz or a narrow band of random noise centered on 1000 Hz.) Loudness level is expressed in **phons**, and the loudness level of any sound in phons is equal to the sound pressure level in decibels of a standard sound deemed to be equally loud. Thus, a sound that is judged as loud as a 40 dB, 1000 Hz tone has a loudness level of 40 phons.

Average reactions of humans to tones are shown in Figure 3 (Robinson and Dadson 1956). The reaction changes when the sound is a band of random noise (Pollack 1952), rather than a pure tone (Figure 4). The figures indicate that people are most sensitive in the mid-frequency range. The contours in Figure 3 are closer together at low frequencies showing that at lower frequencies, although people are less sensitive to sound level, they are more sensitive to changes in level.

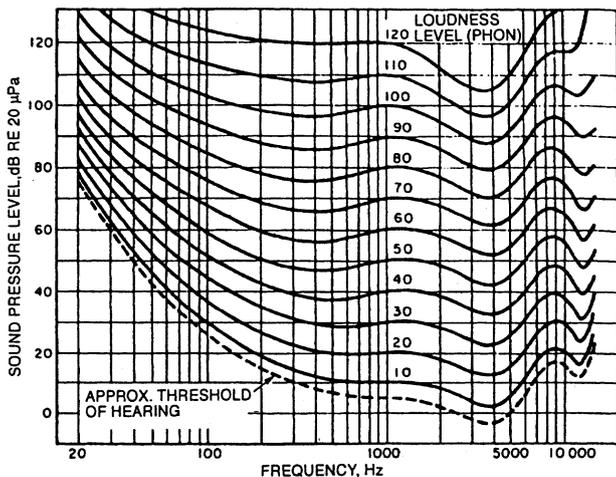

Fig. 3 Free-Field Equal Loudness Contours for Pure Tones

**Table 7 Subjective Effect of Changes in Sound Pressure Level, Broadband Sounds (Frequency > 250 Hz)**

Subjective Change	Objective Change in Sound Level (Approximate)
Much louder	More than +10 dB
Twice as loud	+10 dB
Louder	+5 dB
Just perceptibly louder	+3 dB
Just perceptibly quieter	-3 dB
Quieter	-5 dB
Half as loud	-10 dB
Much quieter	Less than -10 dB

Under carefully controlled experimental conditions, humans can detect small changes in sound level. However, for humans to describe a sound as being half or twice as loud requires changes in overall sound pressure level of about 10 dB. For many people, a 3 dB change is the minimum perceptible difference. This means that halving the power output of the source causes a barely noticeable change in sound pressure level, and the power output must be reduced by a factor of 10 before humans determine that loudness has been halved. Table 7 summarizes the effect of changes in sound levels for simple sounds in the frequency range of 250 Hz and higher.

The phon scale covers the large dynamic range of the ear, but it does not fit a subjective linear loudness scale. Over most of the audible range, a doubling of loudness corresponds to a change of approximately 10 phons. To obtain a quantity proportional to the loudness sensation, a loudness scale is defined in which the unit of loudness is known as a **sone**. One sone equals the loudness level of 40 phons. A rating of two sones corresponds to 50 phons and so on.

The results of such work have led to the development of standard objective methods for calculating loudness. ANSI *Standard S3.4* calculates loudness or loudness level by using octave-band sound pressure level data as a starting point. The loudness index for each octave band is obtained from a graph or by calculation. Total loudness is then calculated by combining the loudnesses for each band according to a formula given in the standard. A more complex calculation method using 1/3 octave band sound pressure levels by Zwicker (ISO *Standard 532*) or the German *Standard DIN 45631* is

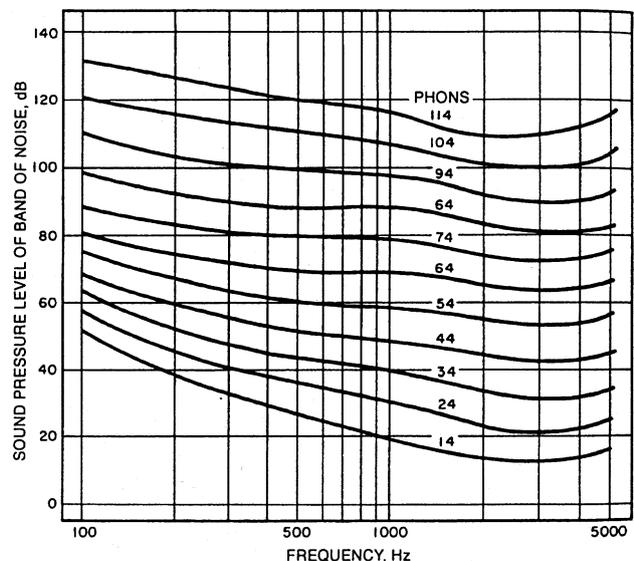

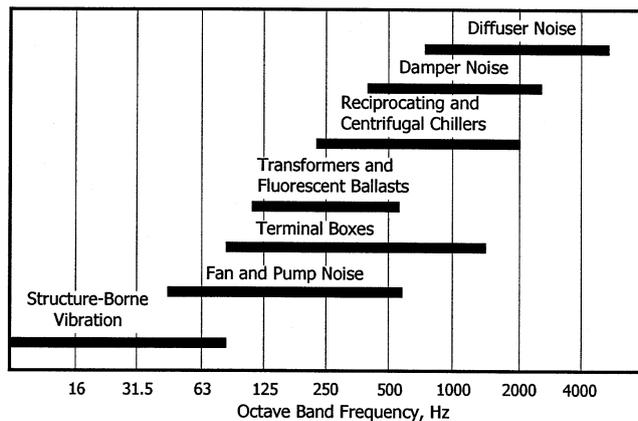

Fig. 4 Equal Loudness Contours for Relatively Narrow Bands of Random Noise

**Fig. 5** Frequencies at Which Various Types of Mechanical and Electrical Equipment Generally Control Sound Spectra

tones. Due to its complexity, loudness has not been widely used in engineering practice in the past. However, with an increased awareness of sound quality and the availability of software for calculating loudness, this measure is now being used more frequently.

AMCA *Publication 302* describes how the **sones method** is applied to rating the relative loudness of fans and ventilators. This calculation method is usually acceptable when the measured sound spectrum has no strong tonal components.

**Acceptable Frequency Spectrum**

The most acceptable frequency spectrum for HVAC sound is a balanced or neutral spectrum. This means that it is not too “hissy” (excessive high frequency content) or too “rumbly” (excessive low-frequency content). Unfortunately, achieving a balanced sound spectrum is not always easy—there may be a multiplicity of sound sources to consider. As a guide to the designer, Figure 5 shows the more common mechanical and electrical sound sources and frequency regions that control the indoor sound spectrum. Chapter 46 of the 1999 *ASHRAE Handbook—Applications* provides more detailed information on treating some of these sound sources.

**SOUND RATING SYSTEMS AND ACOUSTICAL DESIGN GOALS**

Several background sound rating methods are used to rate indoor sound. They include the A-weighted sound pressure level (dBA) and noise criteria (NC), the more recent room criteria (RC) and balanced noise criteria (NCB), and the new RC Mark II. Each sound rating method was developed from data for specific applications; not all methods are equally suitable for the rating of HVAC-related sound in the variety of applications encountered.

The degree of occupant satisfaction achieved with a given level of background sound is determined by many factors. For example, large conference rooms, auditoriums, and recording studios can tolerate only a low level of background sound. On the other hand, higher levels of background sound are acceptable and even desirable in certain situations, such as in open-plan offices where a certain amount of speech and activity masking is essential. Therefore, the system sound control goal varies depending on the required use of the space.

To be unobtrusive, background sound should have the following properties:

- A balanced distribution of sound energy over a broad frequency range
- No audible tonal or other characteristics such as whine, whistle, hum, or rumble

**Table 8** Comparison of Sound Rating Methods

Method	Overview	Evaluates Sound Quality	Used For Rating of
dBA	<ul style="list-style-type: none"> <li>• Can be determined using sound level meter</li> <li>• No quality assessment</li> <li>• Frequently used for outdoor noise ordinances</li> </ul>	No	Cooling towers Water chillers Condensing units
NC	<ul style="list-style-type: none"> <li>• Can rate components</li> <li>• No quality assessment</li> <li>• Does not evaluate low frequency rumble, frequencies &lt;63 Hz</li> </ul>	No	Air terminals Diffusers
NCB	<ul style="list-style-type: none"> <li>• Can rate components</li> <li>• Some quality assessment</li> </ul>	Yes	
RC	<ul style="list-style-type: none"> <li>• Used to evaluate systems</li> <li>• Should not be used to evaluate components</li> <li>• Can be used to evaluate sound quality</li> <li>• Provides some diagnostic capability</li> </ul>	Yes	
RC Mark II	<ul style="list-style-type: none"> <li>• Evaluates sound quality</li> <li>• Provides improved diagnostics capability</li> </ul>	Yes	

- No noticeable time-varying levels from beats or other system-induced aerodynamic instability
- No fluctuations in level such as a throbbing or pulsing

At present, no acceptable process easily characterizes the effects of audible tones and level fluctuations. The preferred sound rating methods generally comprise two distinct parts: a family of criteria curves (specifying sound levels by octave bands), and a companion procedure for rating the calculated or measured sound data relative to the criterion curves. A table of recommended design goals can be found in Chapter 46 of the 1999 *ASHRAE Handbook—Applications*.

Table 8 summarizes the essential differences, advantages and disadvantages of the rating methods that are used to characterize HVAC-related background sound. The text following the table gives more information on each rating. Note that all the ratings in the table consider speech interference effects and all are currently used for rating background noise.

**A-Weighted Sound Level (dBA)**

The A-weighted sound level  $L_A$  is widely used to state acoustical design goals as a single number, but its usefulness is limited because it gives no information on spectrum content. The rating is expressed as a number followed by dBA, for example 40 dBA.

A-weighted sound levels correlate well with human judgments of relative loudness, but give no information on spectral balance. Thus, they do not necessarily correlate well with the annoyance caused by the noise. Many different-sounding spectra can have the same numeric rating, but have quite different subjective qualities. A-weighted comparisons are best used with sounds that sound alike but differ in level. They should not be used to compare sounds with distinctly different spectral characteristics; that is, two sounds at the same sound level but with different spectral content are likely to be judged differently by the listener in terms of acceptability as a background sound. One of the sounds might be completely acceptable, while the other could be objectionable because its spectrum shape was rumbly, hissy, or tonal in character.

A-weighted sound levels are used extensively in outdoor environmental noise standards.

**Noise Criteria (NC) Method**

The NC method is a single-number rating that is somewhat sensitive to the relative loudness and speech interference properties of

a given sound spectrum. The method consists of a family of criteria curves extending from 63 to 8000 Hz, and a **tangency rating procedure** (Beranek 1957). The criteria curves, shown in Figure 6, define the limits of octave band spectra that must not be exceeded to meet occupant acceptance in certain spaces. The rating is expressed as NC followed by a number. For example, the spectrum shown in Figure 6 is rated NC 45 because this is the lowest rating curve that falls entirely above the measured data. An NC 35 design goal is commonly used for private offices. The background sound level meets this goal if no portion of its spectrum lies above the designated NC 35 curve.

The NC method is sensitive to level but has the disadvantage that the tangency method used to determine the rating does not require that the sound spectrum approximate the shape of the NC curves. Thus, many different sounds can have the same numeric rating, but rank differently on the basis of subjective sound quality. In HVAC systems that do not produce excessive low frequency sound, the NC rating correlates relatively well with occupant satisfaction if sound quality is not a significant concern.

Two problems occur in using the NC procedure: (1) when the NC level is determined by a prominent peak in the spectrum, the actual level of resulting background sound may be quieter than that desired for masking unwanted speech and activity sounds, because the spectrum on either side of the tangent peak drops off too rapidly; and (2) when the measured spectrum closely matches the shape of the NC curve, the resulting sound is either rumbly or hissy or both.

The shape of the NC curve is not that of a well-balanced, neutral sound; thus, these curves should be used with caution in critical situations where the background sound of an air-conditioner is required to mask speech and activity sound.

NC contours are used to calculate ratings for some HVAC components such as terminal units and diffusers. NC ratings should not be used to characterize fans and air-handling units.

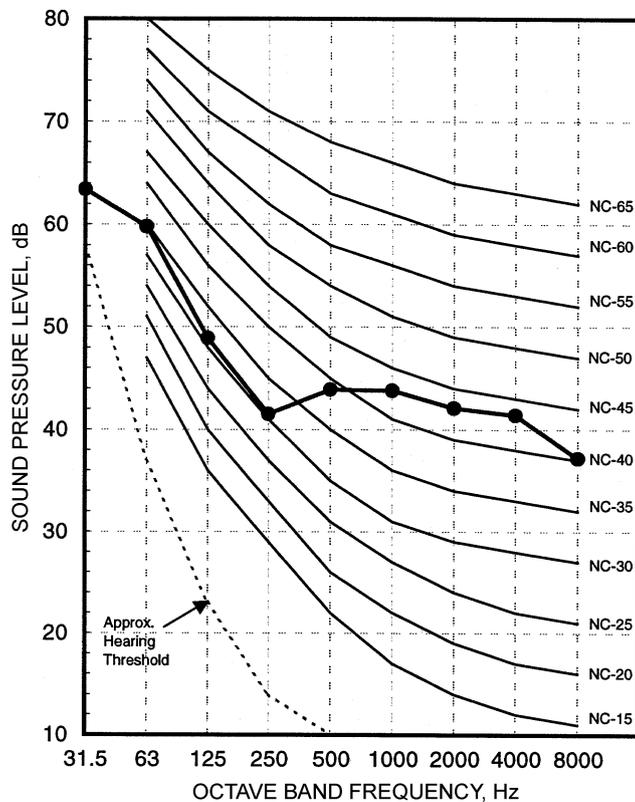

Fig. 6 NC (Noise Criteria) Curves and Sample Spectrum (Curve with Symbols)

### Balanced Noise Criteria (NCB) Method

The NCB method (Beranek 1989, ANSI *Standard* S12.2) is a specification or evaluation of room sound including noise due to occupant activities. The NCB criteria curves (Figure 7) are intended as replacements for the NC curves, and include both the addition of two low-frequency octave bands (16 and 31.5 Hz) and lower permissible sound levels in the high-frequency octave bands (4000 and 8000 Hz). The NCB rating procedure is based on the **speech interference level (SIL)**, which is the arithmetic average of the sound pressure levels in the four frequency bands: 500, 1000, 2000, and 4000 Hz. Additional tests include rumble and hiss compliance. The rating is expressed as NCB followed by a number, for example, NCB 40.

The NCB method is better than the NC method in determining whether a sound spectrum has a shape sufficiently unbalanced to demand corrective action. Also, it addresses the issue of low-frequency sound. The rating procedure is somewhat more complicated than the tangency rating procedure.

### Room Criteria (RC) Method

For some time, the RC method (Blazier 1981a,b; ANSI *Standard* S12.2) was recommended as the preferred method for rating HVAC-related sound. The RC curves were intended to establish HVAC system design goals. The revised RC Mark II method (discussed below) is now preferred.

The RC method consists of a family of criteria curves and a rating procedure. The shape of these curves differs from the NC curves to approximate a well-balanced neutral-sounding spectrum, and two additional octave bands (16 and 31.5 Hz) are added to deal with low-frequency sound. This rating procedure assesses background sound in spaces based on the effect of the sound on speech communication, and on estimates of subjective sound quality. The rating is

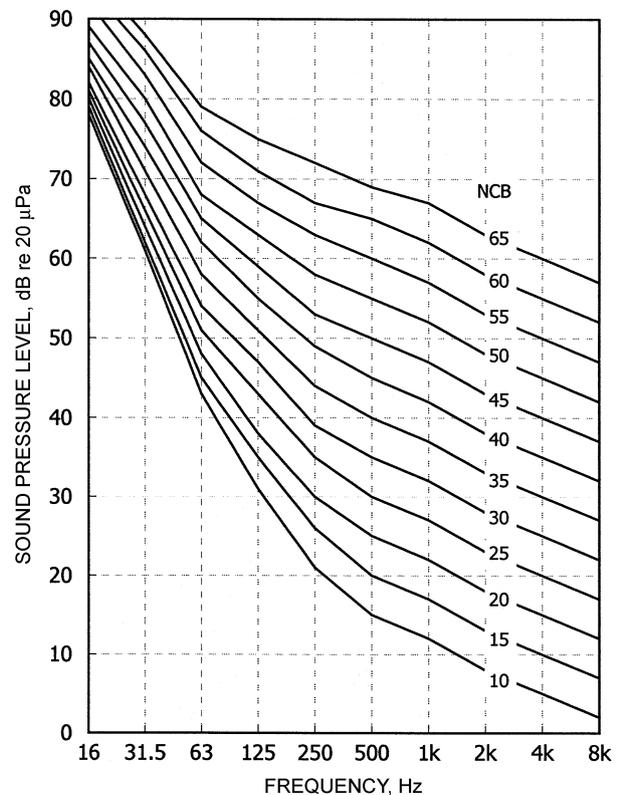

Fig. 7 NCB (Noise Criteria Balanced) Curves Drawn from ANSI *Standard* S12.2

expressed as RC followed by a number to show the level of the sound and a letter to indicate the quality, for example RC 35(N) where N denotes neutral.

**RC Mark II Room Criteria Method**

Based on experience and the findings from ASHRAE-sponsored research, the RC method was revised to the RC Mark II method (Blazier 1997). Like its predecessor, the RC Mark II method is intended for rating the sound performance of an HVAC system as a whole. The method can also be used as a diagnostic tool for analyzing sound problems in the field. The RC Mark II method is more complicated to use than the RC method, but spreadsheet macros are available to do the calculations and graphical analysis.

The RC Mark II method of rating HVAC system sound comprises three parts:

- Family of criteria curves (Figure 8)
- Procedure for determining the RC numerical rating and the sound spectral balance (quality)
- Procedure for estimating occupant satisfaction when the spectrum does not have the shape of an RC curve (Quality Assessment Index) (Blazier 1995)

The rating is expressed as RC followed by a number and a letter, for example, RC 45(N). The number is the arithmetic average rounded to the nearest integer of the sound pressure levels in the 500, 1000, and 2000 Hz octave bands (the principal speech frequency region). The letter is a qualitative descriptor that identifies the perceived character of the sound: (N) for neutral, (LF) for low-frequency rumble, (MF) for mid-frequency roar, and (HF) for

high-frequency hiss. In addition, the low-frequency descriptor has two subcategories: (LF<sub>B</sub>), denoting a moderate but perceptible degree of sound induced ceiling/wall vibration, and (LF<sub>A</sub>), denoting a noticeable degree of sound induced vibration.

Each reference curve in Figure 8 identifies the shape of a neutral, bland-sounding spectrum, indexed to a curve number corresponding to the sound level in the 1000 Hz octave band. The shape of these curves is based on research by Blazier (1981a,b) and modified at 16 Hz following recommendations by Broner (1994). Regions A and B denote levels at which sound can induce vibration in light wall and ceiling constructions that can potentially cause rattles in light fixtures, furniture, etc. Curve T is the octave-band threshold of hearing as defined by ANSI Standard 12.2.

**Procedure for Determining the RC Mark II Rating for a System**

**Step 1.** Determine the appropriate RC reference curve. This is done by obtaining the arithmetic average of the sound levels in the principle speech frequency range represented by the levels in the 500, 1000, and 2000 Hz octave bands. The RC reference curve is chosen as that which has the same value at 1000 Hz as the calculated average value (rounded to the nearest integer). This curve is not to be confused with the speech-interference level (SIL), which is a four-band average obtained by including the 4000 Hz octave band.

**Step 2.** Assign a subjective quality by calculating the **Quality Assessment Index (QAI)** (Blazier 1995). This index is a measure of the degree the shape of the spectrum under evaluation deviates from the shape of the RC reference curve. The procedure requires calculation of the **energy-average spectral deviations** from the RC reference curve in each of three frequency groups: low frequency, LF (16-63 Hz), medium frequency, MF (125-500 Hz), and high frequency, HF (1000-4000 Hz). The procedure for the LF region is given by Equation (15) and is repeated in the MF and HF regions by substituting the corresponding values at each frequency. However, when evaluating typical HVAC-related sounds, a simple arithmetic average of these deviations is often adequate if the range of values does not exceed 3 dB.

$$\Delta LF = 10 \log [10^{0.1\Delta L_{16}} + 10^{0.1\Delta L_{31.5}} + 10^{0.1\Delta L_{63}} / 3] \quad (15)$$

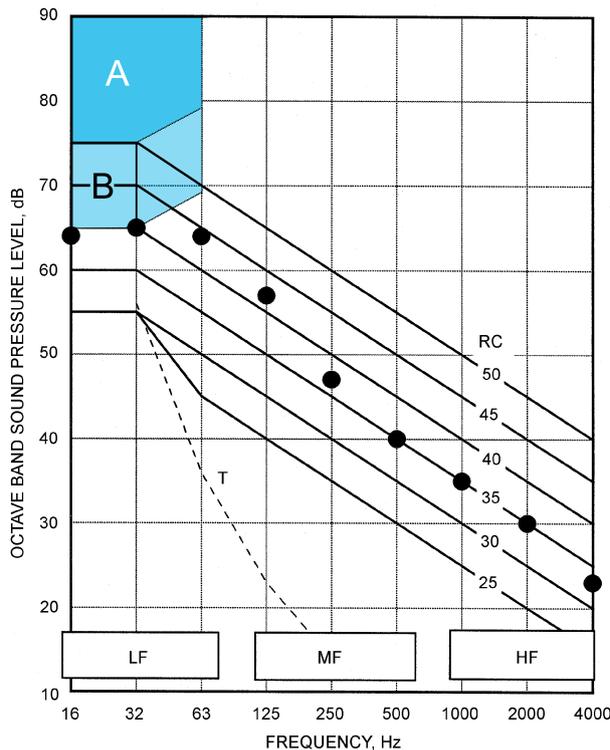

where the  $\Delta L$  terms are the differences between the spectrum being evaluated and the RC reference curve in each frequency band. In this way, three spectral deviation factors ( $\Delta LF$ ,  $\Delta MF$ ,  $\Delta HF$ ), expressed in dB with either positive or negative values, are associated with the spectrum being rated. QAI is the **range** in dB between the highest and lowest values of the spectral deviation factors.

If QAI  $\leq 5$  dB, the spectrum is assigned a neutral (N) rating. If QAI exceeds 5 dB, the sound quality descriptor of the RC rating is the letter designation of the frequency region of the deviation factor having the highest positive value. As an example, the spectrum plotted in Figure 8 is processed in Table 9.

The arithmetic average of the sound levels in the 500, 1000, and 2000 Hz octave bands in Figure 8 is 35 dB, so the RC 35 curve is selected as the reference for spectrum quality evaluation. The spectral deviation factors in the LF, MF, and HF regions are 6.6, 4.0 and -0.6, respectively, giving a QAI of 7.2. The maximum positive deviation factor occurs in the LF region, and the QAI exceeds 5, resulting in a rating of RC 35(LF). An average room occupant should perceive this spectrum as marginally rumbly in character (see Table 10).

**Estimating Occupant Satisfaction Using QAI**

The quality assessment index (QAI) is useful in estimating the probable reaction of an occupant when the system does not produce optimum sound quality. The basis for the procedure outlined here for estimating occupant satisfaction is as follows:

Sound levels in Region B may generate perceptible vibration in light wall and ceiling construction. Rattles in light fixtures, doors, windows, etc., are a slight possibility. Sound levels in Region A have a high probability of generating easily perceptible sound induced vibration in light wall and ceiling construction. Audible rattling in light fixtures, doors, windows etc. may be anticipated. The text explains Regions LF, MF, and HF. The solid dots are octave band sound pressure levels for the example in the text.

**Fig. 8 Room Criteria Curves, Mark II**

**Table 9 Example Calculation of RC Mark II Rating for Sound Spectrum in Figure 8**

	Frequency, Hz								
	16	31.5	63	125	250	500	1000	2000	4000
Sound pressure	64	65	64	57	47	40	35	30	23
Average sound pressure at 500-2000 Hz							35		
RC contour	60	60	55	50	45	40	35	30	25
Levels: RC contour	4	5	9	7	2	0	0	0	-2
	LF			MF			HF		
Spectral deviations	6.6			4.0			-0.6		
QAI	6.6 - (-0.6) = 7.2								
RC Mark II rating	RC 35(LF)								

- Changes in sound level of less than 5 dB do not cause subjects to change their ranking of sounds of similar spectral content. A QAI of 5 dB or less corresponds to a generally acceptable condition, *provided that the perceived level of the sound is in a range consistent with the given type of space occupancy.*
- A QAI that exceeds 5 dB but is less than or equal to 10 dB represents a marginal situation in which the acceptance by an occupant is questionable.
- A QAI greater than 10 dB will likely be objectionable to the average occupant.

Table 10 lists sound quality descriptors and QAI values and relates them to probable occupant reaction to the sound. An exception to this rule occurs when the sound pressure levels in the 16 Hz or 31.5 Hz octave-bands exceed 65 dB. In such cases, the potential for acoustically-induced vibration in typical light office construction should be considered. If the levels in these bands exceed 75 dB, a significant problem with induced vibration is probable.

Undoubtedly situations will occur in the assessment of HVAC-related sound where the numerical part of the RC rating is less than the specified maximum for the space use, but the sound quality descriptor is other than the desirable (N). For example, a maximum of RC 40(N) is specified, but the actual sound environment turns out to be RC 35(MF). Knowledge in this area is insufficient to decide which spectrum is preferable.

Even at moderate levels, if the dominant portion of the background sound occurs in the very low-frequency region, some people experience a sense of oppressiveness or depression in the environment (Persson-Waye et al. 1997). In such situations, the basis for

complaint may result from exposure to that environment for several hours, and thus may not be noticed during a short exposure period.

### Criteria Selection Guidelines

In general, these basic guidelines are important:

- Sound levels below NCB 35 or RC 35 are not detrimental to good speech intelligibility; those at or above NCB 35 or RC 35 may interfere with or mask speech.
- Even if the occupancy sound will be significantly higher than the anticipated background sound level generated by mechanical equipment, the sound design goal should not necessarily be raised to levels approaching the occupancy sound. This avoids occupants having to raise their voices uncomfortably to be heard over the noise.

Table 11 gives recommended design criteria.

## FUNDAMENTALS OF VIBRATION

A rigidly mounted machine transmits its internal vibratory forces directly to the supporting structure. However, by inserting resilient mountings, called **vibration isolators**, between the machine and supporting structure, the magnitude of transmitted vibration can be reduced to only a fraction of the original. Vibration isolators can also be used to protect sensitive equipment from disturbing vibrations that may be present in the floor of the building structure.

### SINGLE-DEGREE-OF-FREEDOM MODEL

The simplest example of a vibration isolation system is the single-degree-of-freedom model illustrated in Figure 9. In this instance only motion along the vertical axis is considered and damping is disregarded. This is the model upon which most manufacturers of vibration isolation hardware base their catalog information.

The application of a single-degree-of-freedom model to the isolation of HVAC equipment is valid only when the stiffness of the supporting structure is large with respect to the stiffness of the vibration isolator. Under these conditions, the natural frequency  $f_n$  of the system is

$$f_n = \frac{1}{2\pi} \sqrt{\frac{k}{M}} \quad (16)$$

**Table 10 Definition of Sound Quality Descriptor and Quality Assessment Index (QAI) to Aid in Interpreting RC Mark II Ratings of HVAC-Related Sound**

Sound Quality Descriptor	Description of Subjective Perception	Magnitude of QAI	Probable Occupant Evaluation, Assuming Level of Specified Criterion is Not Exceeded
(N) Neutral (Bland)	Balanced sound spectrum, no single frequency range dominant	QAI ≤ 5 dB, $L_{16}, L_{31.5} \leq 65$ QAI ≤ 5 dB, $L_{16}, L_{31.5} > 65$	Acceptable Marginal
(LF) Rumble	Low-frequency range dominant (16 – 63 Hz)	5 dB < QAI ≤ 10 dB QAI > 10 dB	Marginal Objectionable
(LFV <sub>B</sub> ) Rumble, with moderately perceptible room surface vibration	Low-frequency range dominant (16 – 63 Hz)	QAI ≤ 5 dB, $65 < L_{16}, L_{31.5} < 75$ 5 dB < QAI ≤ 10 dB QAI > 10 dB	Marginal Marginal Objectionable
(LFV <sub>A</sub> ) Rumble, with clearly perceptible room surface vibration	Low-frequency range dominant (16 – 63 Hz)	QAI ≤ 5 dB, $L_{16}, L_{31.5} > 75$ 5 dB < QAI ≤ 10 dB QAI > 10 dB	Marginal Marginal Objectionable
(MF) Roar	Mid-frequency range dominant (125 – 500 Hz)	5 dB < QAI ≤ 10 dB QAI > 10 dB	Marginal Objectionable
(HF) Hiss	High-frequency range dominant (1000 – 4000 Hz)	5 dB < QAI ≤ 10 dB QAI > 10 dB	Marginal Objectionable

**Table 11 Design Guidelines for HVAC-Related Background Sound in Rooms**

Room Types	RC(N); QAI ≤ 5dB Criterion <sup>a,b</sup>
<b>Residences, Apartments, Condominiums</b>	25 – 35
<b>Hotels/Motels</b>	
Individual rooms or suites	25 – 35
Meeting/banquet rooms	25 – 35
Corridors, lobbies	35 – 45
Service/support areas	35 – 45
<b>Office Buildings</b>	
Executive and private offices	25 – 35
Conference rooms	25 – 35
Teleconference rooms	25 (max)
Open-plan offices	30 – 40
Corridors and lobbies	40 – 45
<b>Hospitals and Clinics</b>	
Private rooms	25 – 35
Wards	30 – 40
Operating rooms	25 – 35
Corridors and public areas	30 – 40
<b>Performing Arts Spaces</b>	
Drama theaters	25 (max)
Concert and recital halls <sup>c</sup>	
Music teaching studios	25 (max)
Music practice rooms	35 (max)
<b>Laboratories (with fume hoods)</b>	
Testing/research, minimal speech communication	45 – 55
Research, extensive telephone use, speech communication	40 – 50
Group teaching	35 – 45
<b>Churches, Mosques, Synagogues</b>	
General assembly	25 – 35
With critical music programs <sup>c</sup>	
<b>Schools<sup>d</sup></b>	
Classrooms up to 70 m <sup>2</sup>	40 (max)
Classrooms over 70 m <sup>2</sup>	35 (max)
Large lecture rooms, without speech amplification	35 (max)

<b>Courtrooms</b>	
Unamplified speech	25 – 35
Amplified speech	30 – 40
<b>Indoor Stadiums, Gymnasiums</b>	
Gymnasiums, natatoriums, and large seating- capacity spaces with speech amplification <sup>e</sup>	40 – 45

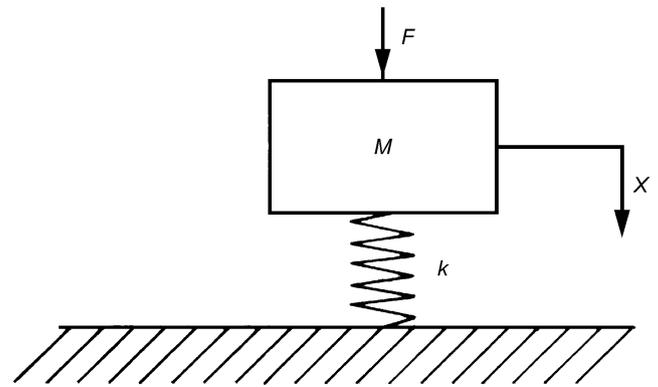

<sup>a</sup>The values and ranges are based on judgment and experience, not on quantitative evaluations of human reactions. They represent general limits of acceptability for typical building occupancies. Higher or lower values may be appropriate and should be based on a careful analysis of economics, space use, and user needs.

<sup>b</sup>When quality of sound in the space is important, specify criteria in terms of RC(N). If the quality of the sound in the space is of secondary concern, the criteria may be specified in terms of NC or NCB levels of similar magnitude.

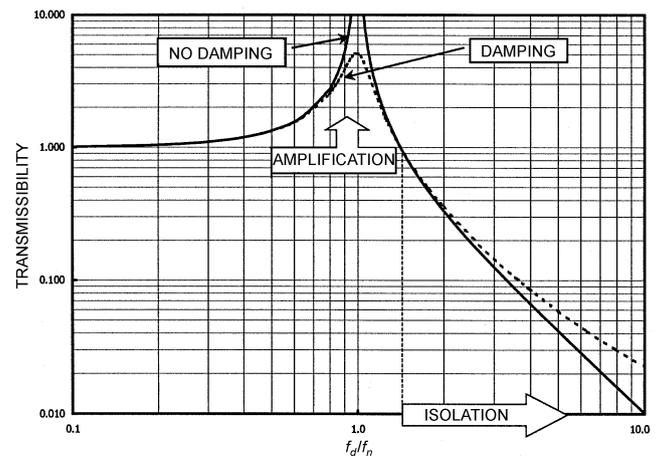

<sup>c</sup>An experienced acoustical consultant should be retained for guidance on acoustically critical spaces (below RC 30) and for all performing arts spaces.

<sup>d</sup>HVAC-related sound criteria for schools, such as those listed in this table, may be too high and impede learning by children in primary grades whose vocabulary is limited, or whose first language is not the language of the class. Some educators and others believe that the HVAC-related background sound should not exceed RC 25(N).

<sup>e</sup>RC or NC criteria for these spaces need only be selected for the desired speech and hearing conditions.

**Fig. 9 Single-Degree-of-Freedom System**

**Fig. 10 Vibration Transmissibility  $T$  as a Function of  $f_d/f_n$**

where  $k$  is the stiffness of the vibration isolator (force per unit deflection) and  $M$  is the mass of the equipment supported by the isolator. This equation simplifies to

$$f_n = \frac{15.8}{\sqrt{\delta_{st}}} \tag{17}$$

where  $\delta_{st}$  is the isolator static deflection in millimetres (the incremental distance the isolator spring compresses under the weight of the supported equipment, or  $k/M = g/\delta_{st}$ ). Thus, to achieve the appropriate system natural frequency for a given application, the corresponding isolator static deflection and the load to be supported at each mounting point is specified.

The **transmissibility** is the ratio of the amplitudes of the force transmitted to the building structure to the exciting force produced by the vibrating equipment. Transmissibility  $T$  is inversely proportional to the square of the ratio of the disturbing frequency  $f_d$  to the system natural frequency  $f_n$ , or

$$T = \left| \frac{1}{1 - (f_d/f_n)^2} \right| \tag{18}$$

At  $f_d = f_n$ , **resonance** occurs (the denominator of Equation (18) equals zero), with theoretically infinite transmission of vibration. In practice, however, some limit on the transmission at resonance exists because inherent damping is always present to some degree. Thus, the magnitude of vibration amplification at resonance always has a finite value. Equation (18) is plotted in Figure 10.

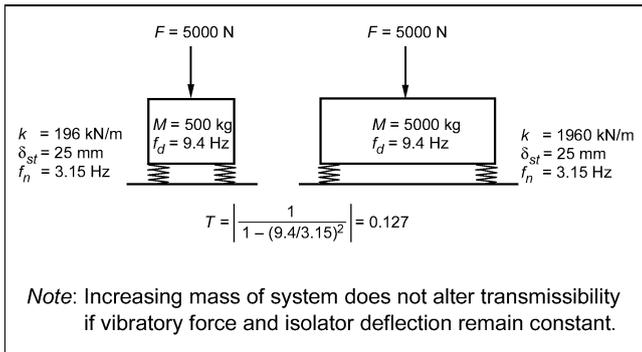

Fig. 11 Effect of Mass on Transmissibility

Vibration isolation does not begin to occur until  $f_d/f_n > 1.4$ . Above this ratio, the vibration transmissibility rapidly decreases. A frequency ratio of at least 3.5 is often specified, which corresponds to an isolation efficiency of about 90%, or 10% transmissibility. Higher ratios may be specified, but in practice this does not generally result in isolation efficiencies any greater than about 90%. The reason is that “wave-effects” and other nonlinear characteristics cause typical isolators to depart from the theoretical curve that limits performance.

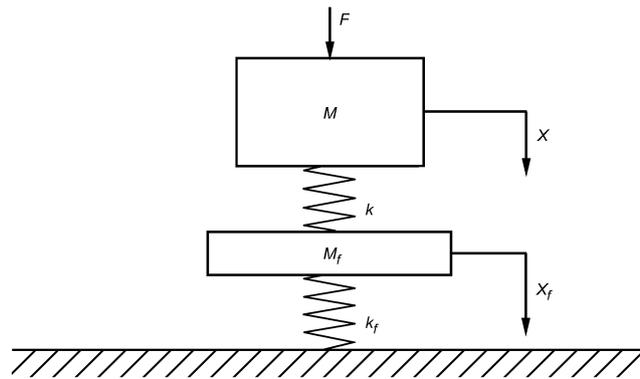

If the mass of the equipment is increased, the resonance frequency decreases, thus increasing the isolation. In practice, the load-carrying capacity of isolators usually requires that their stiffness or their number be increased. Consequently, the static deflection and the transmissibility may remain unchanged. The use of stiffer springs leads, however, to smaller vibration amplitudes—less movement of the equipment. This is one of the main reasons for placing some high-power or highly eccentric equipment on inertia pads.

For example, as shown in Figure 11, a 500 kg piece of equipment installed on isolators with stiffness  $k$  of 196 kN/m results in a 25 mm deflection and a system resonance frequency  $f_n$  of 3.15 Hz. If the equipment is operated at 564 rpm (9.4 Hz) and develops a force of 5000 N, a  $5000 \times 0.127 = 635$  N force is transmitted to the structure. If the total mass is increased to 5000 kg by placing the equipment on a concrete inertia base and the stiffness of the springs is increased to 1960 kN/m, the deflection is still 25 mm, the resonance frequency of the system is maintained at 3.15 Hz, and the force transmitted to the structure remains at 635 N. The increased mass, however, reduces the equipment displacement.

## TWO-DEGREE-OF-FREEDOM MODEL

The single-degree-of-freedom model is valid only when the stiffness of the supporting structure is large with respect to the stiffness of the vibration isolator. This condition is usually satisfied for mechanical equipment in on-grade or basement locations. However, when heavy mechanical equipment is installed on a structural floor, and in particular on the roof of a building, the relative stiffness of the supporting system can no longer be ignored. Significantly “softer” vibration isolators are usually required than in the on-grade or basement case. The appropriate model for the design of vibration isolation in upper-floor locations is the two-degree-of-freedom model illustrated in Figure 12.

The precise behavior of this system with respect to vibration isolation is difficult to determine. The objective is to minimize the motion of the supporting floor  $M_f$  in response to the exciting force  $F$ . This involves evaluating the interaction between two system natural frequencies and the frequency of the exciting force, which is mathematically complex. However, several engineering rules can simplify the calculations used to optimize the isolation system.

Note:  $M$  and  $M_f$  represent effective masses of vibrating equipment and supporting floor, respectively;  $k$  and  $k_f$  are corresponding stiffness of isolator and floor system.

Fig. 12 Two-Degree-of-Freedom System

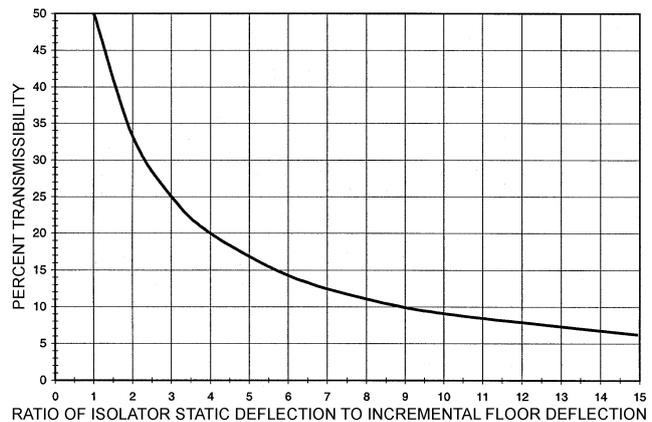

Fig. 13 Transmissibility of Two-Degree-of-Freedom System  
Adapted from Plunkett (1958)

For example, the fraction of vibratory force transmitted across an isolator to the building structure (transmissibility) depends in part on the ratio between the isolator stiffness and that of the supporting floor at the point of loading. Because stiffness is inversely proportional to deflection under the applied load, this relationship can sometimes be expressed more conveniently as a ratio of deflections. To optimize isolation efficiency, the static deflection of the isolator, under the applied load, must be large with respect to the incremental static deflection of the floor that occurs due to the added equipment weight. Ideally, this ratio should be on the order of 10:1 to approach an isolation efficiency of about 90% (10% transmissibility). The relationship is illustrated in Figure 13.

Note that if the static deflection of the vibration isolator is similar to the incremental deflection of the supporting floor under the added weight of the equipment, 50% or more of the vibratory force will transmit directly to the building structure. This situation is a common problem in the field where excessive vibration is attributable to upper floor or rooftop mechanical installations. Frequently, the floor stiffness has been neglected and the static deflection on the installed vibration isolators is inadequate because the selection was made on the basis of the single-degree-of-freedom model.

Problems of this nature can usually be avoided by asking the structural engineer to estimate the incremental static deflection of the floor due to the added weight of the equipment at the point of loading, before selecting a vibration isolator. Then, choose an isolator that will provide a static deflection of 8 to 10 times that of the estimated incremental floor deflection.

## VIBRATION MEASUREMENT BASICS

While the control of HVAC system sound and vibration are of equal importance, the measurement of vibration is not usually necessary for determining the sources or transmission paths of disturbing sound. Because the techniques and instrumentation used for vibration measurement and analysis are specialized, designers should consult other sources (e.g., Harris 1991) for thorough descriptions of vibration measurement and analysis methods.

The typical vibrations measured are periodic motions of a surface. This surface displacement oscillates with one or more frequencies produced by mechanical means (like gears), thermal means (like combustion), or fluid-dynamic means (like airflow through a duct or fan interactions with air). The displacement is generally inversely proportional to the frequency. In other words, if the displacements are high, the frequency is low. The frequencies of interest for most vibration measurements are between 5 Hz and 100 Hz.

A **transducer** can detect displacement, velocity, or acceleration of a surface and convert the motion to electrical signals. Displacement is the basic measure and good for low frequencies. Velocity is good for overall measurements, but requires large transducers. For most HVAC applications, the transducer of choice is an **accelerometer**, a device that detects acceleration. Readout may be as acceleration level in decibels, or acceleration with modifiers of peak, peak-to-peak, or rms.

The simplest measure is the overall signal as a function of time, be it acceleration, acceleration level, or another quantity. This is analogous to the unfiltered sound pressure level for sound. If a detailed frequency analysis is needed, there is a choice of filters similar to those available for sound measurements: octave band, 1/3 octave band or 1/12 octave band filters. In addition, narrow-band analyzers that use the fast Fourier transform (FFT) to analyze and filter a signal are available. While they are widely used, they should only be used by a specialist for accurate results.

The most important issues in vibration measurement include: (1) choosing a transducer with a frequency range appropriate to the measurement, (2) properly mounting the transducer to ensure that the frequency response claimed is achieved, and (3) not using hand-held probes for high frequencies where they are unreliable.

<i>Thermal Nonuniform Conditions and Local Discomfort</i> .....	8.13		

**A** PRINCIPAL purpose of heating, ventilating, and air-conditioning systems is to provide conditions for human thermal comfort. A widely accepted definition is, “Thermal Comfort is that condition of mind that expresses satisfaction with the thermal environment” (ASHRAE *Standard* 55). This definition leaves open what is meant by condition of mind or satisfaction, but it correctly emphasizes that the judgment of comfort is a cognitive process involving many inputs influenced by physical, physiological, psychological, and other processes.

The conscious mind appears to reach conclusions about thermal comfort and discomfort from direct temperature and moisture sensations from the skin, deep body temperatures, and the efforts necessary to regulate body temperatures (Hensel 1973, 1981; Hardy et al. 1971; Gagge 1937; Berglund 1995). In general, comfort occurs when body temperatures are held within narrow ranges, skin moisture is low, and the physiological effort of regulation is minimized.

Comfort also depends on behavioral actions that are initiated unconsciously or by the conscious mind and guided by thermal and moisture sensations to reduce discomfort. Some of the possible behavioral actions to reduce discomfort are altering clothing, altering activity, changing posture or location, changing the thermostat setting, opening a window, complaining, or leaving the space.

Surprisingly, although regional climate conditions, living conditions, and cultures differ widely throughout the world, the temperature that people choose for comfort under like conditions of clothing, activity, humidity, and air movement has been found to be very similar (Fanger 1972; de Dear et al. 1991; Busch 1992).

This chapter summarizes the fundamentals of human thermoregulation and comfort in terms useful to the engineer for operating systems and designing for the comfort and health of building occupants.

### HUMAN THERMOREGULATION

The metabolic activities of the body result almost completely in heat that must be continuously dissipated and regulated to maintain normal body temperatures. Insufficient heat loss leads to overheating, also called **hyperthermia**, and excessive heat loss results in body cooling, also called **hypothermia**. Skin temperature greater than 45°C or less than 18°C causes pain (Hardy et al. 1952). Skin temperatures associated with comfort at sedentary activities are 33 to 34°C and decrease with increasing activity (Fanger 1968). In contrast, internal temperatures rise with activity. The temperature regulatory center in the brain is about 36.8°C at rest in comfort and increases to about 37.4°C when walking and 37.9°C when jogging. An internal temperature less than about 28°C can lead to serious cardiac arrhythmia and death, and a temperature greater than 46°C can cause irreversible brain damage. Therefore, the careful regulation of body temperature is critical to comfort and health.

The heat produced by a resting adult is about 100 W. Because most of this heat is transferred to the environment through the skin, it is often convenient to characterize metabolic activity in terms of heat production per unit area of skin. For the resting person, this is about 58 W/m<sup>2</sup> and is called 1 met. This is based on the average male European, with a skin surface area of about 1.8 m<sup>2</sup>. For comparison, female Europeans have an average surface area of 1.6 m<sup>2</sup>. Systematic differences in this parameter may occur between ethnic and geographical groups. Higher metabolic rates are often described in terms of the resting rate. Thus, a person working at metabolic rate five times the resting rate would have a metabolic rate of 5 met.

The **hypothalamus**, located in the brain, is the central control organ for body temperature. It has hot and cold temperature sensors and is bathed by arterial blood. Since the recirculation rate of blood in the body is rapid and returning blood is mixed together in the heart before returning to the body, arterial blood is indicative of the average internal body temperature. The hypothalamus also receives thermal information from temperature sensors in the skin and perhaps other locations as well (spinal cord, gut), as summarized by Hensel (1981).

The hypothalamus controls various physiological processes of the body to regulate body temperature. Its control behavior is primarily proportional to deviations from set-point temperatures with some integral and derivative response aspects. The most important and often used of the physiological processes is regulating blood flow to the skin. When internal temperatures rise above a set point, an increasing proportion of the total blood is directed to the skin. This **vasodilation** of skin blood vessels can increase skin blood flow by 15 times (from 1.7 mL/(s·m<sup>2</sup>) at resting comfort to 25 mL/(s·m<sup>2</sup>) in extreme heat) to carry internal heat to the skin for transfer to the environment. When body temperatures fall below the set point, skin blood flow is reduced (vasoconstricted) to conserve body heat. The effect of maximum vasoconstriction is equivalent to the insulating effect of a heavy sweater. At temperatures less than the set point, muscle tension increases to generate additional heat; where muscle groups are opposed, this may increase to visible shivering. Shivering can double the resting rate of heat production.

At elevated internal temperatures, sweating occurs. This defense mechanism is a powerful way to cool the skin and increase heat loss from the core. The sweating function of the skin and its control is more advanced in humans than in other animals and is increasingly necessary for comfort at metabolic rates above resting level (Fanger 1968). Sweat glands pump perspiration onto the skin surface for evaporation. If conditions are good for evaporation, the skin can remain relatively dry even at high sweat rates with little perception of sweating. At skin conditions less favorable for evaporation, the sweat must spread out on the skin about the sweat gland until the sweat-covered area is sufficient to evaporate the sweat coming to the surface. The fraction of the skin that is covered with water to account for the observed total evaporation rate is termed **skin wettedness** (Gagge 1937).

The preparation of this chapter is assigned to TC 2.1, Physiology and Human Environment.

Humans are quite good at sensing skin moisture from perspiration (Berglund and Cunningham 1986; Berglund 1994), and skin moisture correlates well with warm discomfort and unpleasantness (Winslow et al. 1937). It is rare for a sedentary or slightly active person to be comfortable with a skin wettedness greater than 25%. In addition to the perception of skin moisture, skin wettedness increases the friction between skin and fabrics, making clothing feel less pleasant and fabrics feel more coarse (Gwosdow et al. 1987). This also occurs with architectural materials and surfaces, particularly smooth, nonhygroscopic surfaces.

With repeated intermittent heat exposure, the set point for the onset of sweating decreases and the proportional gain or temperature sensitivity of the sweating system increases (Gonzalez et al. 1978, Hensel 1981). However, under long-term exposure to hot conditions, the set point increases, perhaps to reduce the physiological effort of sweating. Perspiration as secreted has a lower salt concentration than interstitial body fluid or blood plasma. After prolonged heat exposure, sweat glands further reduce the salt concentration of sweat to conserve salt.

At the surface, the water in sweat evaporates while the dissolved salt and other constituents remain and accumulate. Because salt lowers the vapor pressure of water and thereby impedes its evaporation, the accumulating salt results in increased skin wettedness with time. Some of the relief and pleasure of washing after a warm day is related to the restoration of a hypotonic sweat film and decreased skin wettedness. Other adaptations to heat are increased blood flow and sweating in peripheral regions where heat transfer is better. Such adaptations are examples of **integral control**.

The role of thermoregulatory effort in comfort is highlighted by the experiments of Chatonnet and Cabanac (1965) and observations of Kuno (1995). Chatonnet's experiments compared the sensation of placing the subject's hand in relatively hot or cold water (30 to 38°C) for 30 s given the subject at different thermal states. When the person was overheated or hyperthermic, the cold water was pleasant and the hot water was very unpleasant, but when the subject was in a cold or hypothermic state, the hand felt pleasant in hot water and unpleasant in cold water. Kuno (1995) describes similar observations during transient whole body exposures to hot and cold environment. When a subject is in a state of thermal discomfort, any move away from the thermal stress of the uncomfortable environment is perceived as pleasant during the transition.

## ENERGY BALANCE

Figure 1 shows the thermal interaction of the human body with its environment. The total metabolic rate of work  $M$  produced within the body is the metabolic rate required for the person's activity  $M_{act}$  plus the metabolic level required for shivering  $M_{shiv}$  (should shivering occur). A portion of the body's energy production may be expended as external work done by the muscles  $W$ ; the net heat production  $M - W$  is either stored ( $S$ ), causing the body's temperature to rise, or dissipated to the environment through the skin surface ( $q_{sk}$ ) and respiratory tract ( $q_{res}$ ).

$$\begin{aligned} M - W &= q_{sk} + q_{res} + S \\ &= (C + R + E_{sk}) + (C_{res} + E_{res}) + (S_{sk} + S_{cr}) \end{aligned} \quad (1)$$

where

- $M$  = rate of metabolic heat production,  $W/m^2$
- $W$  = rate of mechanical work accomplished,  $W/m^2$
- $q_{sk}$  = total rate of heat loss from skin,  $W/m^2$
- $q_{res}$  = total rate of heat loss through respiration,  $W/m^2$
- $C + R$  = sensible heat loss from skin,  $W/m^2$
- $E_{sk}$  = total rate of evaporative heat loss from skin,  $W/m^2$
- $C_{res}$  = rate of convective heat loss from respiration,  $W/m^2$
- $E_{res}$  = rate of evaporative heat loss from respiration,  $W/m^2$
- $S_{sk}$  = rate of heat storage in skin compartment,  $W/m^2$
- $S_{cr}$  = rate of heat storage in core compartment,  $W/m^2$

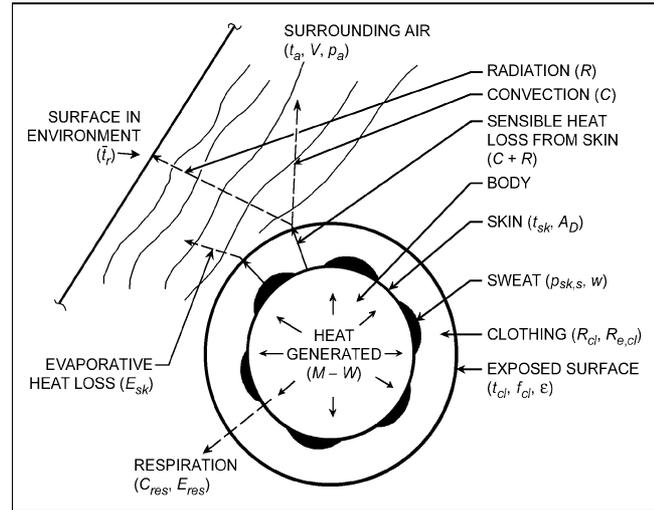

Fig. 1 Thermal Interaction of Human Body and Environment

Heat dissipation from the body to the immediate surroundings occurs by several modes of heat exchange: sensible heat flow  $C + R$  from the skin; latent heat flow from the evaporation of sweat  $E_{rsw}$  and from evaporation of moisture diffused through the skin  $E_{dif}$ ; sensible heat flow during respiration  $C_{res}$ ; and latent heat flow due to evaporation of moisture during respiration  $E_{res}$ . Sensible heat flow from the skin may be a complex mixture of conduction, convection, and radiation for a clothed person; however, it is equal to the sum of the convection  $C$  and radiation  $R$  heat transfer at the outer clothing surface (or exposed skin).

Sensible and latent heat losses from the skin are typically expressed in terms of environmental factors, skin temperature  $t_{sk}$ , and skin wettedness  $w$ . The expressions also incorporate factors that account for the thermal insulation and moisture permeability of clothing. The independent environmental variables can be summarized as air temperature  $t_a$ , mean radiant temperature  $\bar{t}_r$ , relative air velocity  $V$ , and ambient water vapor pressure  $p_a$ . The independent personal variables that influence thermal comfort are activity and clothing.

The rate of heat storage in the body equals the rate of increase in internal energy. The body can be considered as two thermal compartments, the skin and the core (see the section on Two-Node Model under Prediction of Thermal Comfort). The rate of storage can be written separately for each compartment in terms of thermal capacity and time rate of change of temperature in each compartment:

$$S_{cr} = \frac{(1 - \alpha_{sk})mc_{p,b}}{A_D} \frac{dt_{cr}}{d\theta} \quad (2)$$

$$S_{sk} = \frac{\alpha_{sk}mc_{p,b}}{A_D} \frac{dt_{sk}}{d\theta} \quad (3)$$

where

- $\alpha_{sk}$  = fraction of body mass concentrated in skin compartment
- $m$  = body mass, kg
- $c_{p,b}$  = specific heat capacity of body = 3490 J/(kg·K)
- $A_D$  = DuBois surface area,  $m^2$
- $t_{cr}$  = temperature of core compartment, °C
- $t_{sk}$  = temperature of skin compartment, °C
- $\theta$  = time, s

The fractional skin mass  $\alpha_{sk}$  depends on the rate  $\dot{m}_{bl}$  of blood flowing to the skin surface.

### THERMAL EXCHANGES WITH THE ENVIRONMENT

Fanger (1967, 1970), Hardy (1949), Rapp and Gagge (1967), and Gagge and Hardy (1967) give quantitative information on calculating the heat exchange between people and the environment. A summary of the mathematical statements for various terms of heat exchange used in the heat balance equations ( $C$ ,  $R$ ,  $E_{sk}$ ,  $C_{res}$ ,  $E_{res}$ ) follows. Terms describing the heat exchanges associated with the thermoregulatory control mechanisms ( $q_{cr,sk}$ ,  $M_{shiv}$ ,  $E_{rsw}$ ), values for the coefficients, and appropriate equations for  $M_{act}$  and  $A_D$  are presented in later sections.

The mathematical description of the energy balance of the human body represents a combined rational/empirical approach to describing the thermal exchanges with the environment. Fundamental heat transfer theory is used to describe the various mechanisms of sensible and latent heat exchange, while empirical expressions are used to determine the values of the coefficients describing these rates of heat exchange. Empirical equations are also used to describe the thermophysiological control mechanisms as a function of skin and core temperatures in the body.

#### Body Surface Area

The terms in Equation (1) have units of power per unit area and refer to the surface area of the nude body. The most useful measure of nude body surface area, originally proposed by DuBois and DuBois (1916), is described by

$$A_D = 0.202m^{0.425}l^{0.725} \quad (4)$$

where

- $A_D$  = DuBois surface area, m<sup>2</sup>
- $m$  = mass, kg
- $l$  = height, m

A correction factor  $f_{cl} = A_{cl}/A_D$  must be applied to the heat transfer terms from the skin ( $C$ ,  $R$ , and  $E_{sk}$ ) to account for the actual surface area  $A_{cl}$  of the clothed body. This factor can be found in Table 7 for various clothing ensembles. For a 1.73 m tall, 70 kg man,  $A_D = 1.8$  m<sup>2</sup>. All terms in the basic heat balance equations are expressed per unit **DuBois surface area**.

#### Sensible Heat Loss from Skin

Sensible heat exchange from the skin surface must pass through clothing to the surrounding environment. These paths are treated in series and can be described in terms of heat transfer (1) from the skin surface, through the clothing insulation, to the outer clothing surface, and (2) from the outer clothing surface to the environment.

Both convective  $C$  and radiative  $R$  heat losses from the outer surface of a clothed body can be expressed in terms of a heat transfer coefficient and the difference between the mean temperature  $t_{cl}$  of the outer surface of the clothed body and the appropriate environmental temperature:

$$C = f_{cl}h_c(t_{cl} - t_a) \quad (5)$$

$$R = f_{cl}h_r(t_{cl} - \bar{t}_r) \quad (6)$$

where

- $h_c$  = convective heat transfer coefficient, W/(m<sup>2</sup>·K)
- $h_r$  = linear radiative heat transfer coefficient, W/(m<sup>2</sup>·K)
- $f_{cl}$  = clothing area factor  $A_{cl}/A_D$ , dimensionless

The coefficients  $h_c$  and  $h_r$  are both evaluated at the clothing surface. Equations (5) and (6) are commonly combined to describe the total sensible heat exchange by these two mechanisms in terms of an operative temperature  $t_o$  and a combined heat transfer coefficient  $h$ :

$$C + R = f_{cl}h(t_{cl} - t_o) \quad (7)$$

where

$$t_o = \frac{h_r \bar{t}_r + h_c t_a}{h_r + h_c} \quad (8)$$

$$h = h_r + h_c \quad (9)$$

Based on Equation (8), operative temperature  $t_o$  can be defined as the average of the mean radiant and ambient air temperatures, weighted by their respective heat transfer coefficients.

The actual transport of sensible heat through clothing involves conduction, convection, and radiation. It is usually most convenient to combine these into a single thermal resistance value  $R_{cl}$ , defined by

$$C + R = (t_{sk} - t_{cl}) / R_{cl} \quad (10)$$

where  $R_{cl}$  is the thermal resistance of clothing in m<sup>2</sup>·K/W.

Since it is often inconvenient to include the clothing surface temperature in calculations, Equations (7) and (10) can be combined to eliminate  $t_{cl}$ :

$$C + R = \frac{t_{sk} - t_o}{R_{cl} + 1 / (f_{cl}h)} \quad (11)$$

where  $t_o$  is defined in Equation (8).

#### Evaporative Heat Loss from Skin

Evaporative heat loss  $E_{sk}$  from skin depends on the amount of moisture on the skin and the difference between the water vapor pressure at the skin and in the ambient environment:

$$\dot{E}_{sk} = \frac{w(p_{sk,s} - p_a)}{R_{e,cl} + 1 / (f_{cl}h_e)} \quad (12)$$

where

- $w$  = skin wettedness, dimensionless
- $p_{sk,s}$  = water vapor pressure at skin, normally assumed to be that of saturated water vapor at  $t_{sk}$ , kPa
- $p_a$  = water vapor pressure in ambient air, kPa
- $R_{e,cl}$  = evaporative heat transfer resistance of clothing layer (analogous to  $R_{cl}$ ), m<sup>2</sup>·kPa/W
- $h_e$  = evaporative heat transfer coefficient (analogous to  $h_c$ ), W/(m<sup>2</sup>·kPa)

Procedures for calculating  $R_{e,cl}$  and  $h_e$  are given in the section on Engineering Data and Measurements. The skin wettedness fraction is the ratio of the actual evaporative heat loss to the maximum possible evaporative heat loss  $E_{max}$  with the same conditions and a completely wet skin ( $w = 1$ ). Skin wettedness is important in determining evaporative heat loss. Maximum evaporative potential  $E_{max}$  occurs when  $w = 1$ .

Evaporative heat loss from the skin is a combination of the evaporation of sweat secreted due to thermoregulatory control mechanisms  $E_{rsw}$  and the natural diffusion of water through the skin  $E_{dif}$ :

$$E_{sk} = E_{rsw} + E_{dif} \quad (13)$$

Evaporative heat loss by regulatory sweating is directly proportional to the rate of regulatory sweat generation:

$$E_{rsw} = \dot{m}_{rsw} h_{fg} \quad (14)$$

where

- $h_{fg}$  = heat of vaporization of water =  $2.43 \times 10^6$  J/kg at 30°C
- $\dot{m}_{rsw}$  = rate at which regulatory sweat is generated, kg/(s·m<sup>2</sup>)

The portion  $w_{rsw}$  of a body that must be wetted to evaporate the regulatory sweat is

$$w_{rsw} = E_{rsw} / E_{max} \quad (15)$$

With no regulatory sweating, skin wettedness due to diffusion is approximately 0.06 for normal conditions. For large values of  $E_{max}$  or long exposures to low humidities, the value may drop to as low as 0.02, since dehydration of the outer skin layers alters its diffusive characteristics. With regulatory sweating, the 0.06 value applies only to the portion of skin not covered with sweat ( $1 - w_{rsw}$ ); the diffusion evaporative heat loss is

$$E_{dif} = (1 - w_{rsw})0.06E_{max} \quad (16)$$

These equations can be solved for  $w$ , given the maximum evaporative potential  $E_{max}$  and the regulatory sweat generation  $E_{rsw}$ :

$$w = w_{rsw} + 0.06(1 - w_{rsw}) = 0.06 + 0.94E_{rsw} / E_{max} \quad (17)$$

Once skin wettedness is determined, evaporative heat loss from the skin is calculated from Equation (12), or by

$$E_{sk} = wE_{max} \quad (18)$$

To summarize, the following calculations determine  $w$  and  $E_{sk}$ :

$E_{max}$	Equation (12), with $w = 1.0$
$E_{rsw}$	Equation (14)
$w$	Equation (17)
$E_{sk}$	Equation (18) or (12)

Although evaporation from the skin  $E_{sk}$  as described in Equation (12) depends on  $w$ , the body does not directly regulate skin wettedness but, rather, regulates sweat rate  $\dot{m}_{rsw}$  [Equation (14)]. Skin wettedness is then an indirect result of the relative activity of the sweat glands and the evaporative potential of the environment. Skin wettedness of 1.0 is the upper theoretical limit. If the aforementioned calculations yield a wettedness of more than 1.0, then Equation (14) is no longer valid because not all the sweat is evaporated. In this case,  $E_{sk} = E_{max}$ .

Skin wettedness is strongly correlated with warm discomfort and is also a good measure of thermal stress. Theoretically, skin wettedness can approach 1.0 while the body still maintains thermoregulatory control. In most situations, it is difficult to exceed 0.8 (Berglund and Gonzalez 1978). Azer (1982) recommends 0.5 as a practical upper limit for sustained activity for a healthy acclimatized person.

### Respiratory Losses

During respiration, the body loses both sensible and latent heat by convection and evaporation of heat and water vapor from the respiratory tract to the inhaled air. A significant amount of heat can be associated with respiration because the air is inspired at ambient conditions and expired nearly saturated at a temperature only slightly cooler than  $t_{cr}$ .

The total heat and moisture losses due to respiration are

$$q_{res} = C_{res} + E_{res} = \frac{\dot{m}_{res}(h_{ex} - h_a)}{A_D} \quad (19)$$

$$\dot{m}_{w, res} = \frac{\dot{m}_{res}(W_{ex} - W_a)}{A_D} \quad (20)$$

where

$$\begin{aligned} \dot{m}_{res} &= \text{pulmonary ventilation rate, kg/s} \\ h_{ex} &= \text{enthalpy of exhaled air, J/kg (dry air)} \end{aligned}$$

$$\begin{aligned} h_a &= \text{enthalpy of inspired (ambient) air, J/kg (dry air)} \\ \dot{m}_{w, res} &= \text{pulmonary water loss rate, kg/s} \\ W_{ex} &= \text{humidity ratio of exhaled air, kg (water vapor)/kg (dry air)} \\ W_a &= \text{humidity ratio of inspired (ambient) air, kg (water vapor)/kg (dry air)} \end{aligned}$$

Under normal circumstances, pulmonary ventilation rate is primarily a function of metabolic rate (Fanger 1970):

$$\dot{m}_{res} = K_{res}MA_D \quad (21)$$

where

$$\begin{aligned} M &= \text{metabolic rate, W/m}^2 \\ K_{res} &= \text{proportionality constant (1.43} \times 10^{-6} \text{ kg/J)} \end{aligned}$$

Respiratory air is nearly saturated and near the body temperature when exhaled. For typical indoor environments (McCutchan and Taylor 1951), the exhaled temperature and humidity ratio are given in terms of ambient conditions:

$$t_{ex} = 32.6 + 0.066t_a + 32W_a \quad (22)$$

$$W_{ex} = 0.0277 + 0.000065t_a + 0.2W_a \quad (23)$$

where ambient  $t_a$  and exhaled  $t_{ex}$  air temperatures are in °C. For extreme conditions, such as outdoor winter environments, different relationships may be required (Holmer 1984).

The humidity ratio of ambient air can be expressed in terms of total or barometric pressure  $p_t$  and ambient water vapor pressure  $p_a$ :

$$W_a = \frac{0.622p_a}{p_t - p_a} \quad (24)$$

Respiratory heat loss is often expressed in terms of sensible  $C_{res}$  and latent  $E_{res}$  heat losses. Two approximations are commonly used to simplify Equations (22) and (23) for that purpose. First, because the dry respiratory heat loss is relatively small compared to the other terms in the heat balance, an average value for  $t_{ex}$  is determined by evaluating Equation (22) at standard conditions of 20°C, 50% rh, sea level. Second, noting in Equation (23) that there is only a weak dependence on  $t_a$ , the second term in Equation (23) and the denominator in Equation (24) are evaluated at standard conditions. Using these approximations and substituting latent heat  $h_{fg}$  and specific heat of air  $c_{p,a}$  at standard conditions,  $C_{res}$  and  $E_{res}$  can be determined by

$$C_{res} = 0.0014M(34 - t_a) \quad (25)$$

$$E_{res} = 0.0173M(5.87 - p_a) \quad (26)$$

where  $p_a$  is expressed in kPa and  $t_a$  is in °C.

### Alternative Formulations

Equations (11) and (12) describe heat loss from skin for clothed people in terms of clothing parameters  $R_{cl}$ ,  $R_{e,cl}$ , and  $f_{cl}$ ; parameters  $h$  and  $h_e$  describe outer surface resistances. Other parameters and definitions are also used. Although these alternative parameters and definitions may be confusing, note that the information presented in one form can be converted to another form. Table 1 presents common parameters and their qualitative descriptions. Table 2 presents equations showing their relationship to each other. Generally, parameters related to dry or evaporative heat flows are not independent because they both rely, in part, on the same physical processes. The **Lewis relation** describes the relationship between convective heat transfer and mass transfer coefficients for a surface [see Equation (39) in Chapter 5]. The Lewis relation can be used to relate convective and evaporative heat transfer coefficients defined in Equations (5) and (12) according to

Table 1 Parameters Used to Describe Clothing

Sensible Heat Flow	Evaporative Heat Flow
$R_{cl}$ = intrinsic clothing insulation, the thermal resistance of a uniform layer of insulation covering the entire body that has the same effect on sensible heat flow as the actual clothing.	$R_{e,cl}$ = evaporative heat transfer resistance of the clothing, the impedance to transport of water vapor of a uniform layer of insulation covering the entire body that has the same effect on evaporative heat flow as the actual clothing.
$R_t$ = total insulation, the total equivalent uniform thermal resistance between the body and the environment: clothing and boundary resistance.	$R_{e,t}$ = total evaporative resistance, the total equivalent uniform impedance to the transport of water vapor from the skin to the environment.
$R_{cle}$ = effective clothing insulation, the increased body insulation due to clothing as compared to the nude state.	$F_{pcl}$ = permeation efficiency, the ratio of the actual evaporative heat loss to that of a nude body at the same conditions, including an adjustment for the increase in surface area due to the clothing.
$R_a$ = boundary insulation, the thermal resistance at the skin boundary for a nude body.	
$R_{a,cl}$ = outer boundary insulation, the thermal resistance at the outer boundary (skin or clothing).	
$h'$ = overall sensible heat transfer coefficient, overall equivalent uniform conductance between the body (including clothing) and the environment.	<b>Parameters Relating Sensible and Evaporative Heat Flows</b>
$h'_{cl}$ = clothing conductance, the thermal conductance of a uniform layer of insulation covering the entire body that has the same effect on sensible heat flow as the actual clothing.	$i_{cl}$ = clothing vapor permeation efficiency, the ratio of the actual evaporative heat flow capability through the clothing to the sensible heat flow capability as compared to the Lewis ratio.
$F_{cle}$ = effective clothing thermal efficiency, the ratio of the actual sensible heat loss to that of a nude body at the same conditions.	$i_m$ = total vapor permeation efficiency, the ratio of the actual evaporative heat flow capability between the skin and the environment to the sensible heat flow capability as compared to the Lewis ratio.
$F_{cl}$ = intrinsic clothing thermal efficiency, the ratio of the actual sensible heat loss to that of a nude body at the same conditions including an adjustment for the increase in surface area due to the clothing.	$i_a$ = air layer vapor permeation efficiency, the ratio of the actual evaporative heat flow capability through the outer air layer to the sensible heat flow capability as compared to the Lewis ratio.

Table 2 Relationships Between Clothing Parameters

Sensible Heat Flow
$R_t = R_{cl} + 1/(hf_{cl}) = R_{cl} + R_a/f_{cl}$
$R_t = R_{cle} + 1/h = R_{cle} + R_a$
$h'_{cl} = 1/R_{cl}$
$h' = 1/R_t$
$h = 1/R_a$
$R_{a,cl} = R_a/f_{cl}$
$F_{cl} = h'/(hf_{cl}) = 1/(1 + f_{cl}hR_{cl})$
$F_{cle} = h'/h = f_{cl}/(1 + f_{cl}hR_{cl}) = f_{cl}F_{cl}$
Evaporative Heat Flow
$R_{e,t} = R_{e,cl} + 1/(h_e f_{cl}) = R_{e,cl} + R_{e,a}/f_{cl}$
$h_e = 1/R_{e,a}$
$h'_{e,cl} = 1/R_{e,cl}$
$h'_e = 1/R_{e,t} = f_{cl}F_{pcl}h_e$
$F_{pcl} = 1/(1 + f_{cl}h_e R_{e,cl})$
Parameters Relating Sensible and Evaporative Heat Flows
$i_{cl}LR = h'_{e,cl}/h'_{cl} = R_{cl}/R_{e,cl}$
$i_mLR = h'_e/h' = R_e/R_{e,t}$
$i_m = (R_{cl} + R_{a,cl})/[(R_{cl}/i_{cl}) + (R_{a,cl}/i_a)]$
$i_aLR = h_e/h$
$i_a = h_c/(h_c + h_r)$

$$h_e/h_c = LR \quad (27)$$

where LR is the **Lewis ratio** and, at typical indoor conditions, equals approximately 16.5 K/kPa. The Lewis relation applies to surface convection coefficients. Heat transfer coefficients that include the effects of insulation layers and/or radiation are still coupled, but the relationship may deviate significantly from that for a surface. The  $i$  terms in Tables 1 and 2 describe how the actual ratios of these parameters deviate from the ideal Lewis ratio (Woodcock 1962; Oohori et al. 1984).

Depending on the combination of parameters used, heat transfer from the skin can be calculated using several different formulations

Table 3 Skin Heat Loss Equations

Sensible Heat Loss
$C + R = (t_{sk} - t_o)/[R_{cl} + 1/(f_{cl}h)]$
$C + R = (t_{sk} - t_o)/R_t$
$C + R = F_{cle}h(t_{sk} - t_o)$
$C + R = F_{cl}f_{cl}h(t_{sk} - t_o)$
$C + R = h'(t_{sk} - t_o)$
Evaporative Heat Loss
$E_{sk} = w(p_{sk,s} - p_a)/[R_{e,cl} + 1/(f_{cl}h_e)]$
$E_{sk} = w(p_{sk,s} - p_a)/R_{e,t}$
$E_{sk} = wF_{pcl}f_{cl}h_e(p_{sk,s} - p_a)$
$E_{sk} = h'_e w(p_{sk,s} - p_a)$
$E_{sk} = h' w i_m LR(p_{sk,s} - p_a)$

(see Tables 2 and 3). If the parameters are used correctly, the end result will be the same regardless of the formulation used.

**Total Skin Heat Loss**

Total skin heat loss—sensible heat plus evaporative heat—can be calculated from any combination of the equations presented in Table 3. Total skin heat loss is used as a measure of the thermal environment; two combinations of parameters that yield the same total heat loss for a given set of body conditions ( $t_{sk}$  and  $w$ ) are considered to be approximately equivalent. The fully expanded skin heat loss equation, showing each parameter that must be known or specified, is as follows:

$$t_{sk} = \frac{t_o - t_a}{R_{cl} + R_{a,cl}} + \frac{w(p_{sk,s} - p_a)}{R_{e,cl} + 1/(LRh_{cl}f_{cl})} \quad (28)$$

where  $t_o$  is the operative temperature and represents the temperature of a uniform environment ( $t_a - \bar{t}_r$ ) that will transfer dry heat at the same rate as in the actual environment [ $t_o = (\bar{t}_r h_r + t_a h_c)/(h_c + h_r)$ ]. After rearranging, Equation (28) becomes

$$q_{sk} = F_{cl}f_{cl}h(t_{sk} - t_o) + wLR F_{pcl}h_e(p_{sk,s} - p_a) \quad (29)$$

This equation allows the trade-off between any two or more parameters to be evaluated under given conditions. If the trade-off

between two specific variables is to be examined, then a simplified form of the equation suffices. The trade-off between operative temperature and humidity is often of interest. Equation (28) can be written in a simpler form for this purpose (Fobelets and Gagge 1988):

$$q_{sk} = h' [(t_{sk} + w i_m LR p_{sk,s}) - (t_o + w i_m LR p_a)] \quad (30)$$

Equation (30) can be used to define a combined temperature  $t_{com}$  which reflects the combined effect of operative temperature and humidity for an actual environment:

$$t_{com} + w i_m LR p_{t_{com}} = t_o + w i_m LR p_a$$

or

$$t_{com} = t_o + w i_m LR p_a - w i_m LR p_{t_{com}} \quad (31)$$

where  $p_{t_{com}}$  is a vapor pressure related in some fixed way to  $t_{com}$  and is analogous to  $p_{wb,s}$  for  $t_{wb}$ . The term  $w i_m LR p_{t_{com}}$  is constant to the extent that  $i_m$  is constant, and any combination of  $t_o$  and  $p_a$  that gives the same  $t_{com}$  will result in the same total heat loss.

Environmental indices are discussed in the section on Environmental Indices. Two of these, the humid operative temperature  $t_{oh}$  and the effective temperature  $ET^*$ , can be represented in terms of Equation (31). The humid operative temperature is that temperature which at 100% rh yields the same total heat loss as for the actual environment:

$$t_{oh} = t_o + w i_m LR (p_a - p_{oh,s}) \quad (32)$$

where  $p_{oh,s}$  is saturated vapor pressure, in kPa, at  $t_{oh}$ .

The effective temperature is the temperature at 50% rh that yields the same total heat loss from the skin as for the actual environment:

$$ET^* = t_o + w i_m LR (p_a - 0.5 p_{ET^*,s}) \quad (33)$$

where  $p_{ET^*,s}$  is saturated vapor pressure, in kPa, at  $ET^*$ .

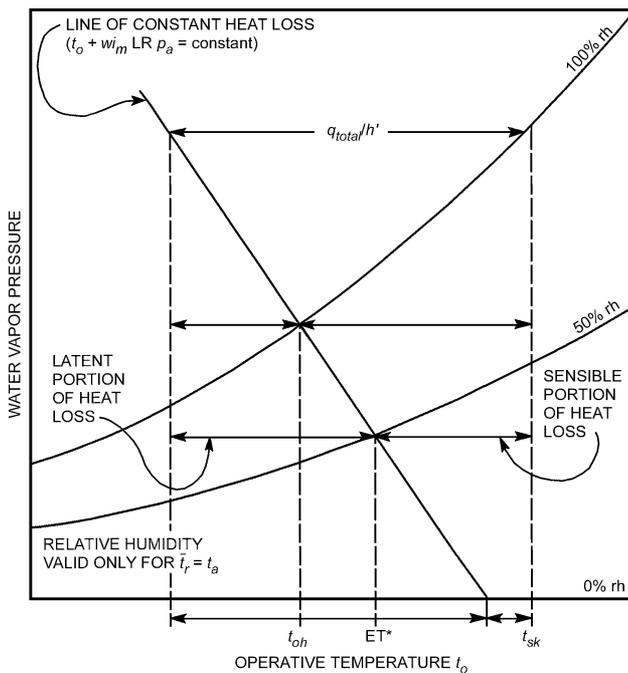

Fig. 2 Constant Skin Heat Loss Line and Its Relationship to  $t_{oh}$  and  $ET^*$

The psychrometric chart in Figure 2 shows a constant total heat loss line and the relationship between these indices. This line represents only one specific skin wettedness and permeation efficiency index. The relationship between indices depends on these two parameters (see the section on Environmental Indices).

### ENGINEERING DATA AND MEASUREMENTS

Applying the preceding basic equations to practical problems of the thermal environment requires quantitative estimates of the body's surface area, metabolic requirements for a given activity and the mechanical efficiency for the work accomplished, evaluation of the heat transfer coefficients  $h_r$  and  $h_c$ , and the general nature of the clothing insulation used. This section provides the necessary data and describes methods used to measure the parameters of the heat balance equation.

#### Metabolic Rate and Mechanical Efficiency

**Maximum Capacity.** In choosing optimal conditions for comfort and health, the rate of work done during routine physical activities must be known, because metabolic power increases in proportion to exercise intensity. Metabolic rate varies over a wide range, depending on the activity, the person, and the conditions under which the activity is performed. Table 4 lists typical metabolic rates for an average adult ( $A_D = 1.8 \text{ m}^2$ ) for activities performed continuously. The highest power a person can maintain for any continuous period is approximately 50% of the maximal capacity to use oxygen (maximum energy capacity).

A unit used to express the metabolic rate per unit DuBois area is the **met**, defined as the metabolic rate of a sedentary person (seated, quiet):  $1 \text{ met} = 58.1 \text{ W/m}^2 = 50 \text{ kcal/(h} \cdot \text{m}^2)$ . A normal, healthy man has a maximum capacity of approximately  $M_{act} = 12 \text{ met}$  at age 20, which drops to 7 met at age 70. Maximum rates for women are about 30% lower. Long-distance runners and trained athletes have maximum rates as high as 20 met. An average 35 year old who does not exercise has a maximum rate of about 10 met, and activities with  $M_{act} > 5 \text{ met}$  are likely to prove exhausting.

**Intermittent Activity.** The activity of many people consists of a mixture of activities or a combination of work-rest periods. A weighted average metabolic rate is generally satisfactory, provided that activities alternate frequently (several times per hour). For example, a person typing 50% of the time, filing while seated 25% of the time, and walking about 25% of the time would have an average metabolic rate of  $0.50 \times 65 + 0.25 \times 70 + 0.25 \times 100 = 75 \text{ W/m}^2$  (see Table 4).

**Accuracy.** Estimating metabolic rates is difficult. The values given in Table 4 indicate metabolic rates only for the specific activities listed. Some entries give a range and some a single value, depending on the source of the data. The level of accuracy depends on the value of  $M_{act}$  and how well the activity can be defined. For well-defined activities with  $M_{act} < 1.5 \text{ met}$  (e.g., reading), Table 4 is sufficiently accurate for most engineering purposes. For values of  $M_{act} > 3$ , where a task is poorly defined or where there are a variety of ways of performing a task (e.g., heavy machine work), the values may be in error by as much as  $\pm 50\%$  for a given application. Engineering calculations should thus allow for potential variations.

**Measurement.** When metabolic rates must be determined more accurately than is possible with tabulated data, physiological measurements with human subjects may be necessary. The rate of metabolic heat produced by the body is most accurately measured by the rate of respiratory oxygen consumption and carbon dioxide production. An empirical equation for metabolic rate is given by Nishi (1981):

**Table 4 Typical Metabolic Heat Generation for Various Activities**

	W/m <sup>2</sup>	met <sup>a</sup>
<b>Resting</b>		
Sleeping	40	0.7
Reclining	45	0.8
Seated, quiet	60	1.0
Standing, relaxed	70	1.2
<b>Walking (on level surface)</b>		
3.2 km/h (0.9 m/s)	115	2.0
4.3 km/h (1.2 m/s)	150	2.6
6.4 km/h (1.8 m/s)	220	3.8
<b>Office Activities</b>		
Reading, seated	55	1.0
Writing	60	1.0
Typing	65	1.1
Filing, seated	70	1.2
Filing, standing	80	1.4
Walking about	100	1.7
Lifting/packing	120	2.1
<b>Driving/Flying</b>		
Car	60 to 115	1.0 to 2.0
Aircraft, routine	70	1.2
Aircraft, instrument landing	105	1.8
Aircraft, combat	140	2.4
Heavy vehicle	185	3.2
<b>Miscellaneous Occupational Activities</b>		
Cooking	95 to 115	1.6 to 2.0
Housecleaning	115 to 200	2.0 to 3.4
Seated, heavy limb movement	130	2.2
<b>Machine work</b>		
sawing (table saw)	105	1.8
light (electrical industry)	115 to 140	2.0 to 2.4
heavy	235	4.0
Handling 50 kg bags	235	4.0
Pick and shovel work	235 to 280	4.0 to 4.8
<b>Miscellaneous Leisure Activities</b>		
Dancing, social	140 to 255	2.4 to 4.4
Calisthenics/exercise	175 to 235	3.0 to 4.0
Tennis, singles	210 to 270	3.6 to 4.0
Basketball	290 to 440	5.0 to 7.6
Wrestling, competitive	410 to 505	7.0 to 8.7

Sources: Compiled from various sources. For additional information, see Buskirk (1960), Passmore and Durmin (1967), and Webb (1964).

<sup>a</sup>1 met = 58.1 W/m<sup>2</sup>

$$M = \frac{21(0.23RQ + 0.77)Q_{O_2}}{A_D} \quad (34)$$

where

$M$  = metabolic rate, W/m<sup>2</sup>

$RQ$  = respiratory quotient; molar ratio of  $Q_{CO_2}$  exhaled to  $Q_{O_2}$  inhaled, dimensionless

$Q_{O_2}$  = volumetric rate of oxygen consumption at conditions (STPD) of 0°C, 101.325 kPa, mL/s

The exact value of the respiratory quotient  $RQ$  used in Equation (34) depends on a person's activity, diet, and physical condition. It can be determined by measuring both carbon dioxide and oxygen in the respiratory airflows, or it can be estimated with reasonable accuracy. A good estimate for the average adult is  $RQ = 0.83$  for light or sedentary activities ( $M < 1.5$  met), increasing proportionately to  $RQ = 1.0$  for extremely heavy exertion ( $M = 5.0$  met). Estimation of  $RQ$  is generally sufficient for all except precision

**Table 5 Heart Rate and Oxygen Consumption at Different Activity Levels**

Level of Exertion	Heart Rate, bpm	Oxygen Consumed, mL/s
Light work	< 90	< 8
Moderate work	90 to 110	8 to 16
Heavy work	110 to 130	16 to 24
Very heavy work	130 to 150	24 to 32
Extremely heavy work	150 to 170	> 32

Source: Astrand and Rodahl (1977).

laboratory measurements since it does not strongly affect the value of the metabolic rate. A 10% error in estimating the respiratory quotient results in an error of less than 3% in the metabolic rate.

A second, much less accurate, method of estimating metabolic rate physiologically is to measure the heart rate. Table 5 shows the relationship between heart rate and oxygen consumption at different levels of physical exertion for a typical person. Once oxygen consumption is estimated from heart rate information, Equation (34) can be used to estimate the metabolic rate. A number of factors other than metabolic rate affect heart rate, such as physical condition, heat, emotional factors, muscles used, etc. Astrand and Rodahl (1977) show that heart rate is only a very approximate measure of metabolic rate and should not be the only source of information where accuracy is required.

**Mechanical Efficiency.** In the heat balance equation, the rate  $W$  of work accomplished must be in the same units as metabolism  $M$  and expressed in terms of  $A_D$  in W/m<sup>2</sup>. The mechanical work done by the muscles for a given task is often expressed in terms of the body's mechanical efficiency  $\mu = W/M$ . It is unusual for  $\mu$  to be more than 0.05 to 0.10; for most activities, it is close to zero. The maximum value under optimal conditions (e.g., bicycle ergometer) is  $\mu = 0.20$  to 0.24 (Nishi 1981). It is common to assume that mechanical work is zero for several reasons: (1) the mechanical work produced is small compared to metabolic rate, especially for office activities; (2) estimates for metabolic rates can often be inaccurate; and (3) this assumption results in a more conservative estimate when designing air-conditioning equipment for upper comfort and health limits. More accurate calculation of heat generation may require estimation of the mechanical work produced for activities where it is significant (walking on a grade, climbing a ladder, bicycling, lifting, etc.). In some cases, it is possible to either estimate or measure the mechanical work. For example, a 90 kg person walking up a 5% grade at 1.0 m/s would be lifting an 882 N (90 kg × 9.8 N/kg) weight over a height of 0.05 m every second, for a work rate of 44 N·m/s = 44 W. This rate of mechanical work would then be subtracted from  $M$  to determine the net heat generated.

### Heat Transfer Coefficients

Values for the linearized radiative heat transfer coefficient, convective heat transfer coefficient, and evaporative heat transfer coefficient are required to solve the equations describing heat transfer from the body.

**Radiative Heat Transfer Coefficient.** The linearized radiative heat transfer coefficient can be calculated by

$$h_r = 4\epsilon \sigma \frac{A_r}{A_D} \left[ 273.2 + \frac{t_{cl} + \bar{t}_r}{2} \right]^3 \quad (35)$$

where

$h_r$  = radiative heat transfer coefficient, W/(m<sup>2</sup>·K)

$\epsilon$  = average emissivity of clothing or body surface, dimensionless

$\sigma$  = Stefan-Boltzmann constant, 5.67 × 10<sup>-8</sup> W/(m<sup>2</sup>·K<sup>4</sup>)

$A_r$  = effective radiation area of body, m<sup>2</sup>

The ratio  $A_r/A_D$  is 0.70 for a sitting person and 0.73 for a standing person (Fanger 1967). Emissivity  $\epsilon$  is close to unity (typically 0.95), unless special reflective materials are used or high-temperature sources are involved. It is not always possible to solve Equation (35) explicitly for  $h_r$ , since  $t_{cl}$  may also be an unknown. Some form of iteration may be necessary if a precise solution is required. Fortunately,  $h_r$  is nearly constant for typical indoor temperatures, and a value of  $4.7 \text{ W}/(\text{m}^2 \cdot \text{K})$  suffices for most calculations. If the emissivity is significantly less than unity, the value should be adjusted by

$$h_r = 4.7\epsilon \quad (36)$$

where  $\epsilon$  represents the area-weighted average emissivity for the clothing/body surface.

**Convective Heat Transfer Coefficient.** Heat transfer by convection is usually caused by air movement within the living space or by body movements. Equations for estimating  $h_c$  under various conditions are presented in Table 6. Where two conditions apply (e.g., walking in moving air), a reasonable estimate can be obtained by taking the larger of the two values for  $h_c$ . Limits have been given to all equations. If no limits were given in the source, reasonable limits have been estimated. Care should be exercised in using these values for seated and reclining persons. The heat transfer coefficients may be accurate, but the effective heat transfer area may be substantially reduced due to body contact with a padded chair or bed.

Quantitative values of  $h_c$  are important, not only in estimating convection loss, but in evaluating (1) operative temperature  $t_o$ , (2) clothing parameters  $I_t$  and  $i_m$ , and (3) rational effective temperatures  $t_{oh}$  and  $ET^*$ . All heat transfer coefficients in Table 6 were evaluated at or near 101.33 kPa. These coefficients should be corrected as follows for atmospheric pressure:

$$h_{cc} = h_c(p_t/101.33)^{0.55} \quad (37)$$

where

$$h_{cc} = \text{corrected convective heat transfer coefficient, W}/(\text{m}^2 \cdot \text{K})$$

$$p_t = \text{local atmospheric pressure, kPa}$$

The combined coefficient  $h$  is the sum of  $h_r$  and  $h_c$ , described in Equation (35) and Table 6, respectively. The coefficient  $h$  governs exchange by radiation and convection from the exposed body surface to the surrounding environment.

**Table 6 Equations for Convection Heat Transfer Coefficients**

Equation	Limits	Condition	Remarks/Sources
$h_c = 8.3V^{0.6}$	$0.2 < V < 4.0$	Seated with moving air	Mitchell (1974)
$h_c = 3.1$	$0 < V < 0.2$		
$h_c = 2.7 + 8.7V^{0.67}$	$0.15 < V < 1.5$	Reclining with moving air	Colin and Houdas (1967)
$h_c = 5.1$	$0 < V < 0.15$		
$h_c = 8.6V^{0.53}$	$0.5 < V < 2.0$	Walking in still air	$V$ is walking speed (Nishi and Gagge 1970)
$h_c = 5.7(M - 0.8)^{0.39}$	$1.1 < M < 3.0$	Active in still air	Gagge et al. (1976)
$h_c = 6.5V^{0.39}$	$0.5 < V < 2.0$	Walking on treadmill in still air	$V$ is treadmill speed (Nishi and Gagge 1970)
$h_c = 14.8V^{0.69}$	$0.15 < V < 1.5$	Standing person in moving air	Developed from data presented by Seppanen et al. (1972)
$h_c = 4.0$	$0 < V < 0.15$		

Note:  $h_c$  in  $\text{W}/(\text{m}^2 \cdot \text{K})$ ,  $V$  in m/s, and  $M$  in mets, where 1 met =  $58.1 \text{ W}/\text{m}^2$ .

**Evaporative Heat Transfer Coefficient.** The evaporative heat transfer coefficient  $h_e$  for the outer air layer of a nude or clothed person can be estimated from the convective heat transfer coefficient using the Lewis relation given in Equation (27). If the atmospheric pressure is significantly different from the reference value (101.33 kPa), the correction to the value obtained from Equation (27) is

$$h_{ec} = h_e(101.33/p_t)^{0.45} \quad (38)$$

where  $h_{ec}$  is the corrected evaporative heat transfer coefficient in  $\text{W}/(\text{m}^2 \cdot \text{kPa})$ .

### Clothing Insulation and Permeation Efficiency

**Thermal Insulation.** The most accurate methods for determining clothing insulation are (1) measurements on heated mannequins (McCullough and Jones 1984, Olesen and Nielsen 1983) and (2) measurements on active subjects (Nishi et al. 1975). For most routine engineering work, estimates based on tables and equations presented in this section are sufficient. Thermal mannequins can measure the sensible heat loss from the "skin" ( $C + R$ ) in a given environment. Equation (11) can then be used to evaluate  $R_{cl}$  if the environmental conditions are well defined and  $f_{cl}$  is measured. Evaluation of clothing insulation on subjects requires measurement of  $t_{sk}$ ,  $t_{cl}$ , and  $t_o$ . The clothing thermal efficiency is calculated by

$$F_{cl} = \frac{t_{cl} - t_o}{t_{sk} - t_o} \quad (39)$$

The intrinsic clothing insulation can then be calculated from mannequin measurements by the following relationship, provided  $f_{cl}$  is measured and conditions are sufficiently well defined to make an accurate determination of  $h$ :

$$R_{cl} = \frac{t_{sk} - t_o}{q} - \frac{1}{hf_{cl}} \quad (40)$$

where  $q$  is heat loss from the mannequin in  $\text{W}/\text{m}^2$ .

Clothing insulation value may be expressed in clo units. In order to avoid confusion, the symbol  $I$  is used with the clo unit instead of the symbol  $R$ . The relationship between the two is

$$R = 0.155I \quad (41)$$

or 1.0 clo is equivalent to  $0.155 \text{ m}^2 \cdot \text{K}/\text{W}$ .

Because clothing insulation cannot be measured for most routine engineering applications, tables of measured values for various clothing ensembles can be used to select an ensemble comparable to the one(s) in question. Table 7 gives values for typical indoor clothing ensembles. More detailed tables are presented by McCullough and Jones (1984) and Olesen and Nielsen (1983). Accuracies for  $I_{cl}$  on the order of  $\pm 20\%$  are typical if good matches between ensembles are found.

Often it is not possible to find an already measured clothing ensemble that matches the one in question. In this case, the ensemble insulation can be estimated from the insulation of individual garments. Table 8 gives a list of individual garments commonly worn. The insulation of an ensemble is estimated from the individual values using a summation formula (McCullough and Jones 1984):

$$I_{cl} = 0.835 \sum_i I_{clu,i} + 0.161 \quad (42)$$

where  $I_{clu,i}$  is the effective insulation of garment  $i$ , and  $I_{cl}$ , as before, is the insulation for the entire ensemble. A simpler and nearly as accurate summation formula is (Olesen 1985)

**Table 7 Typical Insulation and Permeation Efficiency Values for Clothing Ensembles**

Ensemble Description <sup>a</sup>	$I_{cl}$ (clo)	$I_t^b$ (clo)	$f_{cl}$	$i_{cl}$	$i_m^b$

$$I_{cl} = \sum_i I_{clu,i} \tag{43}$$

Either Equation (42) or (43) gives acceptable accuracy for typical indoor clothing. The main source of inaccuracy is in determining the appropriate values for individual garments. Overall accuracies are on the order of ±25% if the tables are used carefully. If it is important to include a specific garment that is not included in Table 8, its insulation can be estimated by (McCullough and Jones 1984)

$$I_{clu,i} = (0.534 + 0.135x_f)(A_G/A_D) - 0.0549 \tag{44}$$

where

$x_f$  = fabric thickness, mm  
 $A_G$  = body surface area covered by garment, m<sup>2</sup>

Values in Table 7 may be adjusted by information in Table 8 and a summation formula. Using this method, values of  $I_{clu,i}$  for the selected items in Table 8 are then added to or subtracted from the ensemble value of  $I_{cl}$  in Table 7.

When a person is sitting, the chair generally has the effect of increasing clothing insulation by up to 0.15 clo, depending on the contact area  $A_{ch}$  between the chair and body (McCullough et al. 1994). A string webbed or beach chair has little or no contact area, and the insulation actually decreases by about 0.1 clo due likely to compression of the clothing in the contact area. In contrast, a cushioned executive chair has a large contact area that can increase the intrinsic clothing insulation by 0.15 clo. For other chairs, the increase in intrinsic insulation ( $\Delta I_{cl}$ ) can be estimated from

$$\Delta I_{cl} = 0.748A_{ch} - 0.1 \tag{45}$$

where  $A_{ch}$  is in m<sup>2</sup>.

For example, a desk chair with a body contact area of 0.27 m<sup>2</sup> has a  $\Delta I_{cl}$  of 0.1 clo. This amount should be added to the intrinsic insulation of the standing clothing ensemble to obtain the insulation of the ensemble when sitting in the desk chair.

Although sitting has the effect of increasing clothing insulation, walking decreases it (McCullough and Hong 1994). The change in

<sup>c</sup>Knee-length

clothing insulation ( $\Delta I_{cl}$ ) can be estimated from the standing intrinsic insulation of the ensemble ( $I_{cl}$ ) and the walking speed (Walkspeed) in steps per minute:

$$\Delta I_{cl} = -0.504I_{cl} - 0.00281(\text{Walkspeed}) + 0.24 \quad (46)$$

For example, the clothing insulation of a person wearing a winter business suit with a standing intrinsic insulation of 1 clo would decrease by 0.52 clo when the person walks at 90 steps per minute (about 3.7 km/h). Thus, when the person is walking, the intrinsic insulation of the ensemble would be 0.48 clo.

**Permeation Efficiency.** Permeation efficiency data for some clothing ensembles are presented in terms of  $i_{cl}$  and  $i_m$  in Table 7. The values of  $i_m$  can be used to calculate  $R_{e,t}$  using the relationships in Table 2. Ensembles worn indoors generally fall in the range  $0.3 < i_m < 0.5$ , and assuming  $i_m = 0.4$  is reasonably accurate (McCullough et al. 1989). This latter value may be used if a good match to ensembles in Table 7 cannot be made. The value of  $i_m$  or  $R_{e,t}$  may be substituted directly into equations for body heat loss calculations (see Table 3). However,  $i_m$  for a given clothing ensemble is a function of the environment as well as the clothing properties. Unless  $i_m$  is evaluated at conditions very similar to the intended application, it is more rigorous to use  $i_{cl}$  to describe the permeation efficiency of the clothing. The value of  $i_{cl}$  is not as sensitive to environmental conditions; thus, given data are more accurate over a wider range of air velocity and radiant and air temperature combinations for  $i_{cl}$  than for  $i_m$ . The relationships in Table 2 can be used to determine  $R_{e,cl}$  from  $i_{cl}$ , and  $i_{cl}$  or  $R_{e,cl}$  can then be used for body heat loss calculations (see Table 3). McCullough et al. (1989) found an average value of  $i_{cl} = 0.34$  for common indoor clothing; this value can be used when other data are not available.

Measurements of  $i_m$  or  $i_{cl}$  may be necessary if unusual clothing (e.g., impermeable or metallized) and/or extreme environments (e.g., high radiant temperatures or high air velocities) are to be addressed. There are three different methods for measuring the permeation efficiency of clothing: the first uses a wet mannequin to measure the effect of sweat evaporation on heat loss (McCullough 1986); the second uses permeation efficiency measurements on component fabrics as well as dry mannequin measurements (Umbach 1980); and the third uses measurements from sweating subjects (Nishi et al. 1975; Holmer 1984).

**Clothing Surface Area.** Many clothing heat transfer calculations require that clothing area factor  $f_{cl}$  be known. The most reliable approach is to measure it using photographic methods (Olesen et al. 1982). Other than actual measurements, the best method is to use previously tabulated data for similar clothing ensembles. Table 7 is adequate for most indoor clothing ensembles. No good method of estimating  $f_{cl}$  for a clothing ensemble from other information is available, although a rough estimate can be made by (McCullough and Jones 1984)

$$f_{cl} = 1.0 + 0.3I_{cl} \quad (47)$$

### Total Evaporative Heat Loss

The total evaporative heat loss (latent heat) from the body due to both respiratory losses and skin losses,  $E_{sk} + E_{res}$ , can be measured directly from the body's rate of mass loss as observed by a sensitive scale:

$$E_{sk} + E_{res} = \frac{h_{fg}}{A_D} \frac{dm}{d\theta} \quad (48)$$

where

- $h_{fg}$  = latent heat of vaporization of water, J/kg
- $m$  = body mass, kg
- $\theta$  = time, s

When using Equation (48), adjustments should be made for any materials consumed (e.g., food and drink), body effluents (e.g., wastes), and metabolic mass losses. Metabolism contributes slightly to mass loss primarily because the oxygen absorbed during respiration is converted to heavier  $\text{CO}_2$  and exhaled. It can be calculated by

$$\frac{dm_{ge}}{d\theta} = Q_{O_2}(1.977RQ - 1.429)/10^6 \quad (49)$$

where

- $dm_{ge}/d\theta$  = rate of mass loss due to respiratory gas exchange, kg/s
- $Q_{O_2}$  = oxygen uptake at STPD, mL/s
- RQ = respiratory quotient
- 1.977 = density of  $\text{CO}_2$  at STPD, kg/m<sup>3</sup>
- 1.429 = density of  $\text{O}_2$  at STPD, kg/m<sup>3</sup>
- STPD = standard temperature and pressure of dry air at 0°C and 101.325 kPa

### Environmental Parameters

The parameters describing the thermal environment that must be measured or otherwise quantified if accurate estimates of human thermal response are to be made are divided into two groups—those that can be measured directly and those that are calculated from other measurements.

**Directly Measured.** Seven of the parameters frequently used to describe the thermal environment are psychrometric and include (1) air temperature  $t_a$ ; (2) wet-bulb temperature  $t_{wb}$ ; (3) dew-point temperature  $t_{dp}$ ; (4) water vapor pressure  $p_a$ ; (5) total atmospheric pressure  $p_r$ ; (6) relative humidity (rh); and (7) humidity ratio  $W_a$ . These parameters are discussed in detail in Chapter 6, and methods for measuring them are discussed in Chapter 14. Two other important parameters include air velocity  $V$  and mean radiant temperature  $\bar{t}_r$ . Air velocity measurements are also discussed in Chapter 14. The radiant temperature is the temperature of an exposed surface in the environment. The temperatures of individual surfaces are usually combined into a mean radiant temperature  $\bar{t}_r$ . Finally, globe temperature  $t_g$ , which can also be measured directly, is a good approximation of the operative temperature  $t_o$  and is also used with other measurements to calculate the mean radiant temperature.

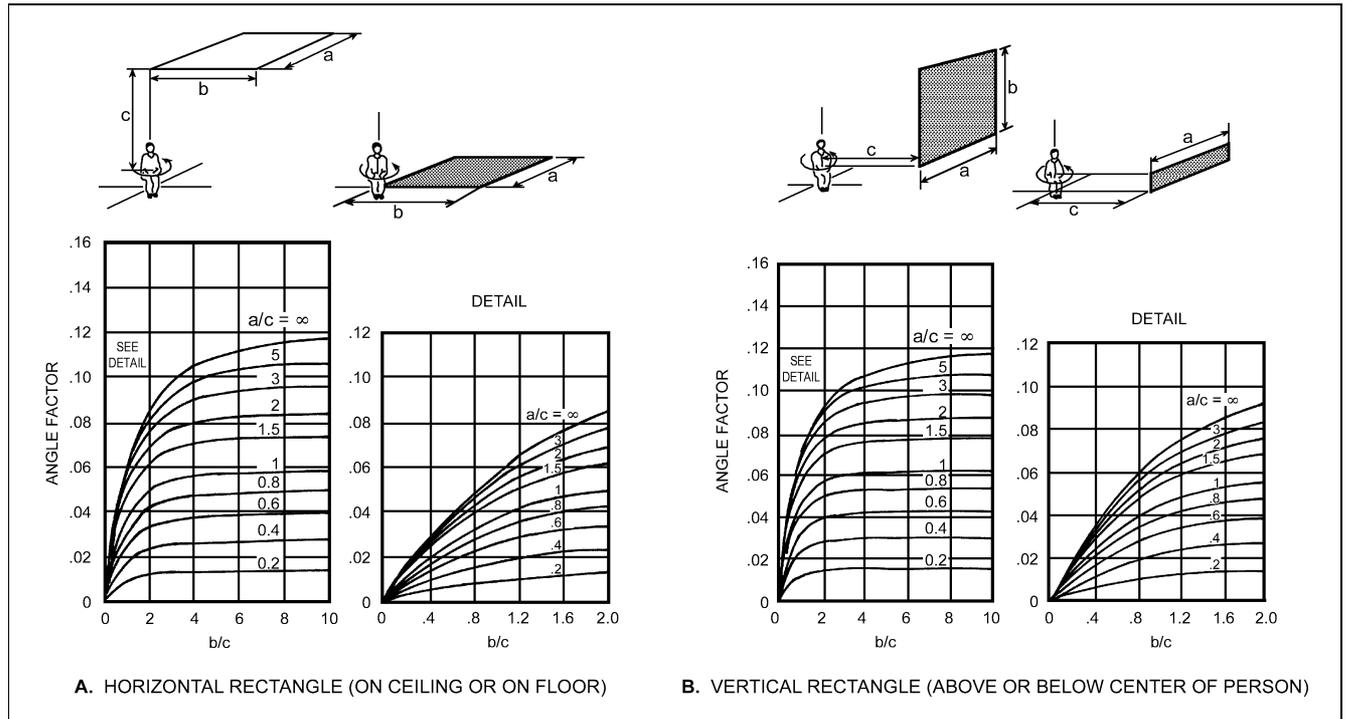

**Calculated Parameters.** The mean radiant temperature  $\bar{t}_r$  is a key variable in making thermal calculations for the human body. It is the uniform temperature of an imaginary enclosure in which radiant heat transfer from the human body equals the radiant heat transfer in the actual nonuniform enclosure. Measurements of the globe temperature, air temperature, and air velocity can be combined to estimate the mean radiant temperature (see Chapter 14). The accuracy of the mean radiant temperature determined this way varies considerably depending on the type of environment and the accuracy of the individual measurements. Since the mean radiant temperature is defined with respect to the human body, the shape of the sensor is also a factor. The spherical shape of the globe thermometer gives a reasonable approximation of a seated person; an ellipsoid-shaped sensor gives a better approximation of the shape of a human, both upright and seated.

The mean radiant temperature can also be calculated from measured values of the temperature of the surrounding walls and surfaces and their positions with respect to the person. As most building materials have a high emittance  $\epsilon$ , all the surfaces in the room can be assumed to be black. The following equation is then used:

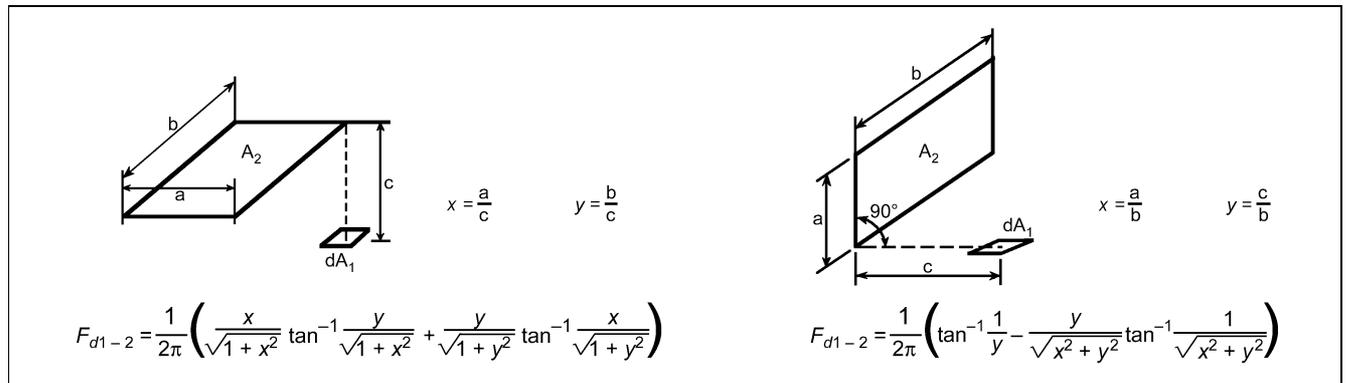

$$\bar{T}_r^4 = T_1^4 F_{p-1} + T_2^4 F_{p-2} + \dots + T_N^4 F_{p-N} \quad (50)$$

where

- $\bar{T}_r$  = mean radiant temperature, K
- $T_N$  = surface temperature of surface  $N$ , K
- $F_{p-N}$  = angle factor between a person and surface  $N$

**Fig. 3 Mean Value of Angle Factor Between Seated Person and Horizontal or Vertical Rectangle when Person is Rotated Around Vertical Axis**  
(Fanger 1982)

**Fig. 4 Analytical Formulas for Calculating Angle Factor for Small Plane Element**

Because the sum of the angle factors is unity, the fourth power of mean radiant temperature equals the mean value of the surrounding surface temperatures to the fourth power, weighted by the respective angle factors. In general, angle factors are difficult to determine, although Figures 3A and 3B may be used to estimate them for rectangular surfaces. The angle factor normally depends on the position and orientation of the person (Fanger 1982).

If relatively small temperature differences exist between the surfaces of the enclosure, Equation (50) can be simplified to a linear form:

$$\bar{t}_r = t_1 F_{p-1} + t_2 F_{p-2} + \dots + t_N F_{p-N} \quad (51)$$

Equation (51) always gives a slightly lower mean radiant temperature than Equation (50), but in many cases the difference is small. If, for example, half the surroundings ( $F_{p-N} = 0.5$ ) has a temperature 5 K higher than the other half, the difference between the

calculated mean radiant temperatures—according to Equations (50) and (51)—is only 0.2 K. If, however, this difference is 100 K, the mean radiant temperature calculated by Equation (51) is 10 K too low.

The mean radiant temperature may also be calculated from the plane radiant temperature  $t_{pr}$  (defined below) in six directions (up, down, right, left, front, back) and for the projected area factors of a person in the same six directions. For a standing person, the mean radiant temperature may be estimated as

$$\begin{aligned} \bar{t}_r = & \{0.08[t_{pr}(\text{up}) + t_{pr}(\text{down})] + 0.23[t_{pr}(\text{right}) \\ & + t_{pr}(\text{left})] + 0.35[t_{pr}(\text{front}) + t_{pr}(\text{back})]\} \\ & \div [2(0.08 + 0.23 + 0.35)] \end{aligned} \quad (52)$$

For a seated person, the mean radiant temperature may be estimated as

$$\begin{aligned} \bar{t}_r = & \{0.18[t_{pr}(\text{up}) + t_{pr}(\text{down})] + 0.22[t_{pr}(\text{right}) \\ & + t_{pr}(\text{left})] + 0.30[t_{pr}(\text{front}) + t_{pr}(\text{back})]\} \\ & + [2(0.18 + 0.22 + 0.30)] \end{aligned} \quad (53)$$

The **plane radiant temperature**  $t_{pr}$ , first introduced by Korsgaard (1949), is the uniform temperature of an enclosure in which the incident radiant flux on one side of a small plane element is the same as that in the actual environment. The plane radiant temperature describes the thermal radiation in one direction, and its value thus depends on the direction. In comparison, the mean radiant temperature  $\bar{t}_r$  describes the thermal radiation for the human body from all directions. The plane radiant temperature can be calculated using Equations (50) and (51) with the same limitations. Area factors are determined from Figure 4.

The **radiant temperature asymmetry**  $\Delta t_{pr}$  is the difference between the plane radiant temperature of the opposite sides of a small plane element. This parameter describes the asymmetry of the radiant environment and is especially important in comfort conditions. Because it is defined with respect to a plane element, its value depends on the orientation of that plane. This orientation may be specified in some situations (e.g., floor to ceiling asymmetry) and not in others. If direction is not specified, the radiant asymmetry should be for the orientation that gives the maximum value.

**CONDITIONS FOR THERMAL COMFORT**

In addition to the previously discussed independent environmental and personal variables influencing thermal response and comfort, other factors may also have some effect. These factors, such as nonuniformity of the environment, visual stimuli, age, and outdoor climate are generally considered secondary factors. Studies by Rohles and Nevins (1971) and Rohles (1973) on 1600 college-age students revealed correlations between comfort level, temperature, humidity, sex, and length of exposure. Many of these correlations are given in Table 9. The thermal sensation scale developed for these studies is called the **ASHRAE thermal sensation scale**:

- +3 hot
- +2 warm
- +1 slightly warm
- 0 neutral
- 1 slightly cool
- 2 cool
- 3 cold

The equations in Table 9 indicate that the women of this study were more sensitive to temperature and less sensitive to humidity than the

**Table 9 Equations for Predicting Thermal Sensation (Y) of Men, Women, and Men and Women Combined**

Exposure Period, h	Subjects	Regression Equations <sup>a, b</sup>	
		$t = \text{dry-bulb temperature, } ^\circ\text{C}$	$p = \text{vapor pressure, kPa}$
1.0	Men	$Y = 0.220 t + 0.233 p - 5.673$	
	Women	$Y = 0.272 t + 0.248 p - 7.245$	
	Both	$Y = 0.245 t + 0.248 p - 6.475$	
2.0	Men	$Y = 0.221 t + 0.270 p - 6.024$	
	Women	$Y = 0.283 t + 0.210 p - 7.694$	
	Both	$Y = 0.252 t + 0.240 p - 6.859$	
3.0	Men	$Y = 0.212 t + 0.293 p - 5.949$	
	Women	$Y = 0.275 t + 0.255 p - 8.622$	
	Both	$Y = 0.243 t + 0.278 p - 6.802$	

<sup>a</sup>Y values refer to the ASHRAE thermal sensation scale.  
<sup>b</sup>For young adult subjects with sedentary activity and wearing clothing with a thermal resistance of approximately 0.5 clo,  $\bar{t}_r = t_a$  and air velocities < 0.2 m/s.

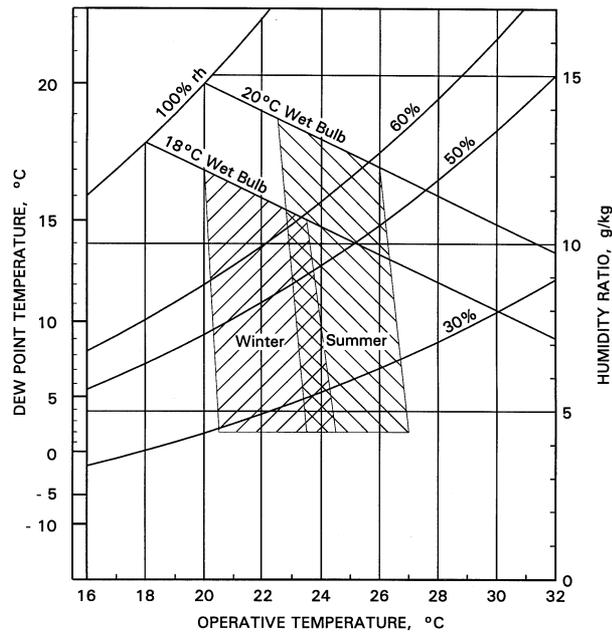

men. But in general about a 3 K change in temperature or a 3 kPa change in water vapor pressure is necessary to change a thermal sensation vote by one unit or temperature category.

Current and past studies are periodically reviewed to update *ASHRAE Standard 55*, Thermal Environmental Conditions for Human Occupancy. This standard specifies conditions or comfort zones where 80% of sedentary or slightly active persons find the environment thermally acceptable.

Because people typically change their clothing for the seasonal weather, *ASHRAE Standard 55* specifies summer and winter comfort zones appropriate for clothing insulation levels of 0.5 and 0.9 clo (0.078 and 0.14 m<sup>2</sup>·K/W), respectively (Figure 5) (Addendum 55a to *ASHRAE Standard 55*). The warmer and cooler temperature borders of the comfort zones are affected by humidity and coincide with lines of constant ET\*. In the middle region of a zone, a typical person wearing the prescribed clothing would have a thermal sensation at or very near neutral. Near the boundary of the warmer zone, a person would feel about +0.5 warmer on the ASHRAE thermal sensation scale; near the boundary of the cooler zone, that person may have a thermal sensation of -0.5.

Comfort zones for other clothing levels can be approximated by decreasing the temperature borders of the zone by 0.6 K for each 0.1 clo increase in clothing insulation and vice versa. Similarly a zone's temperatures can be decreased by 1.4 K per met increase in activity above 1.2 met.

The upper and lower humidity levels of the comfort zones are less precise. Low humidity can lead to drying of the skin and mucous surfaces. Comfort complaints about dry nose, throat, eyes, and skin occur in low-humidity conditions, typically when the dew point is less than 0°C. Liviana et al. (1988) found eye discomfort increased with time in low-humidity environments (dew point < 2°C). Green (1982) quantified that respiratory illness and absenteeism increase in winter with decreasing humidity and found that any increase in humidity from very low levels decreased absenteeism in winter. In compliance with these and other discomfort observations, *ASHRAE Standard 55* recommends that the dew-point temperature of occupied spaces not be less than 2°C.

**Fig. 5 ASHRAE Summer and Winter Comfort Zones**  
 (Acceptable ranges of operative temperature and humidity for people in typical summer and winter clothing during primarily sedentary activity.)

At high humidity levels, too much skin moisture tends to increase discomfort (Gagge 1937, Berglund and Cunningham 1986), particularly skin moisture that is physiological in origin (water diffusion and perspiration). At high humidity levels, thermal sensation alone is not a reliable predictor of thermal comfort (Tanabe et al. 1987). The discomfort appears to be due to the feeling of the moisture itself, increased friction between skin and clothing with skin moisture (Gwosdow et al. 1986), and other factors. To prevent warm discomfort, Nevins et al. (1975) recommended that on the warm side of the comfort zone the relative humidity not exceed 60%.

The upper humidity limits of ASHRAE *Standard 55* were developed theoretically from limited data. However, thermal acceptability data gathered at medium and high humidity levels at summer comfort temperatures with subjects wearing 0.55 clo corroborated the shape of the upper limit and found it corresponded to an 80% thermal acceptability level (Berglund 1995).

### THERMAL NONUNIFORM CONDITIONS AND LOCAL DISCOMFORT

A person may feel thermally neutral as a whole but still feel uncomfortable if one or more parts of the body are too warm or too cold. Nonuniformities may be due to a cold window, a hot surface, a draft, or a temporal variation of these. Even small variations in heat flow cause the thermal regulatory system to compensate, thus increasing the physiological effort of maintaining body temperatures. The boundaries of the comfort zones (Figure 5) of ASHRAE *Standard 55* provide a thermal acceptability level of 90% if the environment is thermally uniform. Because the standard's objective is to specify conditions for 80% acceptability, the standard permits nonuniformities to decrease acceptability by 10%. Fortunately for the designer and user, the effect of common thermal nonuniformities on comfort is quantifiable and predictable as discussed in the following sections. Furthermore, most humans are fairly insensitive to small nonuniformities.

#### Asymmetric Thermal Radiation

Asymmetric or nonuniform thermal radiation in a space may be caused by cold windows, uninsulated walls, cold products, cold or warm machinery, or improperly sized heating panels on the wall or ceiling. In residential buildings, offices, restaurants, etc., the most common reasons for discomfort due to asymmetric thermal radiation are large windows in the winter or improperly sized or installed

ceiling heating panels. At industrial workplaces, the reasons include cold or warm products, cold or warm equipment, etc.

The recommendations in ISO *Standard 7730* and ASHRAE *Standard 55* are based primarily on studies reported by Fanger et al. (1980). These standards include guidelines regarding the radiant temperature asymmetry from an overhead warm surface (heated ceiling) and a vertical cold surface (cold window). Among the studies conducted on the influence of asymmetric thermal radiation are those by McIntyre (1974, 1976), McIntyre and Griffiths (1975), Fanger and Langkilde (1975), McNall and Biddison (1970), and Olesen et al. (1972). These studies all used seated subjects. In these studies, the subjects were always in thermal neutrality and exposed only to the discomfort resulting from excessive asymmetry.

The subjects gave their reactions on their comfort sensation, and a relationship between the radiant temperature asymmetry and the number of subjects feeling dissatisfied was established (Figure 6). Radiant asymmetry, as defined in the section on Environmental Parameters, is the difference in radiant temperature of the environment on opposite sides of the person. More precisely, radiant asymmetry is the difference in radiant temperatures seen by a small flat element looking in opposite directions.

Figure 6 shows that people are more sensitive to asymmetry caused by an overhead warm surface than by a vertical cold surface. The influence of an overhead cold surface and a vertical warm surface is much less. These data are particularly important when applying radiant panels to provide comfort in spaces with large cold surfaces or cold windows.

Other studies of clothed persons in neutral environments found thermal acceptability unaffected by radiant temperature asymmetries of 10 K or less (Berglund and Fobelets 1987) and comfort unaffected by radiant temperature asymmetries of 20 K or less (McIntyre 1975).

#### Draft

Draft is an undesired local cooling of the human body caused by air movement. This is a serious problem, not only in many ventilated buildings but also in automobiles, trains, and aircraft. Draft has been identified as one of the most annoying factors in offices. When people sense draft, they often demand higher air temperatures in the room or that ventilation systems be stopped.

Fanger and Christensen (1986) aimed to establish the percentage of the population feeling draft when exposed to a given mean velocity. Figure 7 shows the percentage of subjects who felt draft on the head region (the dissatisfied) as a function of the mean air velocity at the neck. The head region comprises head, neck, shoulders, and back. The air temperature had a significant influence on the percentage of dissatisfied. There was no significant difference between responses of men and women to draft. The data in Figure 7 apply only to persons wearing normal indoor clothing and performing light, mainly sedentary work. Persons with higher activity levels are not as sensitive to draft (Jones et al. 1986).

A study of the effect of air velocity over the whole body found thermal acceptability unaffected in neutral environments by air speeds of 0.25 m/s or less (Berglund and Fobelets 1987). This study also found no interaction between air speed and radiant temperature asymmetry on subjective responses. This means that acceptability changes and the percent dissatisfied due to draft and radiant asymmetry are independent and additive.

Fanger et al. (1989) investigated the effect of turbulence intensity on sensation of draft. The turbulence intensity had a significant effect on the occurrence of draft sensation. The following model predicts the percentage of people dissatisfied because of draft intensity. The model can be used for quantifying draft risk in spaces and for developing air distribution systems with a low draft risk.

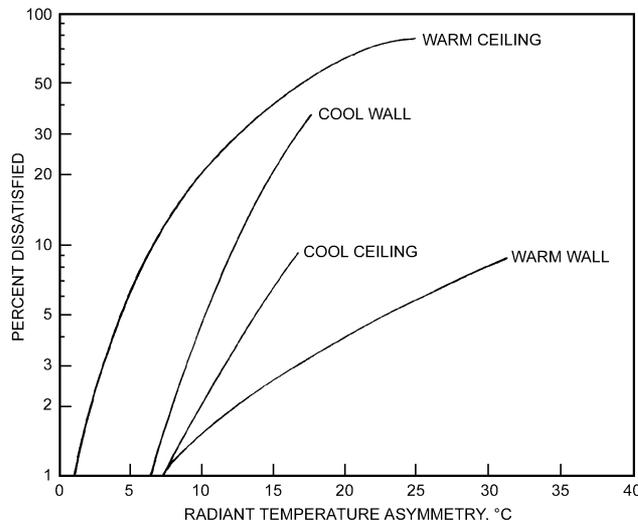

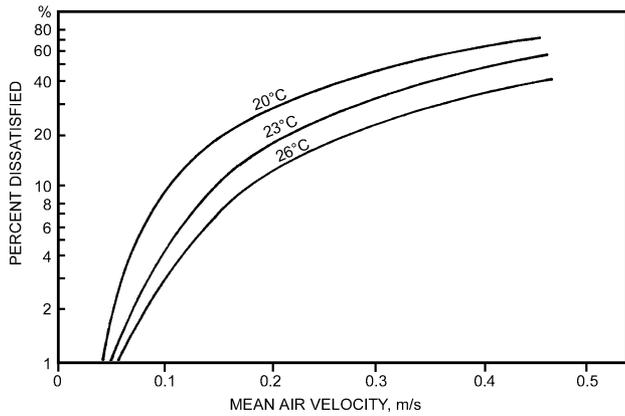

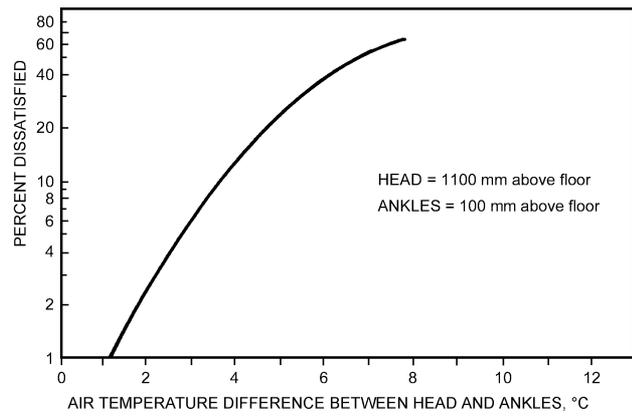

Fig. 6 Percentage of People Expressing Discomfort due to Asymmetric Radiation

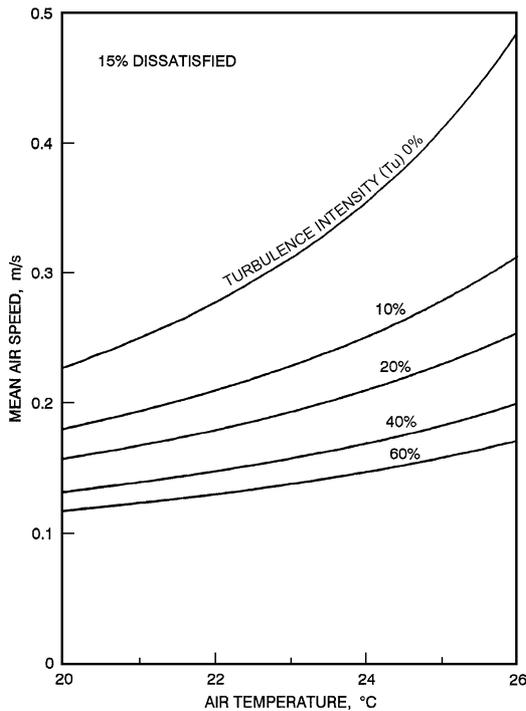

$$PD = (34 - t_a)(V - 0.05)^{0.62}(0.37V Tu + 3.14) \quad (54)$$

**Fig. 7 Percentage of People Dissatisfied as Function of Mean Air Velocity**

**Fig. 9 Percentage of Seated People Dissatisfied as Function of Air Temperature Difference Between Head and Ankles**

**Fig. 8 Draft Conditions Dissatisfying 15% of Population**

where  $Tu$  is the turbulence intensity in % defined by

$$Tu = 100 \frac{V_{sd}}{V} \tag{55}$$

For  $V < 0.05$  m/s, insert  $V = 0.05$ ; and for  $PD > 100\%$ , insert  $PD = 100\%$ .  $V_{sd}$  is the standard deviation of the velocity measured with an omnidirectional anemometer having a 0.2 s time constant.

The model extends the Fanger and Christensen (1986) draft chart model to include turbulence intensity. In this study,  $Tu$  decreases when  $V$  increases. This means that the effect of  $V$  for the experimental data to which the model is fitted are:  $20 < t_a < 26^\circ\text{C}$ ,  $0.05 < V < 0.5$  m/s, and  $0 < Tu < 70\%$ . Figure 8 gives more precisely the curves that result from intersections between planes of constant  $Tu$  and the surfaces of  $PD = 15\%$ .

**Vertical Air Temperature Difference**

In most spaces in buildings, the air temperature normally increases with height above the floor. If the gradient is sufficiently

large, local warm discomfort can occur at the head and/or cold discomfort can occur at the feet, although the body as a whole is thermally neutral. Among the few studies of vertical air temperature differences and the influence of thermal comfort reported are Olesen et al. (1979), McNair (1973), McNair and Fishman (1974), and Eriksson (1975). Subjects were seated in a climatic chamber so they were individually exposed to different air temperature differences between head and ankles (Olesen et al. 1979). During the tests, the subjects were in thermal neutrality because they were allowed to change the temperature level in the test room whenever they desired; the vertical temperature difference, however, was kept unchanged. The subjects gave subjective reactions to their thermal sensation; Figure 9 shows the percentage of dissatisfied as a function of the vertical air temperature difference between head (1.1 m above the floor) and ankles (0.1 m above the floor).

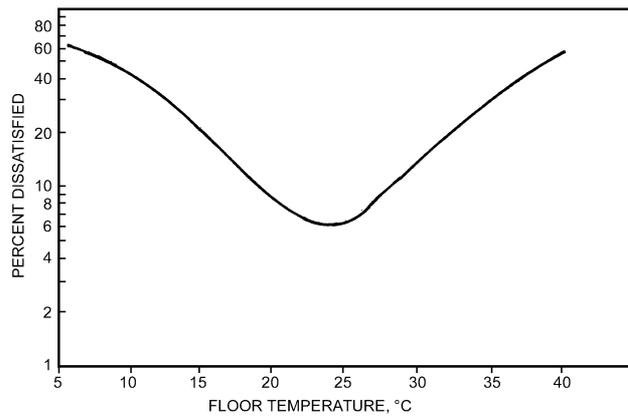

The case where the air temperature at head level is lower than that at ankle level will not be as critical for the occupants. Eriksson (1975) indicated that his subjects could tolerate much greater differences if the head were cooler. This observation is verified in the experiments with asymmetric thermal radiation from a cooled ceiling (Fanger et al. 1985).

**Warm or Cold Floors**

Due to the direct contact between the feet and the floor, local discomfort of the feet can often be caused by a too-high or too-low floor temperature. Also, the floor temperature has a significant influence on the mean radiant temperature in a room. The floor temperature is greatly influenced by the way a building is constructed (e.g., insulation of the floor, above a basement, directly on the ground, above another room, use of floor heating, floors in radiant heated areas). If a floor is too cold and the occupants feel cold discomfort in their feet, a common reaction is to increase the temperature level in the room; in the heating season, this also increases energy consumption. A radiant system, which radiates heat from the floor, can also prevent discomfort from cold floors.

The most extensive studies of the influence of floor temperature on feet comfort were performed by Olesen (1977a, 1977b), who, based on his own experiments and reanalysis of the data from Nevins and Flinner (1958), Nevins et al. (1964), and Nevins and Feyerherm (1967), recorded the following results. For floors occupied by people with bare feet (in swimming halls, gymnasiums, dressing rooms, bathrooms, and bedrooms), flooring material is important. Ranges for some typical floor materials are as follows

Textiles (rugs)	21 to 28°C
Pine floor	22.5 to 28°C
Oak floor	24.5 to 28°C

**Fig. 10 Percentage of People Dissatisfied as Function of Floor Temperature**

Hard linoleum	24 to 28°C
Concrete	26 to 28.5°C

To save energy, flooring materials with a low contact coefficient (cork, wood, carpets), radiant heated floors, or floor heating systems can be used to eliminate the desire for higher ambient temperatures caused by cold feet. These recommendations should also be followed in schools, where children often play directly on the floor.

For floors occupied by people with normal indoor footwear, flooring material is insignificant. Olesen (1977b) found an optimal temperature of 25°C for sedentary and 23°C for standing or walking persons. At the optimal temperature, 6% of the occupants felt warm or cold discomfort in the feet. Figure 10 shows the relationship between floor temperature and percentage of dissatisfied, combining data from experiments with seated and standing subjects. In all experiments, the subjects were in thermal neutrality; thus, the percentage of dissatisfied is only related to the discomfort due to cold or warm feet. No significant difference in floor temperature was preferred by females and males.

## SECONDARY FACTORS AFFECTING COMFORT

Temperature, air speed, humidity, their variation, and personal parameters of metabolism and clothing insulation are primary factors that directly affect energy flow and thermal comfort. However, many secondary factors, some of which are discussed in this section, may more subtly influence comfort.

### Day-to-Day Variations

Fanger (1973) conducted an experiment with a group of subjects, where the preferred ambient temperature for each subject under identical conditions was determined on four different days. Since the standard deviation was only 0.6 K, Fanger concluded that the comfort conditions for the individual can be reproduced and will vary only slightly from day to day.

### Age

Because metabolism decreases slightly with age, many have stated that comfort conditions based on experiments with young and healthy subjects cannot be used for other age groups. Fanger (1982), Fanger and Langkilde (1975), Langkilde (1979), Nevins et al. (1966), and Rohles and Johnson (1972) conducted comfort studies in Denmark and the United States on different age groups (mean age 21 to 84). The studies revealed that the thermal environments preferred by older people do not differ from those preferred by younger people. The lower metabolism in older people is compensated for

by a lower evaporative loss. Collins and Hoinville (1980) confirmed these results.

The fact that young and old people prefer the same thermal environment does not necessarily mean that they are equally sensitive to cold or heat. In practice, the ambient temperature level in the homes of older people is often higher than that for younger people. This may be explained by the lower activity level of elderly people, who are normally sedentary for a greater part of the day.

### Adaptation

Many believe that people can acclimatize themselves by exposure to hot or cold surroundings, so that they prefer other thermal environments. Fanger (1982) conducted experiments involving subjects from the United States, Denmark, and tropical countries. The latter group was tested in Copenhagen immediately after their arrival by plane from the tropics where they had lived all their lives. Other experiments were conducted for two groups exposed to cold daily. One group comprised subjects who had been doing sedentary work in cold surroundings (in the meat-packing industry) for 8 h daily for at least 1 year. The other group consisted of winter swimmers who bathed in the sea daily.

Only slight differences in both the preferred ambient temperature and the physiological parameters in the comfort conditions were reported for the various groups. These results indicate that people cannot adapt to preferring warmer or colder environments. It is therefore likely that the same comfort conditions can be applied throughout the world. However, in determining the preferred ambient temperature from the comfort equations, a clo-value that corresponds to the local clothing habits should be used. A comparison of field comfort studies from different parts of the world shows significant differences in clothing habits depending on, among other things, the outdoor climate (Nicol and Humphreys 1972). According to these results, adaptation has little influence on the preferred ambient temperature. In uncomfortable warm or cold environments, however, adaptation will often have an influence. People used to working and living in warm climates can more easily accept and maintain a higher work performance in hot environments than people from colder climates.

### Sex

Previously cited experiments by Fanger (1982), Fanger and Langkilde (1975), and Nevins et al. (1966) used equal numbers of male and female subjects, so comfort conditions for the two sexes can be compared. The experiments show that men and women prefer almost the same thermal environments. Women's skin temperature and evaporative loss are slightly lower than those for men, and this balances the somewhat lower metabolism of women. The reason that women often prefer higher ambient temperatures than men may be partly explained by the lighter clothing normally worn by women.

### Seasonal and Circadian Rhythms

Since people cannot adapt to prefer warmer or colder environments, it follows that there is no difference between comfort conditions in winter and in summer. McNall et al. (1968) confirmed this in an investigation where results of winter and summer experiments showed no difference. On the other hand, it is reasonable to expect the comfort conditions to alter during the day because the internal body temperature has a daily rhythm—a maximum occurring late in the afternoon, and a minimum early in the morning.

In determining the preferred ambient temperature for each of 16 subjects both in the morning and in the evening, Fanger et al. (1974) and Ostberg and McNicholl (1973) observed no difference. Furthermore, Fanger et al. (1973) found only small fluctuations in the preferred ambient temperature during a simulated 8 h workday (sedentary work). There is a slight tendency to prefer somewhat

warmer surroundings before lunch, but none of the fluctuations are significant.

### PREDICTION OF THERMAL COMFORT

Thermal comfort and thermal sensation can be predicted several ways. One way is to use Figure 5 and Table 9 and adjust for clothing and activity levels that differ from those of the figure. More numerical and rigorous predictions are possible by using the PMV-PPD and two-node models described in this section.

#### Steady-State Energy Balance

Fanger (1982) related the comfort data to physiological variables. At a given level of metabolic activity  $M$ , and when the body is not far from thermal neutrality, the mean skin temperature  $t_{sk}$  and sweat rate  $E_{rsw}$  are the only physiological parameters influencing the heat balance. However, heat balance alone is not sufficient to establish thermal comfort. In the wide range of environmental conditions where heat balance can be obtained, only a narrow range provides thermal comfort. The following linear regression equations based on data from Rohles and Nevins (1971) indicate values of  $t_{sk}$  and  $E_{rsw}$  that provide thermal comfort.

$$t_{sk,req} = 35.7 - 0.0275(M - W) \quad (56)$$

$$E_{rsw,req} = 0.42(M - W - 58.15) \quad (57)$$

At higher activity levels, sweat loss increases and the mean skin temperature decreases. Both reactions increase the heat loss from the body core to the environment. These two empirical relationships link the physiological and heat flow equations and thermal comfort perceptions. By substituting these values into Equation (11) for  $C + R$ , and into Equations (17) and (18) for  $E_{sk}$ , Equation (1), the energy balance equation, can be used to determine combinations of the six environmental and personal parameters that optimize comfort for steady-state conditions.

Fanger (1982) reduced these relationships to a single equation, which assumed all sweat generated is evaporated, eliminating clothing permeation efficiency  $i_{cl}$  as a factor in the equation. This assumption is valid for normal indoor clothing worn in typical indoor environments with low or moderate activity levels. At higher activity levels ( $M_{act} > 3$  met), where a significant amount of sweating occurs even at optimum comfort conditions, this assumption may limit accuracy. The reduced equation is slightly different from the heat transfer equations developed here. The radiant heat exchange is expressed in terms of the Stefan-Boltzmann law (instead of using  $h_r$ ), and diffusion of water vapor through the skin is expressed as a diffusivity coefficient and a linear approximation for saturated vapor pressure evaluated at  $t_{sk}$ . The combination of environmental and personal variables that produces a neutral sensation may be expressed as follows:

$$\begin{aligned} M - W = & 3.96 \times 10^{-8} f_{cl} [(t_{cl} + 273)^4 - (\bar{t}_r + 273)^4] \\ & + f_{cl} h_c (t_{cl} - t_a) \\ & + 3.05 [5.73 - 0.007(M - W) - p_a] \\ & + 0.42 [(M - W) - 58.15] \\ & + 0.0173M(5.87 - p_a) \\ & + 0.0014M(34 - t_a) \end{aligned} \quad (58)$$

where

$$\begin{aligned} t_{cl} = & 35.7 - 0.0275(M - W) \\ & - R_{cl} \{ (M - W) \\ & - 3.05 [5.73 - 0.007(M - W) - p_a] \\ & - 0.42 [(M - W) - 58.15] - 0.0173M(5.87 - p_a) \\ & - 0.0014M(34 - t_a) \} \end{aligned} \quad (59)$$

The values of  $h_c$  and  $f_{cl}$  can be estimated from tables and equations given in the section on Engineering Data and Measurements. Fanger used the following relationships:

$$h_c = \begin{cases} 2.38(t_{cl} - t_a)^{0.25} & 2.38(t_{cl} - t_a)^{0.25} > 12.1\sqrt{V} \\ 12.1\sqrt{V} & 2.38(t_{cl} - t_a)^{0.25} < 12.1\sqrt{V} \end{cases} \quad (60)$$

$$f_{cl} = \begin{cases} 1.0 + 0.2 I_{cl} & I_{cl} < 0.5 \text{ clo} \\ 1.05 + 0.1 I_{cl} & I_{cl} > 0.5 \text{ clo} \end{cases} \quad (61)$$

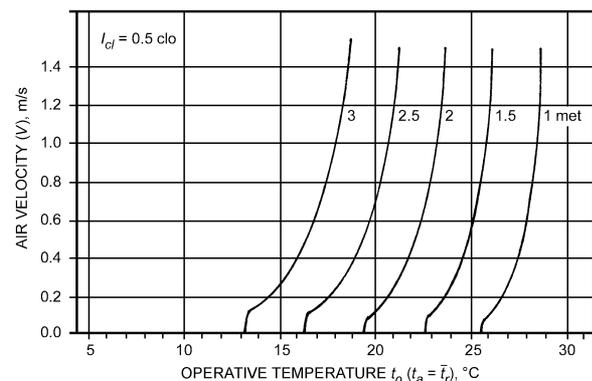

Figures 11 and 12 show examples of how Equation (58) can be used.

Equation (58) is expanded to include a range of thermal sensations by using a **predicted mean vote (PMV) index**. The PMV index predicts the mean response of a large group of people according to the ASHRAE thermal sensation scale. Fanger (1970) related PMV to the imbalance between the actual heat flow from the body in a given environment and the heat flow required for optimum comfort at the specified activity by the following equation:

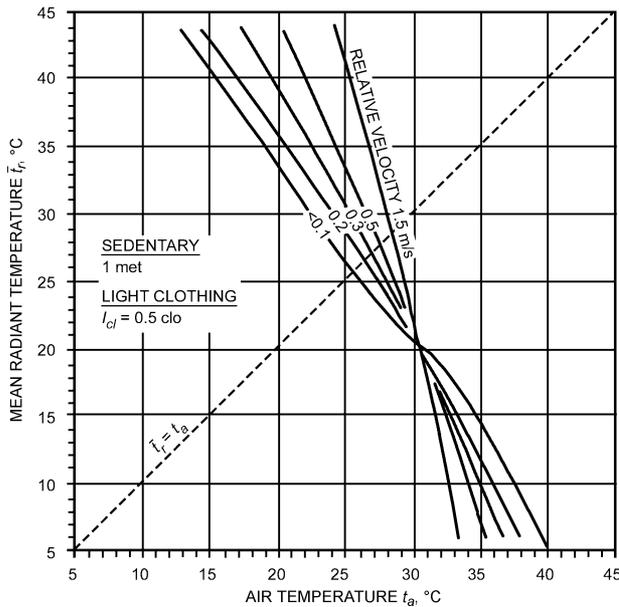

$$PMV = [0.303 \exp(-0.036M) + 0.028]L \quad (62)$$

where  $L$  is the thermal load on the body, defined as the difference between internal heat production and heat loss to the actual environment for a person hypothetically kept at comfort values of  $t_{sk}$  and  $E_{rsw}$  at the actual activity level. Thermal load  $L$  is then the difference between the left and right sides of Equation (58) calculated for the actual values of the environmental conditions. As part of this calculation, the clothing temperature  $t_{cl}$  is found by iteration as

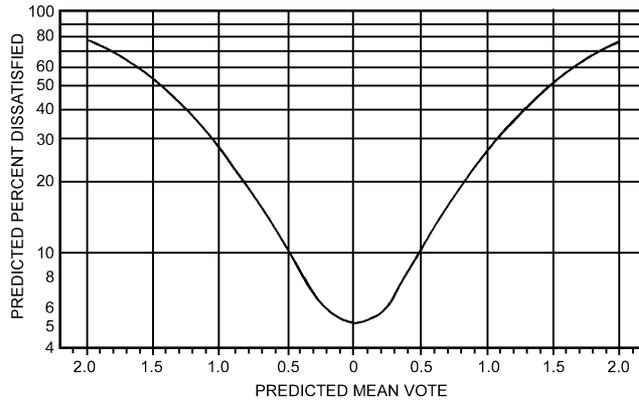

$$\begin{aligned} t_{cl} = & 35.7 - 0.028(M - W) \\ & - R_{cl} \{ 39.6 \times 10^{-9} f_{cl} [(t_{cl} + 273)^4 - (\bar{t}_r + 273)^4] \\ & + f_{cl} h_c (t_{cl} - t_a) \} \end{aligned} \quad (63)$$

**Fig. 11 Air Velocities and Operative Temperatures at 50% rh Necessary for Comfort (PMV = 0) of Persons in Summer Clothing at Various Levels of Activity**

**Fig. 12 Air Temperatures and Mean Radiant Temperatures Necessary for Comfort (PMV = 0) of Sedentary Persons in Summer Clothing at 50% rh**

**Fig. 13 Predicted Percentage of Dissatisfied (PPD) as Function of Predicted Mean Vote (PMV)**

After estimating the PMV with Equation (62) or another method, the **predicted percent dissatisfied** (PPD) with a condition can also be estimated. Fanger (1982) related the PPD to the PMV as follows:

$$PPD = 100 - 95 \exp[-(0.03353 PMV^4 + 0.2179 PMV^2)] \quad (64)$$

where dissatisfied is defined as anybody not voting -1, +1, or 0. This relationship is shown in Figure 13. A PPD of 10% corresponds to the PMV range of  $\pm 0.5$ , and even with PMV = 0, about 5% of the people are dissatisfied.

The **PMV-PPD model** is widely used and accepted for design and field assessment of comfort conditions. ISO *Standard 7730* includes a short computer listing that facilitates computing PMV and PPD for a wide range of parameters.

### Two-Node Model

The PMV model is useful only for predicting steady-state comfort responses. The two-node model can be used to predict physiological responses or responses to transient situations, at least for low

and moderate activity levels in cool to very hot environments (Gagge et al. 1971, 1986). The two-node model is a simplification of more complex thermoregulatory models developed by Stolwijk and Hardy (1966). The simple, lumped parameter model considers a human as two concentric thermal compartments that represent the skin and the core of the body.

The **skin compartment** simulates the epidermis and dermis and is about 1.6 mm thick. Its mass, which is about 10% of the total body, depends on the amount of blood flowing through it for thermoregulation. The temperature in a compartment is assumed to be uniform so that the only temperature gradients are between compartments. In a cold environment, blood flow to the extremities may be reduced to conserve the heat of vital organs, resulting in axial temperature gradients in the arms, legs, hands, and feet. Heavy exercise with certain muscle groups or asymmetric environmental conditions may also cause nonuniform compartment temperatures and limit the accuracy of the model.

All the heat is assumed to be generated in the **core compartment**. In the cold, shivering and muscle tension may generate additional metabolic heat. This increase is related to skin and core temperature depressions from their set point values, or

$$M_{shiv} = 19.4(34 - t_{sk})(37 - t_{cr}) \quad (65)$$

where the temperature terms are set to zero if they become negative.

The core loses energy when the muscles do work on the surroundings. Heat is also lost from the core through respiration. The rate of respiratory heat loss is due to sensible and latent changes in the respired air and the ventilation rate as in Equations (19) and (20).

In addition, heat is conducted passively from the core to the skin. This is modeled as a massless thermal conductor [ $K = 5.28 \text{ W}/(\text{m}^2 \cdot \text{K})$ ]. A controllable heat loss path from the core consists of pumping variable amounts of warm blood to the skin for cooling. This peripheral blood flow  $Q_{bl}$  in  $\text{L}/\text{h} \cdot \text{m}^2$  depends on skin and core temperature deviations from their respective set points:

$$Q_{bl} = \frac{BFN + c_{dil}(t_{cr} - 37)}{1 + S_{ir}(34 - t_{sk})} \quad (66)$$

The temperature terms can only be  $> 0$ . If the deviation is negative, the term is set to zero. For average persons, the coefficients BFN,  $c_{dil}$ , and  $S_{ir}$  are 6.3, 175 and 0.5. Further, skin blood flow  $Q_{bl}$  is limited to a maximum of  $90 \text{ L}/(\text{h} \cdot \text{m}^2)$ .

Dry (sensible) heat loss  $q_{dry}$  from the skin flows through the clothing by conduction and then by parallel paths to the air and surrounding surfaces. Evaporative heat follows a similar path, flowing through the clothing and through the air boundary layer. Maximum evaporation  $E_{max}$  occurs if the skin is completely covered with sweat. The actual evaporation rate  $E_{sw}$  depends on the size  $w$  of the sweat film:

$$E_{sw} = w E_{max} \quad (67)$$

where  $w$  is  $E_{rsw}/E_{max}$ .

The rate of regulatory sweating  $E_{rsw}$  (rate at which water is brought to the surface of the skin in  $\text{W}/\text{m}^2$ ) can be predicted by skin and core temperature deviations from their set points:

$$E_{rsw} = c_{sw}(t_b - t_{bset}) \exp[-(t_{sk} - 34)/10.7] \quad (68)$$

where  $t_b = (1 - \alpha_{sk})t_{cr} + \alpha_{sk}t_{sk}$  and is the mean body temperature, and  $c_{sw} = 170 \text{ W}/(\text{m}^2 \cdot \text{K})$ . The temperature deviation terms are set to zero when negative.  $\alpha_{sk}$  is the fraction of the total body mass that is considered to be thermally in the skin compartment.

$$\alpha_{sk} = 0.0418 + \frac{0.745}{10.8Q_{bl} - 0.585} \quad (69)$$

Regulatory sweating  $Q_{rsw}$  in the model is limited to 1 L/h·m<sup>2</sup> or 670 W/m<sup>2</sup>.  $E_{rsw}$  evaporates from the skin, but if  $E_{rsw}$  is greater than  $E_{max}$ , the excess drips off.

An energy balance on the core yields

$$M + M_{shiv} = W + q_{res} + (K + SKBFC_{p, bl})(t_{cr} - t_{sk}) + m_{cr}c_{cr}\frac{dt_{cr}}{d\theta} \quad (70)$$

and for the skin,

$$(K + SKBFC_{p, bl})(t_{cr} - t_{sk}) = q_{dry} + q_{evap} + m_{sk}c_{sk}\frac{dt_{sk}}{d\theta} \quad (71)$$

where  $c_{cr}$ ,  $c_{sk}$ , and  $c_{p,bl}$  are specific heats of core, skin, and blood [3500, 3500, and 4190 J/(kg·K), respectively], and SKBF is  $\rho_{bl}Q_{bl}$  where  $\rho_{bl}$  is density of blood (12.9 kg/L).

Equations (70) and (71) can be rearranged in terms of  $dt_{sk}/d\theta$  and  $dt_{cr}/d\theta$  and numerically integrated with small time steps (10 to 60 s) from initial conditions or previous values to find  $t_{cr}$  and  $t_{sk}$  at any time.

After calculating values of  $t_{sk}$ ,  $t_{cr}$ , and  $w$ , the model uses empirical expressions to predict thermal sensation (TSENS) and thermal discomfort (DISC). These indices are based on 11-point numerical scales, where positive values represent the warm side of neutral sensation or comfort, and negative values represent the cool side. TSENS is based on the same scale as PMV, but with extra terms for  $\pm 4$  (very hot/cold) and  $\pm 5$  (intolerably hot/cold). Recognizing the same positive/negative convention for warm/cold discomfort, DISC is defined as

- 5 intolerable
- 4 limited tolerance
- 3 very uncomfortable
- 2 uncomfortable and unpleasant
- 1 slightly uncomfortable but acceptable
- 0 comfortable

TSENS is defined in terms of deviations of mean body temperature  $t_b$  from cold and hot set points representing the lower and upper limits for the zone of evaporative regulation:  $t_{b,c}$  and  $t_{b,h}$ , respectively. The values of these set points depend on the net rate of internal heat production and are calculated by

$$t_{b,c} = \frac{0.194}{58.15}(M - W) + 36.301 \quad (72)$$

$$t_{b,h} = \frac{0.347}{58.15}(M - W) + 36.669 \quad (73)$$

TSENS is then determined by

$$\text{TSENS} = \begin{cases} 0.4685(t_b - t_{b,c}) & t_b < t_{b,c} \\ 4.7\eta_v(t_b - t_{b,c}) / (t_{b,h} - t_{b,c}) & t_{b,c} \leq t_b \leq t_{b,h} \\ 4.7\eta_v + 0.4685(t_b - t_{b,h}) & t_{b,h} < t_b \end{cases} \quad (74)$$

where  $\eta_v$  is the evaporative efficiency (assumed to be 0.85).

DISC is numerically equal to TSENS when  $t_b$  is below its cold set point  $t_{b,c}$  and it is related to skin wettedness when body temperature is regulated by sweating:

$$\text{DISC} = \begin{cases} 0.4685(t_b - t_{b,c}) & t_b < t_{b,c} \\ \frac{4.7(E_{rsw} - E_{rsw,req})}{E_{max} - E_{rsw,req} - E_{dif}} & t_{b,c} \leq t_b \end{cases} \quad (75)$$

where  $E_{rsw,req}$  is calculated as in Fanger's model, using Equation (57).

### Adaptive Models

Adaptive models do not actually predict comfort responses but rather the almost constant conditions under which people are likely to be comfortable in buildings. In general, people naturally adapt and may also make various adjustments to themselves and their surroundings to reduce discomfort and physiological strain. It has been observed that, through adaptive actions, an acceptable degree of comfort in residences and offices is possible over a range of air temperatures from about 17 to 31°C (Humphreys and Nicol 1998).

The adaptive adjustments are typically conscious behavioral actions such as altering clothing, posture, activity schedules, activity levels, rate of working, diet, ventilation, air movement, and local temperature. The adaptations may also include unconscious longer term changes to physiological set points and gains for the control of shivering, skin blood flow, and sweating, as well as adjustments to body fluid levels and salt loss. However, only limited documentation and information on such changes is available.

An important driving force behind the adaptive process is the pattern of outside weather conditions and the exposure to them. This is the principal input to the adaptive models that have evolved to date, and these models predict likely comfort temperatures  $t_c$  or ranges of  $t_c$  from monthly mean outdoor temperatures  $t_{out}$ . Such a model (Humphreys and Nicol 1998), based on data from a wide range of buildings, climates, and cultures is

$$t_c = 24.2 + 0.43(t_{out} - 22)\exp\left(-\frac{(t_{out} - 22)^2}{24\sqrt{2}}\right) \quad (76)$$

The adaptive models are useful to guide design and energy decisions. They may also be useful to specify building temperatures set points throughout the year. A recent ASHRAE-sponsored study on adaptive models compiled an extensive database from past field studies to study, develop, and test adaptive models. For climates and buildings where cooling and central heating are not required, the study suggests the following model (de Dear and Brager 1998):

$$t_{oc} = 18.9 + 0.255t_{out} \quad (77)$$

where  $t_{oc}$  is the operative comfort temperature.

In general, the value of using an adaptive model to specify set points or guide temperature control strategies is likely to increase with the freedom that occupants are given to adapt (e.g., by having flexible working hours, locations, or dress codes).

### Zones of Comfort and Discomfort

The section on Two-Node Model shows that comfort and thermal sensation are not necessarily the same variable, especially for a person in the zone of evaporative thermal regulation. Figures 14 and 15 show this difference for the standard combination of met-clo-air movement used in the standard effective temperature. Figure 14 demonstrates that practically all basic physiological variables predicted by the two-node model are functions of ambient temperature and are relatively independent of vapor pressure. All exceptions occur at relative humidities above 80% and as the isotherms reach the  $ET^* = 41.5^\circ\text{C}$  line, where regulation by evaporation fails. Figure 15 shows that lines of constant  $ET^*$  and wettedness are functions of both ambient temperature and vapor

pressure. Thus, human thermal responses are divided into two classes—those in Figure 14, which respond only to heat stress from the environment, and those in Figure 15, which respond to both the heat stress from the environment and the resultant heat strain (Stolwijk et al. 1968).

For warm environments, any index with isotherms parallel to skin temperature is a reliable index of thermal sensation alone, and not of discomfort caused by increased humidity. Indices with isotherms parallel to  $ET^*$  are reliable indicators of discomfort or dissatisfaction with thermal environments. For a fixed exposure time to cold, lines of constant  $t_{sk}$ ,  $ET^*$ , and  $t_o$  are essentially identical, and cold sensation is no different from cold discomfort. For a state of comfort with sedentary or light activity, lines of constant  $t_{sk}$  and  $ET^*$  coincide. Thus comfort and thermal sensations coincide in this region as well. The upper and lower temperature limits for comfort at these levels can be specified either by thermal sensation (Fanger 1982) or by  $ET^*$ , as is done in ASHRAE Standard 55, since lines of constant comfort and lines of constant thermal sensation should be identical.

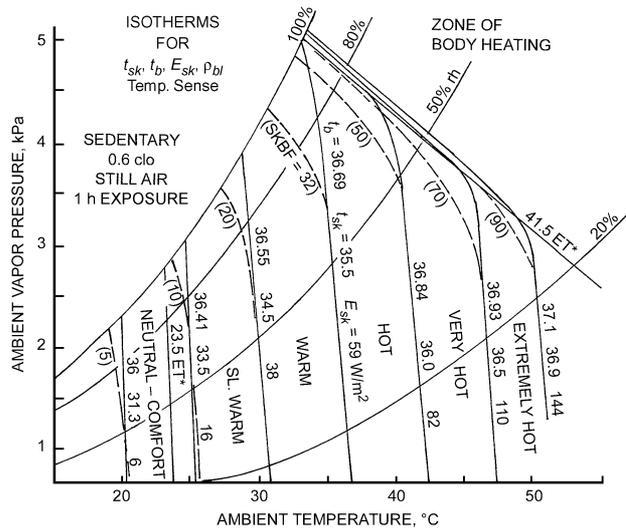

Fig. 14 Effect of Environmental Conditions on Physiological Variables

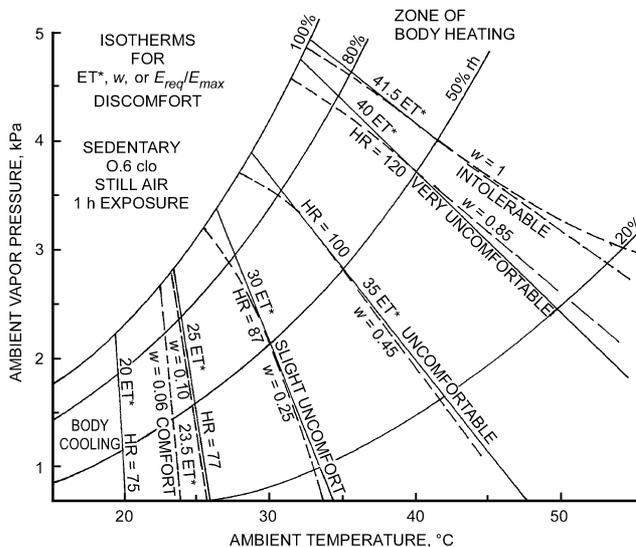

Fig. 15 Effect of Thermal Environment on Discomfort

ENVIRONMENTAL INDICES

An environmental index combines two or more parameters (e.g., air temperature, mean radiant temperature, humidity, or air velocity) into a single variable. Indices simplify the description of the thermal environment and the stress imposed by an environment. Environmental indices may be classified according to how they are developed. Rational indices are based on the theoretical concepts presented earlier. Empirical indices are based on measurements with subjects or on simplified relationships that do not necessarily follow theory. Indices may also be classified according to their application, generally either heat stress or cold stress.

Effective Temperature

The **effective temperature**  $ET^*$  is probably the most common environmental index, and it has the widest range of application. It combines temperature and humidity into a single index, so two environments with the same  $ET^*$  should evoke the same thermal response even though they have different temperatures and humidities; but they must have the same air velocities.

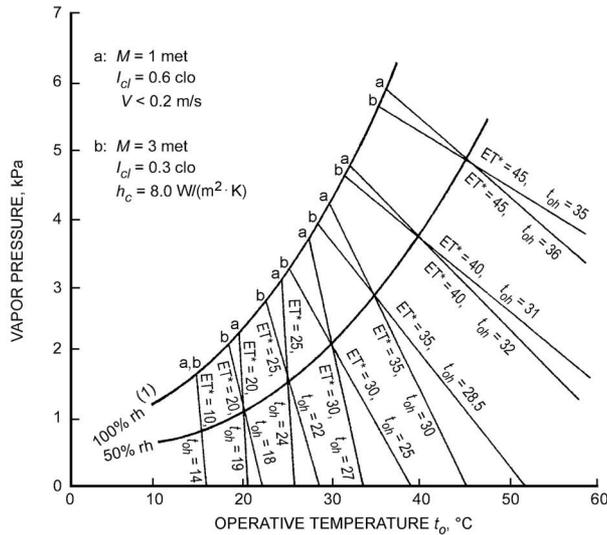

The original empirical effective temperature was developed by Houghten and Yaglou (1923). Gagge et al. (1971) defined a new effective temperature using a rational approach. Defined mathematically in Equation (33), this is the temperature of an environment at 50% rh that results in the same total heat loss  $E_{sk}$  from the skin as in the actual environment.

Because the index is defined in terms of operative temperature  $t_o$ , it combines the effects of three parameters ( $t_r$ ,  $t_a$ , and  $p_a$ ) into a single index. Skin wettedness  $w$  and the permeability index  $i_m$  must be specified and are constant for a given  $ET^*$  line for a particular situation. The two-node model is used to determine skin wettedness in the zone of evaporative regulation. At the upper limit of regulation,  $w$  approaches 1.0; at the lower limit,  $w$  approaches 0.06. Skin wettedness equals one of these values when the body is outside the zone of evaporative regulation. Since the slope of a constant  $ET^*$  line depends on skin wettedness and clothing moisture permeability, effective temperature for a given temperature and humidity may depend on the clothing and activity of the person. This difference is shown in Figure 16. At low skin wettedness, the air humidity has little influence, and lines of constant  $ET^*$  are nearly vertical. As skin wettedness increases due to activity and/or heat stress, the lines become more horizontal and the influence of humidity is much more pronounced. The ASHRAE comfort envelope shown in Figure 5 is described in terms of  $ET^*$ .

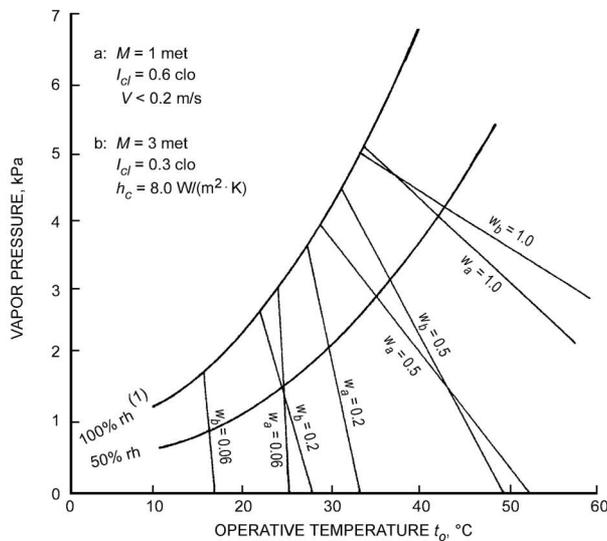

Since  $ET^*$  depends on clothing and activity, it is not possible to generate a universal  $ET^*$  chart. Calculation of  $ET^*$  can also be tedious, requiring the solution of multiple coupled equations to determine skin wettedness. A standard set of conditions representative of typical indoor applications is used to define a **standard effective temperature**  $SET^*$ . The standard effective temperature is then defined as the equivalent air temperature of an isothermal environment at 50% rh in which a subject, while wearing clothing standardized for the activity concerned, has the same heat stress (skin temperature  $t_{sk}$ ) and thermoregulatory strain (skin wettedness  $w$ ) as in the actual environment.

Humid Operative Temperature

The **humid operative temperature**  $t_{oh}$  is the temperature of a uniform environment at 100% rh in which a person loses the same total amount of heat from the skin as in the actual environment. This index is defined mathematically in Equation (32). It is analogous to  $ET^*$ , the only difference being that it is defined at 100% rh and 0% rh rather than at 50% rh. Figures 2 and 16 indicate that lines of constant  $ET^*$  are also lines of constant  $t_{oh}$ . However, the values of these two indices differ for a given environment.

A. EFFECT OF CONDITIONS ON ET\*, t<sub>oh</sub>

B. EFFECT OF CONDITIONS ON WETTEDNESS, w

Fig. 16 Effective Temperature ET\* and Skin Wettedness w [Adapted from Nishi et al. (1975) and Gonzalez et al. (1978)]

**Heat Stress Index**

Originally proposed by Belding and Hatch (1955), this rational index is the ratio of the total evaporative heat loss  $E_{sk}$  required for thermal equilibrium (the sum of metabolism plus dry heat load) to the maximum evaporative heat loss  $E_{max}$  possible for the environment, multiplied by 100, for steady-state conditions ( $S_{sk}$  and  $S_{cr}$  are zero) and with  $t_{sk}$  held constant at 35°C. The ratio  $E_{sk}/E_{max}$  equals skin wettedness  $w$  [Equation (18)]. When **heat stress index (HSI)** > 100, body heating occurs; when HSI < 0, body cooling occurs. Belding and Hatch (1955) limited  $E_{max}$  to 700 W/m<sup>2</sup>, which corresponds to a sweat rate of approximately 280 mg/(s·m<sup>2</sup>). When  $t_{sk}$  is constant, loci of constant HSI coincide with lines of constant ET\* on a psychrometric chart. Other indices based on wettedness have the same applications (Gonzalez et al. 1978, Belding 1970, ISO Standard 7933) but differ in their treatment of  $E_{max}$  and the effect of clothing. Table 10 describes physiological factors associated with HSI values.

Table 10 Evaluation of Heat Stress Index

Heat Stress Index	Physiological and Hygienic Implications of 8 h Exposures to Various Heat Stresses
0	No thermal strain.
10	Mild to moderate heat strain. If job involves higher intellectual functions, dexterity, or alertness, subtle to substantial decrements in performance may be expected. In performing heavy physical work, little decrement is expected, unless ability of individuals to perform such work under no thermal stress is marginal.
20	
30	
40	Severe heat strain involving a threat to health unless men are physically fit. Break-in period required for men not previously acclimatized. Some decrement in performance of physical work is to be expected. Medical selection of personnel desirable, because these conditions are unsuitable for those with cardiovascular or respiratory impairment or with chronic dermatitis. These working conditions are also unsuitable for activities requiring sustained mental effort.
50	
60	
70	Very severe heat strain. Only a small percentage of the population may be expected to qualify for this work. Personnel should be selected: (a) by medical examination, and (b) by trial on the job (after acclimatization). Special measures are needed to assure adequate water and salt intake. Amelioration of working conditions by any feasible means is highly desirable, and may be expected to decrease the health hazard while increasing job efficiency. Slight "indisposition," which in most jobs would be insufficient to affect performance, may render workers unfit for this exposure.
80	
90	
100	The maximum strain tolerated daily by fit, acclimatized young men.

**Index of Skin Wettedness**

**Skin wettedness**  $w$  is the ratio of observed skin sweating  $E_{sk}$  to the  $E_{max}$  of the environment as defined by  $t_{sk}$ ,  $t_a$ , humidity, air movement, and clothing in Equation (12). Except for the factor of 100, it is essentially the same as HSI. Skin wettedness is more closely related to the sense of discomfort or unpleasantness than to temperature sensation (Gagge et al. 1969a,b; Gonzalez et al. 1978).

**Wet-Bulb Globe Temperature**

The WBGT is an environmental heat stress index that combines dry-bulb temperature  $t_{db}$ , a **naturally ventilated** (not aspirated) wet-bulb temperature  $t_{nwb}$ , and black globe temperature  $t_g$ , according to the relation (Dukes-Dobos and Henschel 1971, 1973)

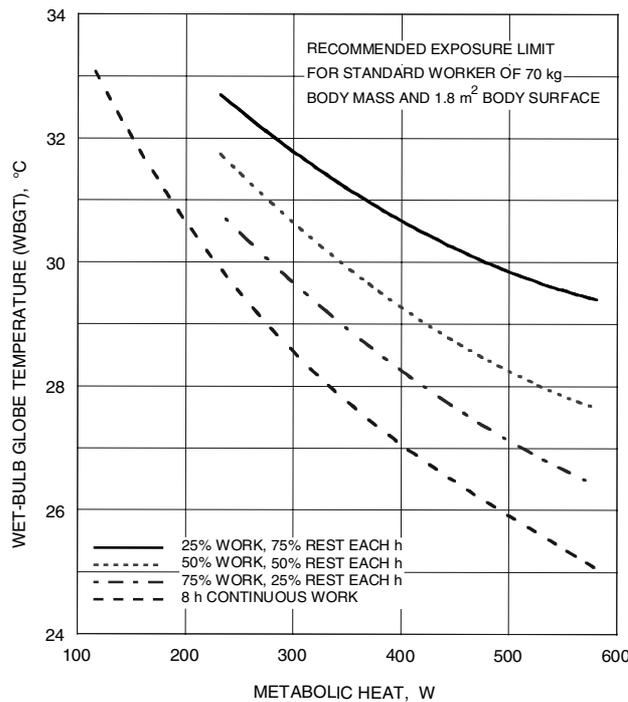

$$WBGT = 0.7t_{nwb} + 0.2t_g + 0.1t_a \quad (78)$$

This form of the equation is usually used where solar radiation is present. The naturally ventilated wet-bulb thermometer is left exposed to the sunlight, but the air temperature  $t_a$  sensor is shaded. In enclosed environments, Equation (78) is simplified by dropping the  $t_a$  term and using a 0.3 weighting factor for  $t_g$ .

The black globe thermometer responds to air temperature, mean radiant temperature, and air movement, while the naturally ventilated wet-bulb thermometer responds to air humidity, air movement, radiant temperature, and air temperature. Thus, WBGT is a function of all four environmental factors affecting human environmental heat stress.

The WBGT is a better index of heat stress than the old ET; it shows almost as good a correlation with sweat rate as do the later corrected effective temperature (CET) and effective temperature with radiation (ETR) indices (Minard 1961); the CET and ETR both require direct measurement of wind velocity which, for accuracy, requires special instruments and trained technicians.

The WBGT index is widely used for estimating the heat stress potential of industrial environments (Davis 1976). In the United States, the National Institute of Occupational Safety and Health (NIOSH) developed criteria for a heat-stress-limiting standard (NIOSH 1986). ISO Standard 7243 also uses the WBGT. Figure 17 graphically summarizes the permissible heat exposure limits,

**Fig. 17 Recommended Heat Stress Exposure Limits for Heat Acclimatized Workers**  
[Adapted from NIOSH (1986)]

expressed as working time per hour, for a fit individual, as specified for various WBGT levels. Values apply for normal permeable clothing (0.6 clo) and must be adjusted for heavy or partly vapor-permeable clothing. The USAF has recommended adjusting the measured WBGT upwards by 6 K for personnel wearing chemical protective clothing or body armor. This type of clothing increases the resistance to sweat evaporation about threefold (higher if it is totally impermeable), requiring an adjustment in WBGT level to compensate for reduced evaporative cooling at the skin.

Several mathematical models are available for predicting WBGT from the environmental factors: air temperature, psychrometric wet-bulb temperature, mean radiant temperature, and air motion (Azer and Hsu 1977; Sullivan and Gorton 1976). A simpler approach, involving plotting WBGT lines on a psychrometric chart, is recommended. Isotherms of WBGT are parallel and have negative slopes varying from 0.17 kPa/K for still air to 0.20 kPa/K for air motion greater than 1 m/s. By comparison, psychrometric wet-bulb lines have negative slopes of about 0.07 kPa/K, or about 35% as steep.

**Wet-Globe Temperature**

The WGT, introduced by Botsford (1971), is a simpler approach to measuring environmental heat stress than the WBGT. The measurement is made with a wetted globe thermometer called a Botsball, which consists of a 65 mm black copper sphere covered with a fitted wet black mesh fabric, into which the sensor of a dial thermometer is inserted. A polished stem attached to the sphere supports the thermometer and contains a water reservoir for keeping the sphere covering wet. This instrument is suspended by the stem at the indoor (or outdoor) site to be measured.

Onkaram et al. (1980) have shown that WBGT can be predicted with reasonable accuracy from WGT for temperate to warm environments with medium to high humidities. With air temperatures

between 20 and 35°C, dew points ranging from 7 to 25°C (relative humidities above 30%), and wind speeds of 7 m/s or less, the experimental regression equation ( $r = 0.98$ ) in °C for an outdoor environment is

$$WBGT = 1.044(WGT) - 0.187 \tag{79}$$

This equation should not be used outside the experimental range given because data from hot-dry desert environments show differences between WBGT and WGT that are too large (6 K and above) to be adjusted by Equation (79) (Matthew et al. 1986). At very low humidity and high wind, WGT approaches the psychrometric wet-bulb temperature, which is greatly depressed below  $t_a$ . However, in the WBGT,  $t_{wgb}$  accounts for only 70% of the index value, with the remaining 30% at or above  $t_a$ .

Ciriello and Snook (1977) handle the problem by providing a series of regression equations, the choice depending on the levels of wind speed, humidity, and radiant heat. They report an accuracy of conversion from WGT to WBGT within 0.4 K (90% confidence level), if good estimates of wind speed, humidity, and radiation level are available.

**Wind Chill Index**

The wind chill index (WCI) is an empirical index developed from cooling measurements obtained in Antarctica on a cylindrical flask partly filled with water (Siple and Passel 1945). The index describes the rate of heat loss from the cylinder by radiation and convection for a surface temperature of 33°C, as a function of ambient temperature and wind velocity. As originally proposed,

$$WCI = (10.45 + 10\sqrt{V} - V)(33 - t_a) \text{ in kcal/ (m}^2 \cdot \text{h)} \tag{80}$$

where  $V$  and  $t_a$  are in m/s and °C, respectively, and WCI units are kcal/(h·m<sup>2</sup>). Multiply WCI by 1.162 to convert to SI units of W/m<sup>2</sup>. The 33°C surface temperature was chosen to be representative of the mean skin temperature of a resting human in comfortable surroundings.

A number of valid objections have been raised about this formulation. Cooling rate data from which it was derived were measured on a 57 mm diameter plastic cylinder, making it unlikely that WCI would be an accurate measure of heat loss from exposed flesh, which has different characteristics from the plastic (curvature, roughness, and radiation exchange properties) and is invariably below 33°C in a cold environment. Moreover, values given by the equation peak at 90 km/h, then decrease with increasing velocity.

Nevertheless, for velocities below 80 km/h, this index reliably expresses combined effects of temperature and wind on subjective discomfort. For example, if the calculated WCI is less than 1400 and actual air temperature is above -10°C, there is little risk of frostbite during brief exposures (1 h or less), even for bare skin. However, at a WCI of 2000 or more, the probability is high that exposed flesh will begin to freeze in 1 min or less unless measures are taken to shield the exposed skin (such as a fur ruff to break up the wind around the face).

Rather than using the WCI to express the severity of a cold environment, meteorologists use an index derived from the WCI called the **equivalent wind chill temperature**. This is the ambient temperature that would produce, in a calm wind (defined for this application as 6.4 km/h), the same WCI as the actual combination of air temperature and wind velocity. Equivalent wind chill temperature  $t_{eq,wc}$  can be calculated by

$$t_{eq,wc} = -0.04544(WCI) + 33 \tag{81}$$

Table 11 Equivalent Wind Chill Temperatures of Cold Environments

Wind Speed, km/h	Actual Thermometer Reading, °C												
	10	5	0	-5	-10	-15	-20	-25	-30	-35	-40	-45	-50
Equivalent Wind Chill Temperature, °C

Notes: Cooling power of environment expressed as an equivalent temperature under calm conditions [Equation (81)].

Winds greater than 70 km/h have little added chilling effect.

where  $t_{eq,wc}$  is in °C (and frequently referred to as a **wind chill factor**), thus distinguishing it from WCI, which is given either as a cooling rate or as a plain number with no units. For velocities less than 6.4 km/h (1.8 m/s), Equation (81) does not apply, and the wind chill temperature is equal to the air temperature.

Equation (81) does not imply cooling to below ambient temperature, but recognizes that, because of wind, the cooling rate is increased as though it were occurring at the lower equivalent wind chill temperature. Wind accelerates the rate of heat loss, so that the skin surface is cooling faster toward the ambient temperature. Table 11 shows a typical wind chill chart, expressed in equivalent wind chill temperature.

**SPECIAL ENVIRONMENTS**

**Infrared Heating**

Optical and thermal properties of skin must be considered in studies concerning the effects of infrared radiation in (1) producing changes in skin temperature and skin blood flow, and (2) evoking sensations of temperature and comfort (Hardy 1961). Although the body can be considered to have the properties of water, thermal sensation and heat transfer with the environment require a study of the skin and its interaction with visible and infrared radiation.

Figure 18 shows how skin reflectance and absorptance vary for a blackbody heat source at the temperature (in K) indicated. These curves show that darkly pigmented skin is heated more by direct radiation from a high-intensity heater at 2500 K than is lightly pigmented skin. With low-temperature and low-intensity heating equipment used for total area heating, there is minimal, if any, difference. Also, in practice, clothing minimizes differences.

Changes in skin temperature caused by high-intensity infrared radiation depend on the thermal conductivity, density, and specific heat of the living skin (Lipkin and Hardy 1954). Modeling of skin heating with the heat transfer theory yields a parabolic relation between exposure time and skin temperature rise for nonpenetrating radiation:

$$t_{sf} - t_{si} = \Delta t = 2J\alpha\sqrt{\theta / (\pi k\rho c_p)} \tag{82}$$

where

- $t_{sf}$  = final skin temperature, °C
- $t_{si}$  = initial skin temperature, °C
- $J$  = irradiance from source radiation temperatures, W/m<sup>2</sup>
- $\theta$  = time, h
- $k$  = specific thermal conductivity of tissue, W/(m·K)

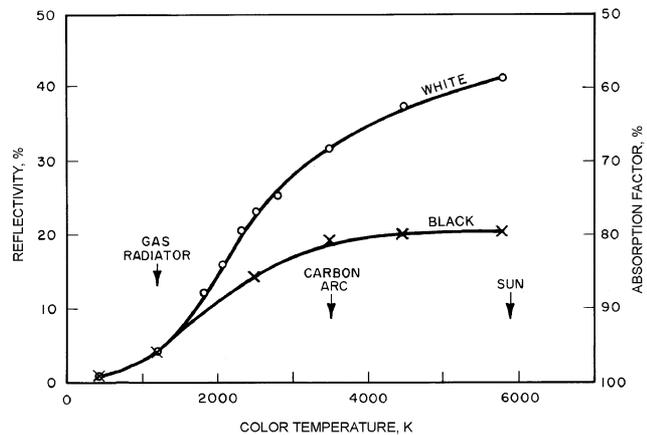

Fig. 18 Variation in Skin Reflection and Absorptivity for Blackbody Heat Sources

- $\rho$  = density, kg/m<sup>3</sup>
- $c_p$  = specific heat, J/kg·K
- $\alpha$  = skin absorptance at radiation temperatures, dimensionless

Product  $k\rho c_p$  is the physiologically important quantity that determines temperature elevation of skin or other tissue on exposure to nonpenetrating radiation. Fatty tissue, because of its relatively low specific heat, is heated more rapidly than moist skin or bone. Experimentally,  $k\rho c_p$  values can be determined by plotting  $\Delta t^2$  against  $1.13J^2\theta$  (Figure 19). The relationship is linear, and the slopes are inversely proportional to the  $k\rho c_p$  of the specimen. Comparing leather and water with body tissues suggests that thermal inertia values depend largely on tissue water content.

Living tissues do not conform strictly to this simple mathematical formula. Figure 20 compares excised skin with living skin with normal blood flow, and skin with blood flow occluded. For short exposure times, the  $k\rho c_p$  of normal skin is the same as that in which blood flow has been stopped; excised skin heats more rapidly due to unavoidable dehydration that occurs postmortem. However, with longer exposure to thermal radiation, vasodilation increases blood flow, cooling the skin. For the first 20 s of irradiation, skin with normally constricted blood vessels has a  $k\rho c_p$  value one-fourth that for skin with fully dilated vessels.

Skin temperature is the best single index of thermal comfort. The most rapid changes in skin temperature occur during the first 60 s of

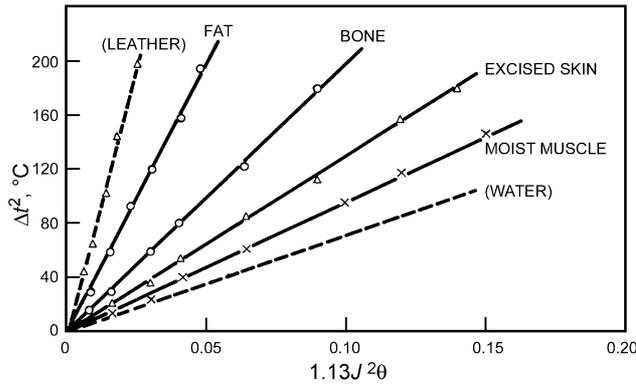

Fig. 19 Comparing Thermal Inertia of Fat, Bone, Moist Muscle, and Excised Skin to That of Leather and Water

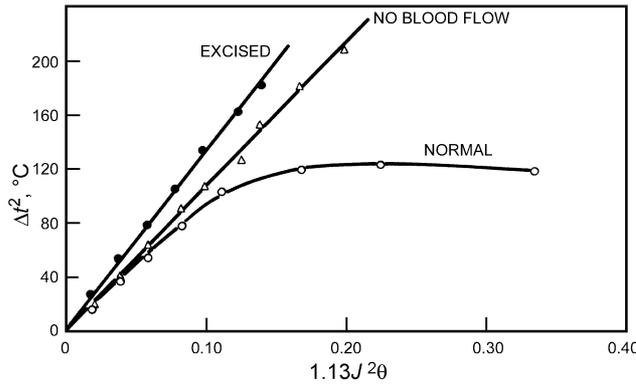

Fig. 20 Thermal Inertias of Excised, Bloodless, and Normal Living Skin

exposure to infrared radiation. During this initial period, thermal sensation and the heating rate of the skin vary with the quality of infrared radiation (color temperature in K). Because radiant heat from a gas-fired heater is absorbed at the skin surface, the same unit level of absorbed radiation during the first 60 s of exposure can cause an even warmer initial sensation than penetrating solar radiation. Skin heating curves tend to level off after a 60 s exposure (Figure 20); this means that a relative balance is quickly created between heat absorbed, heat flow to the skin surface, and heat loss to the ambient environment. Therefore, the effects of radiant heating on thermal comfort should be examined for conditions approaching thermal equilibrium.

Stolwijk and Hardy (1966) described an unclothed subject's response for a 2 h exposure to temperatures of 5 to 35°C. Nevins et al. (1966) showed a relation between ambient temperatures and thermal comfort of clothed, resting subjects. For any given uniform environmental temperature, both initial physiological response and degree of comfort can be determined for a subject at rest.

Physiological implications for radiant heating can be defined by two environmental temperatures: (1) mean radiant temperature  $\bar{t}_r$  and (2) ambient air temperature  $t_a$ . For this discussion on radiant heat, assume that (1) relative humidity is less than 50%, and (2) air movement is low and constant, with an equivalent convection coefficient of 2.9 W/(m<sup>2</sup>·K).

The equilibrium equation, describing heat exchange between skin surface at mean temperature  $t_{sk}$  and the radiant environment, is given in Equation (28), and can be transformed to give (see Table 2)

$$M' - E_{sk} - F_{cle}[h_r(t_{sk} - \bar{t}_r) + h_c(t_{sk} - t_o)] = 0 \quad (83)$$

where  $M'$  is the net heat production ( $M - W$ ) less respiratory losses. By algebraic transformation, Equation (83) can be rewritten as

$$M' + \text{ERF} \cdot F_{cle} = E_{sk} + (h_r + h_c)(t_{sk} - t_a)F_{cle} \quad (84)$$

where  $\text{ERF} = h_r(\bar{t}_r - t_a)$  is the effective radiant field and represents the additional radiant exchange with the body when  $\bar{t}_r \neq t_a$ .

The last term in Equation (84) describes heat exchange with an environment uniformly heated to temperature  $t_a$ . The term  $h_r$ , evaluated in Equation (35), is also a function of posture, for which factor  $A_r/A_D$  can vary from 0.67 for crouching to 0.73 for standing. For preliminary analysis, a useful value for  $h_r$  is 4.7 W/(m<sup>2</sup>·K), which corresponds to a normally clothed (at 24°C) sedentary subject. Ambient air movement affects  $h_c$ , which appears only in the right-hand term of Equation (84).

Although the linear radiation coefficient  $h_r$  is used in Equations (83) and (84), the same definition of ERF follows if the fourth power radiation law is used. By this law, assuming emissivity of the body surface is unity, the ERF term in Equation (84) is

$$\text{ERF} = \sigma(A_r/A_D)[(\bar{t}_r + 273)^4 - (t_a + 273)^4]F_{cle} \quad (85)$$

where  $\sigma$  is the Stefan-Boltzmann constant,  $5.67 \times 10^{-8}$  W/(m<sup>2</sup>·K<sup>4</sup>).

Because  $\bar{t}_r$  equals the radiation of several surfaces at different temperatures ( $T_1, T_2, \dots, T_j$ ),

$$\text{ERF} = (\text{ERF})_1 + (\text{ERF})_2 + \dots + (\text{ERF})_j \quad (86)$$

where

$$\begin{aligned} \text{ERF}_j &= \sigma(A_r/A_D)\alpha_j F_{m-j}(T_j^4 - T_a^4)F_{cle} \\ \alpha_j &= \text{absorptance of skin or clothing surface for source radiating at temperature } T_j \\ F_{m-j} &= \text{angle factor to subject } m \text{ from source } j \\ T_a &= \text{ambient air temperature, K} \end{aligned}$$

ERF is the sum of the fields caused by each surface  $T_j$  [e.g.,  $T_1$  may be an infrared beam heater;  $T_2$ , a heated floor;  $T_3$ , a warm ceiling;  $T_4$ , a cold plate glass window ( $T_4 < T_a$ ); etc.]. Only surfaces with  $T_j$  differing from  $T_a$  contribute to the ERF.

### Comfort Equations for Radiant Heating

The **comfort equation for radiant heat** (Gagge et al. 1967a,b) follows from definition of ERF and Equation (8):

$$t_o \text{ (for comfort)} = t_a + \text{ERF (for comfort)}/h \quad (87)$$

Thus, operative temperature for comfort is the temperature of the ambient air plus a temperature increment  $\text{ERF}/h$ , a ratio that measures the effectiveness of the incident radiant heating on occupants. Higher air movement (which increases the value of  $h$  or  $h_c$ ) reduces the effectiveness of radiant heating systems. Clothing lowers  $t_o$  for comfort and for thermal neutrality.

Values for ERF and  $h$  must be determined to apply the comfort equation for radiant heating. Table 3 may be used to estimate  $h$ . One method of determining ERF is to calculate it directly from radiometric data that give (1) radiation emission spectrum of the source, (2) concentration of the beam, (3) radiation from the floor, ceiling, and windows, and (4) corresponding angle factors involved. This analytical approach is described in Chapter 52 of the 1999 *ASHRAE Handbook—Applications*.

For direct measurement, a skin-colored or black globe, 150 mm in diameter, can measure the radiant field ERF for comfort, by the following relation:

$$\text{ERF} = (A_r/A_D)[6.1 + 13.6\sqrt{V}](t_g - t_a) \quad (88)$$

where  $t_g$  is uncorrected globe temperature in °C and  $V$  is air movement in m/s. The average value of  $A_i/A_D$  is 0.7. For a skin-colored globe, no correction is needed for the quality of radiation. For a black globe, ERF must be multiplied by  $\alpha$  for the exposed clothing/skin surface. For a subject with 0.6 to 1.0 clo,  $t_o$  for comfort should agree numerically with  $t_a$  for comfort in Figure 5. When  $t_o$  replaces  $t_a$  in Figure 5, humidity is measured in vapor pressure rather than relative humidity, which refers only to air temperature.

Other methods may be used to measure ERF. The most accurate is by physiological means. In Equation (84), when  $M, t_{sk} - t_a$ , and the associated transfer coefficients are experimentally held constant,

$$\Delta E = \Delta ERF \tag{89}$$

The variation in evaporative heat loss  $E$  (rate of mass loss) caused by changing the wattage of two T-3 infrared lamps is a measure in absolute terms of the radiant heat received by the body.

A third method uses a directional radiometer to measure ERF directly. For example, radiation absorbed at the body surface [in  $W/m^2$ ] is

$$ERF = \alpha(A_i/A_D)J \tag{90}$$

where irradiance  $J$  can be measured by a directional (Hardy-type) radiometer;  $\alpha$  is the surface absorptance effective for the source used; and  $A_i$  is the projection area of the body normal to the directional irradiance. Equation (90) can be used to calculate ERF only for the simplest geometrical arrangements. For a human subject lying supine and irradiated uniformly from above,  $A_i/A_D$  is 0.3. Figure 18 shows variance of  $\alpha$  for human skin with blackbody temperature (in K) of the radiating source. When irradiance  $J$  is uneven and coming from many directions, as is usually the case, the previous physiological method can be used to obtain an effective  $A_i/A_D$  from the observed  $\Delta E$  and  $\Delta(\alpha J)$ .

**Hot and Humid Environments**

Tolerance limits to high temperature vary with the ability to (1) sense temperature, (2) lose heat by regulatory sweating, and (3) move heat from the body core by blood flow to the skin surface, where cooling is the most effective. Many interrelating processes are involved in heat stress (Figure 21).

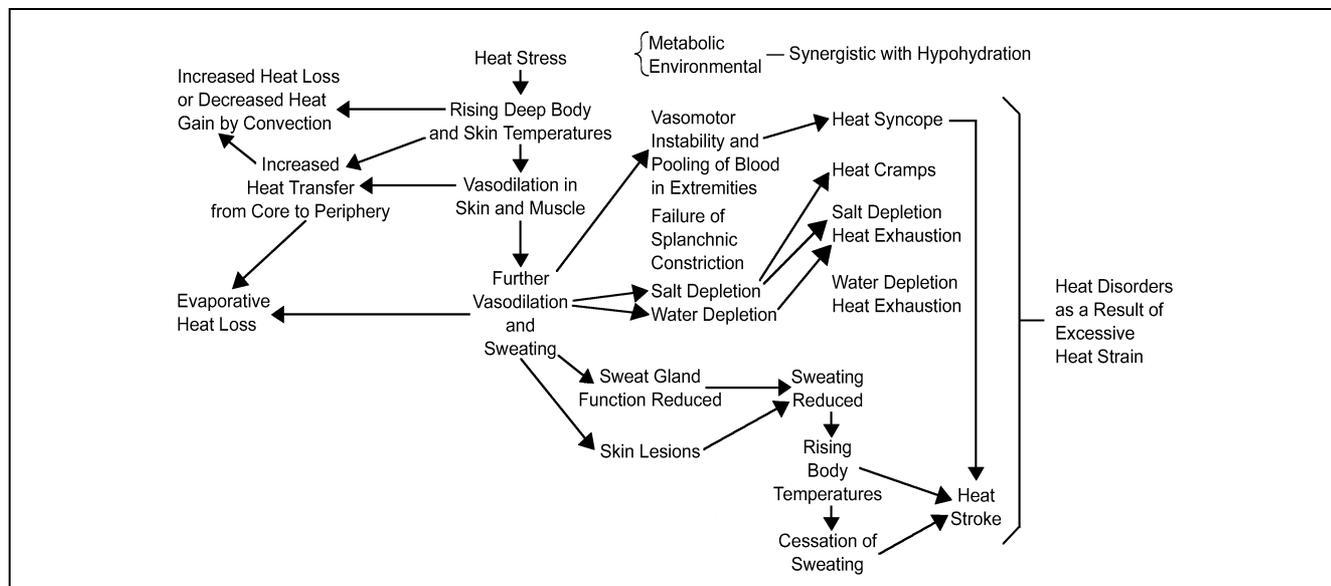

Skin surface temperatures of 46°C trigger pain receptors in the skin; direct contact with metal at this temperature is painful. However, since thermal insulation of the air layer around the skin is high, much higher dry air temperatures can be tolerated. For lightly clothed subjects at rest, tolerance times of nearly 50 min have been reported at 82°C dry-bulb temperature; 33 min at 93°C; 26 min at 104°C; and 24 min at 115°C. In each case, dew points were lower than 30°C. Many individuals are stimulated by brief periods of exposure to 85°C dry air in a sauna. Short exposures to these extremely hot environments are tolerable because of cooling by sweat evaporation. However, when ambient vapor pressure approaches 6.0 kPa (36°C dew point, typically found on sweating skin), tolerance is drastically reduced. Temperatures of 50°C can be intolerable if the dew-point temperature is greater than 25°C, and both deep body temperature and heart rate rise within minutes (Gonzalez et al. 1978).

The rate at which and length of time a body can sweat are limited. The maximum rate of sweating for an average man is about 0.5 g/s. If all this sweat evaporates from the skin surface under conditions of low humidity and air movement, maximum cooling is about 675 W/m<sup>2</sup>. However, this value does not normally occur because sweat rolls off the skin surface without evaporative cooling or is absorbed by or evaporated within clothing. A more typical cooling limit is 6 mets, 350 W/m<sup>2</sup>, representing approximately 0.3 g/s (1 L/h) of sweating for the average man.

Thermal equilibrium is maintained by dissipation of resting heat production (1 met) plus any radiant and convective load. If the environment does not limit heat loss from the body during heavy activity, decreasing skin temperature compensates for the core temperature rise. Therefore, mean body temperature is maintained, although the gradient from core to skin is increased. Blood flow through the skin is reduced, but muscle blood flow necessary for exercise is preserved. The upper limit of skin blood flow is about 25 g/s (Burton and Bazett 1936).

Body heat storage of 335 kJ (or a rise in  $t_b$  of 1.4 K) for an average-sized man represents an average voluntary tolerance limit. Continuing work beyond this limit increases the risk of heat exhaustion. Collapse can occur at about 670 kJ of storage (2.8 K rise); few individuals can tolerate heat storage of 920 kJ (3.8 K above normal).

The cardiovascular system affects tolerance limits. In normal, healthy subjects exposed to extreme heat, heart rate and cardiac output increase in an attempt to maintain blood pressure and supply of

**Fig. 21 Schematic Design of Heat Stress and Heat Disorders**  
 [Modified by Buskirk from scale diagram by Belding (1967) and Leithead and Lind (1964)]

blood to the brain. At a heart rate of about 180 bpm, the short time between contractions prevents adequate blood supply to the heart chambers. As heart rate continues to increase, cardiac output drops, causing inadequate convective blood exchange with the skin and, perhaps more important, inadequate blood supply to the brain. Victims of this heat exhaustion faint or black out. Accelerated heart rate can also result from inadequate venous return to the heart caused by pooling of blood in the skin and lower extremities. In this case, cardiac output is limited because not enough blood is available to refill the heart between beats. This occurs most frequently when an overheated individual, having worked hard in the heat, suddenly stops working. The muscles no longer massage the blood back past the valves in the veins toward the heart. Dehydration compounds the problem, since fluid volume in the vascular system is reduced.

If core temperature  $t_{cr}$  increases above 41°C, critical hypothalamic proteins can be damaged, resulting in inappropriate vasoconstriction, cessation of sweating, increased heat production by shivering, or some combination of these. Heat stroke damage is frequently irreversible and carries a high risk of fatality.

A final problem, hyperventilation, occurs predominantly in hot-wet conditions, when too much CO<sub>2</sub> is washed from the blood. This can lead to tingling sensations, skin numbness, and vasoconstriction in the brain with occasional loss of consciousness.

Since a rise in heart rate or rectal temperature is essentially linear with ambient vapor pressure above a dew point of 25°C, these two changes can measure severe heat stress. Although individual heart rate and rectal temperature responses to mild heat stress vary, severe heat stress saturates physiological regulating systems, producing uniform increases in heart rate and rectal temperature. In contrast, sweat production measures stress under milder conditions but becomes less useful under more severe stress. The maximal sweat rate compatible with body cooling varies with (1) degree of heat acclimatization, (2) duration of sweating, and (3) whether the sweat evaporates or merely saturates the skin and drips off. Total sweat rates in excess of 2 L/h can occur in short exposures, but about 1 L/h is an average maximum sustainable level for an acclimatized man.

Figure 22 illustrates the decline in heart rate, rectal temperature, and skin temperature when exercising subjects are exposed to 40°C over a period of days. Acclimatization can be achieved by working in the heat for 100 min each day—30% improvement occurs after the first day, 50% after 3 days, and 95% after 6 or 7 days. Increased sweat secretion while working in the heat can be induced by rest. Although reducing salt intake during the first few days in the heat can conserve sodium, heat cramps may result. Working regularly in the heat improves cardiovascular efficiency, sweat secretion, and sodium conservation. Once induced, heat acclimatization can be maintained by as few as once-a-week workouts in the heat; otherwise, it diminishes slowly over a 2- to 3-week period and disappears.

**Extreme Cold Environments**

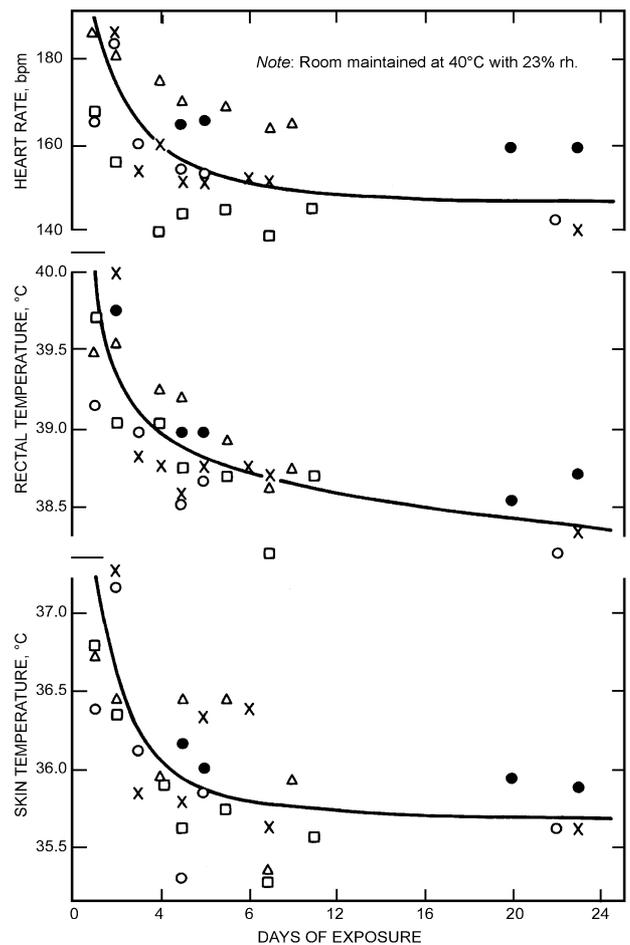

Human performance in extreme cold ultimately depends on maintaining thermal balance. Subjective discomfort is reported by a 70 kg man with 1.8 m<sup>2</sup> of body surface area when a heat debt of about 104 kJ is incurred. A heat debt of about 630 kJ is acutely uncomfortable; this represents a drop of approximately 2.6 K (or about 7% of total heat content) in mean body temperature.

This loss can occur during 1 to 2 h of sedentary activity outdoors. A sleeping individual will awake after losing about 314 kJ, decreasing mean skin temperature by about 3 K and deep body temperature by about 0.5 K. A drop in deep body temperature (e.g., rectal temperature) below 35°C threatens a loss of body temperature regulation, while 28°C is considered critical for survival, despite recorded survival from a deep body temperature of 18°C. Temperature is more crucial than rate of temperature change; Witherspoon et al. (1971) observed a rate of fall in the core temperature of 3 K per hour in subjects immersed in 10°C water, without residual effect.

Activity level also affects human performance. Subjective sensations reported by sedentary subjects at a mean skin temperature of 33.3°C, are comfortable; at 31°C, uncomfortably cold; at 30°C, shivering cold; and at 29°C, extremely cold. The critical subjective tolerance limit (without numbing) for mean skin temperature appears to be about 25°C. However, during moderate to heavy activity, subjects reported the same skin temperatures as comfortable. Although mean skin temperature is significant, the temperature of the extremities is more frequently the critical factor for comfort in the cold. Consistent with this, one of the first responses to cold exposure is vasoconstriction, which reduces circulatory heat input to the hands and feet. A hand-skin temperature of 20°C causes a report of uncomfortably cold; 15°C, extremely cold; and 5°C, painful. Identical verbal responses for the foot surface occur at approximately 1.5 to 2 K warmer temperatures.

An ambient temperature of -35°C is the lower limit for useful outdoor activity, even with adequate insulative clothing. At -50°C, almost all outdoor effort becomes exceedingly difficult; even with appropriate protective equipment, only limited exposure is possible. Reported exposures of 30 min at -75°C have occurred in the Antarctic without injury.

In response to extreme heat loss, maximal heat production becomes very important. When the less efficient vasoconstriction cannot prevent body heat loss, shivering is an automatic, more efficient defense against cold. This can be triggered by low deep body temperature, low skin temperature, rapid change of skin temperature, or some combination of all three. Shivering is usually preceded

**Fig. 22 Acclimatization to Heat Resulting from Daily Exposure of Five Subjects to Extremely Hot Room**  
(Robinson et al. 1943)

by an imperceptible increase in muscle tension and by noticeable gooseflesh produced by muscle contraction in the skin. It begins slowly in small muscle groups, initially increasing total heat production by 1.5 to 2 times resting levels. As body cooling increases, the reaction spreads to additional body segments. Ultimately violent, whole body shivering causes maximum heat production of about 6 times resting levels, rendering the individual totally ineffective.

Given sufficient cold exposure, the body undergoes changes that indicate cold acclimatization. These physiological changes include, (1) endocrine changes (e.g., sensitivity to norepinephrine), causing nonshivering heat production by metabolism of free fatty acids released from adipose tissue; (2) improved circulatory heat flow to skin, causing an overall sensation of greater comfort; and (3) improved circulatory heat flow to the extremities, reducing the risk of injury and permitting activities at what ordinarily would be severely uncomfortable temperatures in the extremities. Generally, these physiological changes are minor and are induced only by repeated extreme exposures. Nonphysiological factors, including training, experience, and selection of adequate protective clothing, are more useful and may be safer than dependence on physiological changes.

The energy requirement for adequately clothed subjects in extreme cold is only slightly greater than that for subjects living and working in temperate climates. This greater requirement results from added work caused by (1) carrying the weight of heavy clothing (energy cost for heavy protective footwear may be six times that of an equivalent weight on the torso); and (2) the inefficiency of walking in snow, snowshoeing, or skiing, which can increase energy cost up to 300%.

To achieve proper protection in low temperatures, a person must either maintain high metabolic heat production by activity or reduce heat loss by controlling the body's microclimate with clothing. Other protective measures include spot radiant heating, showers of hot air for work at a fixed site, and warm-air-ventilated or electrically heated clothing. The extremities, such as fingers and toes, pose more of a problem than the torso because, as thin cylinders, they are particularly susceptible to heat loss and difficult to insulate without increasing the surface for heat loss. Vasoconstriction can reduce circulatory heat input to extremities by over 90%.

Although there is no ideal insulating material for protective clothing, radiation-reflective materials are promising. Insulation is primarily a function of clothing thickness; the thickness of trapped air, rather than fibers used, determines insulation effectiveness.

Protection for the respiratory tract seems unnecessary in healthy individuals, even at  $-45^{\circ}\text{C}$ . However, asthmatics or individuals with mild cardiovascular problems may benefit from a face mask that warms inspired air. Masks are unnecessary for protecting the face because heat to facial skin is not reduced by local vasoconstriction, as it is for hands. If wind chill is great, there is always a risk of cold injury caused by freezing of exposed skin. Using properly designed torso clothing, such as a parka with a fur-lined hood to minimize wind penetration to the face, and 10 W of auxiliary heat to each hand and foot, inactive people can tolerate  $-55^{\circ}\text{C}$  with a 16 km/h wind for more than 6 h. As long as the skin temperature of fingers remains above  $15^{\circ}\text{C}$ , manual dexterity can be maintained and useful work performed without difficulty.

## SYMBOLS

A	= area, $\text{m}^2$
$A_{ch}$	= contact area between chair and body
$A_{cl}$	= surface area of clothed body
$A_D$	= DuBois surface area of nude body
$A_G$	= body surface area covered by garment
$A_r$	= effective radiation area of body
BFN	= neutral skin blood flow, $\text{L}/(\text{h}\cdot\text{m}^2)$
c	= specific heat, $\text{J}/(\text{kg}\cdot\text{K})$

$c_{cr}$	= body core
$c_{sk}$	= skin
$c_p$	= at constant pressure
$c_{p,a}$	= of air
$c_{p,b}$	= of body tissue
$c_{p,bl}$	= of blood
$c_{dil}$	= constant for skin blood flow
$c_{sw}$	= proportionality constant for sweat control
C	= convective heat loss, $\text{W}/\text{m}^2$
$C_{res}$	= sensible heat loss due to respiration, $\text{W}/\text{m}^2$
$C + R$	= total sensible heat loss from skin, $\text{W}/\text{m}^2$
E	= evaporative heat loss, $\text{W}/\text{m}^2$
$E_{dif}$	= due to moisture diffusion through skin
$E_{max}$	= maximum possible
$E_{rsw}$	= due to regulatory sweating
$E_{res}$	= due to respiration
$E_{rsw,req}$	= required for comfort
$E_{sw}$	= actual evaporation rate
$E_{sk}$	= total from skin
ERF	= effective radiant field, $\text{W}/\text{m}^2$
ET	= original effective temperature based on 100% rh, $^{\circ}\text{C}$
ET*	= effective temperature, based on 50% rh, $^{\circ}\text{C}$
$f_{cl}$	= clothing area factor, $A_{cl}/A_D$ , dimensionless
$\bar{F}_{cl}$	= intrinsic clothing thermal efficiency, dimensionless
$F_{cle}$	= effective clothing thermal efficiency, dimensionless
$\bar{F}_{pcl}$	= permeation efficiency, dimensionless
$F_{m-j}$	= angle factor to person from source $j$ , dimensionless
$F_{p-N}$	= angle factor between person and source $N$ , dimensionless
$h$	= sensible heat transfer coefficient, $\text{W}/(\text{m}^2\cdot\text{K})$
$h$	= total at surface
$h'$	= overall including clothing
$h_c$	= convection at surface
$h_{cc}$	= corrected convection at surface
$h_r$	= radiation
$h_e$	= evaporative heat transfer coefficient, $\text{W}/(\text{m}^2\cdot\text{kPa})$
$h_e$	= at surface
$h_{ec}$	= at surface, corrected for atmospheric pressure
$h'_{e,cl}$	= clothing evaporative conductance, the evaporative conductance of a uniform layer of insulation covering the entire body that has same effect on evaporative heat flow as the actual clothing.
$h'_e$	= overall including clothing
$h_a$	= enthalpy of ambient air, $\text{J}/\text{kg}$ (dry air)
$h_{ex}$	= enthalpy of exhaled air, $\text{J}/\text{kg}$ (dry air)
$h_{fg}$	= heat of vaporization of water, $\text{J}/\text{kg}$
$i$	= vapor permeation efficiency, dimensionless
$i_a$	= air layer
$i_{cl}$	= clothing
$i_m$	= total
I	= thermal resistance in clo units, clo
All subscripts given for symbol $R$ apply to symbol $I$	
$I_{clu,i}^*$	= effective insulation of garment $i$
$J$	= irradiance, $\text{W}/\text{m}^2$
$k$	= thermal conductivity of body tissue, $\text{W}/(\text{m}\cdot\text{K})$
$K$	= effective conductance between core and skin, $\text{W}/(\text{m}^2\cdot\text{K})$
$l$	= height, m
$L$	= thermal load on body, $\text{W}/\text{m}^2$
LR	= Lewis ratio, $\text{K}/\text{kPa}$
$m$	= body mass, kg
$m_{cr}$	= mass of body core
$m_{sk}$	= mass of skin
$m_{ge}$	= mass to gas exchange, kg
$\dot{m}$	= mass flow, $\text{kg}/(\text{s}\cdot\text{m}^2)$
$\dot{m}_{res}$	= pulmonary ventilation flow rate, $\text{kg}/\text{s}$
$\dot{m}_{w,res}$	= pulmonary water loss rate, $\text{kg}/\text{s}$
$M$	= metabolic heat production, $\text{W}/\text{m}^2$
$M$	= total
$M'$	= net ( $M - W$ )
$M_{act}$	= due to activity
$M_{shiv}$	= due to shivering
$p$	= water vapor pressure, kPa
$p_a$	= in ambient air
$p_{ET^*_s}$	= saturated at ET*
$p_{oh,s}$	= saturated at $t_{oh}$

$p_t$	$p_{sk,s}$ = saturated at $t_{sk}$ = atmospheric pressure, kPa
$q$	$p_{t,com}$ = related to $t_{com}$ = heat flow, W/m <sup>2</sup> $q_{dry}$ = sensible from skin $q_{evap}$ = latent from skin $q_{cr,sk}$ = from core to skin $q_{res}$ = total due to respiration $q_{sk}$ = total from the skin $Q_{bl}$ = blood flow between core and skin, [L/(h·m <sup>2</sup> )] $Q_{CO_2}$ = volume rate of CO <sub>2</sub> produced, mL/s $Q_{O_2}$ = volume rate of O <sub>2</sub> consumed, mL/s $Q_{rsww}$ = rate of regulatory sweat generation, [L/(h·m <sup>2</sup> )] $R$ = radiative heat loss from skin, W/m <sup>2</sup> $R$ = thermal resistance, m <sup>2</sup> ·K/W $R_a$ = air layer on nude skin $R_{a,cl}$ = air layer at outer surface $R_{cl}$ = clothing $R_{cle}$ = change due to clothing $R_e$ = evaporative resistance, m <sup>2</sup> ·kPa/W $R_{e,a}$ = outer boundary layer air $R_{e,cl}$ = clothing $R_{e,t}$ = total $R_t$ = total RQ = respiratory quotient, dimensionless $S$ = heat storage, W/m <sup>2</sup> $S_{cr}$ = in core compartment $S_{sk}$ = in skin compartment $S_{tr}$ = constriction constant for skin blood flow SET* = standard effective temperature, °C SKBF = skin blood flow lb/h-ft <sup>2</sup> $t$ = temperature, °C $t_a$ = ambient air $t_b$ = average of body $t_{b,c}$ = lower limit for evaporative regulation zone $t_{b,h}$ = upper limit for evaporative regulation zone $t_c$ = comfort $t_{cl}$ = clothing surface $t_{com}$ = combined temperature $t_{cr}$ = core compartment $t_{db}$ = dry bulb $t_{dp}$ = dew point $t_{eq,wc}$ = equivalent wind chill temperature $t_{ex}$ = of exhaled air $t_g$ = globe $t_N$ = of surface $N$ $t_{nwb}$ = naturally ventilated wet bulb $t_o$ = operative $t_{oc}$ = operative comfort $t_{oh}$ = humid operation $t_{out}$ = monthly mean outside $t_{pr}$ = plane radiant $t_r$ = mean radiant $t_{sf}$ = final skin $t_{si}$ = initial skin $t_{sk}$ = skin compartment $t_{sk,n}$ = at neutrality $t_{sk,req}$ = required for comfort $t_{wb}$ = wet bulb $T$ = absolute temperature, K All subscripts that apply to symbol $t$ may apply to symbol $T$ . Tu = turbulence intensity, % $V$ = air velocity, m/s $w$ = skin wettedness, dimensionless $w_{rsww}$ = required to evaporate regulatory sweat $W$ = external work accomplished, W/m <sup>2</sup> $W_a$ = humidity ratio of ambient air, kg (water vapor)/kg (dry air) $W_{ex}$ = humidity ratio of exhaled air, kg (water vapor)/kg (dry air) WBGF = wet-bulb globe temperature, °C WCI = wind chill index, kcal/(h·m <sup>2</sup> ) WGT = wet-globe temperature, °C $\alpha$ = skin absorptance, dimensionless $\alpha_{sk}$ = fraction of total body mass concentrated in skin compartment, dimensionless

$\epsilon$	= emissivity, dimensionless
$\eta_v$	= evaporative efficiency, dimensionless
$\mu$	= body's mechanical efficiency = $W/M$ , dimensionless
$\rho$	= density, kg/m <sup>3</sup>
$\sigma$	= Stefan-Boltzmann constant = $5.67 \times 10^{-8}$ W/(m <sup>2</sup> ·K <sup>4</sup> )
$\theta$	= time, s

### INTRODUCTION

**T**HIS CHAPTER INTRODUCES the field of environmental health as it pertains to the indoor environment of buildings, briefly covering problem identification and control and regulations. The role of HVAC designers in delivering clean, appropriately conditioned air and removing contaminants is vital, both in industrial and nonindustrial environments. Some knowledge of indoor environmental health will assist in that delivery. In many cases, architectural, structural, cleaning, maintenance, materials use, and other activities that affect the environment are outside the control of that individual. Nevertheless, whenever possible, the HVAC designer should encourage features and decisions that create a healthy building environment.

### TERMINOLOGY

The most clearly defined area of indoor environmental health is occupational health, particularly as it pertains to workplace air contaminants. Poisoning incidents as well as human and animal laboratory studies have generated reasonable consensus on safe and unsafe workplace exposures to about one thousand chemicals and dusts. Consequently, many countries regulate exposures of workers. However, contaminant concentrations meeting occupational health criteria usually exceed levels found acceptable to occupants in nonindustrial spaces such as offices, schools, and residences, where exposures are often longer in duration and may involve mixtures of many contaminants and a less robust population (NAS 1981).

Operational definitions of health, disease, and discomfort are controversial (Cain et al. 1995). The World Health Organization (WHO) defines health as “a state of complete physical, mental, and social well-being and not merely the absence of disease or disability.” Last (1983) defines health as “a state characterized by anatomic integrity, ability to perform personally valued family, work, and social roles; ability to deal with physical, biologic, and social stress; a feeling of well-being; and freedom from the risk of disease and untimely death.” Higgins (1983) defines an adverse health effect as a biological change that reduces the level of well-being or functional capacity. These definitions indicate that good health is a function of freedom from active ill health or disease (i.e., short- and long-term disability or impairment, freedom from risk of disease in the future resulting from current exposures, and current subjective well-being).

The preparation of this chapter is assigned to the Environmental Health Committee.

Definitions of comfort are also varying. Traditionally comfort refers to immediate satisfaction. It encompasses perception of the environment (hot, cold, noisy, etc.) and a value rating of affective implications (too hot, too cold, etc.). Rohles et al. (1989) noted that acceptability may represent a more useful concept as it allows progression toward a concrete goal. This serves as the foundation of a number of standards including thermal comfort, acoustics, etc. Nevertheless, acceptability may change over time (secular drift) as expectations change.

### SCOPE

This chapter covers indoor environmental health issues such as effects of air contaminants, thermal comfort, acoustics, exposure to radiation, ergonomics, and electrical safety. It presents information on the mechanisms by which the environment affects the human body, gives guidance on recognizing problems, and discusses standards and guidelines that provide protection. Since the number of air contaminants is very large, the introductory material on types, their characteristics, typical levels, and measurement methods is given in Chapter 12. Chapter 13 covers odors.

This chapter also covers indoor air quality (IAQ). The field of indoor air quality is distinct from that of occupational health in several ways, including locations of concern, which are mainly nonindustrial and include offices, schools, public and commercial buildings, and residences; existence of both comfort and health issues; presence of multiple contaminants at low concentrations rather than single ones at high concentration; and impacts of noncontaminant-related issues such as thermal comfort.

More is known about industrial exposures to air contaminants than is known about residential and light commercial exposures. Therefore, most of this chapter focusses on industrial environments.

### DESCRIPTIONS OF SELECTED HEALTH SCIENCES

Normal interactions of the human body with its surrounding environment occur in predictable fashions. Light, heat, cold, and sound at extremes of the exposure range can result in such diseases as frostbite, burns, and noise-induced hearing loss. Some transitions between normal and disease states are more difficult to delineate. Pain from bright light, erythema from heat, and nausea from vibration represent reversible effects but are interpreted by health professionals as abnormal. Study of these effects includes a number of scientific disciplines.

## EPIDEMIOLOGY AND BIostatISTICS

Epidemiology is the study of distributions and determinants of disease. It represents the application of quantitative methods to evaluate diseases or conditions of interest. The subjects may be humans, animals, or even buildings. Epidemiology is traditionally subdivided into observational and analytical components. It may be primarily descriptive, or it may attempt to identify causal associations. Some classical criteria for determining causal relationships in epidemiology are consistency, temporality, plausibility, specificity, strength of the association, and dose-response relationships.

Observational studies are generally performed by defining some group of interest because of a specific exposure or risk factor. A control group is selected on the basis of similar criteria, but without the factor of interest. Observations conducted at one point in time are considered cross-sectional studies. On the other hand, a group may be defined by some criteria at a specific time, for example, all employees who worked in a certain building for at least one month in 1982. They may then be followed over time, leading to an observational cohort study.

Analytical studies may be either experimental or case-control studies. In experimental studies, individuals are selectively exposed to specific agents or conditions. Such studies are generally performed with the consent of the participants, unless the conditions are part of their usual working conditions and known to be harmless. Sometimes exposures cannot be controlled on an individual basis, and the intervention must be applied to entire groups. Control groups must be observed in parallel. Case-control studies are conducted by identifying individuals with the condition of interest and comparing risk factors between these people and individuals without that condition.

All factors of interest must be measured in an unbiased fashion to avoid a subconscious influence of the investigator. The method of measurement should be repeatable and the technique meaningful. Statistical methods for data analysis follow standard procedures. Tests of hypotheses are performed at a specific probability level. They must have adequate power; that is, if a sample size or a measurement difference between the factors or groups is too small, a statistically significant association may not be found even if one is present.

Results obtained in a specific situation (i.e., in a sample of exposed individuals) may be generalized to others only if they share the same characteristics. For example, it may not be legitimate to assume that all individuals have the same tolerance of thermal conditions irrespective of their heritage. Therefore, the results of studies and groups must be evaluated as they apply to a specific situation.

## TOXICOLOGY

Toxicology is the study of the influence of poisons on health. Most researchers hold that essentially all substances may function as poisons and that only smaller doses prevent them from becoming harmful. Of fundamental importance is defining which component of the chemical structure predicts the harmful effect. The second issue is defining the dose-response relationships. The definition of dose may refer to delivered dose (exposure that is presented to the lungs) or absorbed dose (the dose that is actually absorbed through the lungs into the body and available for metabolism). Measures of exposure may be quite distinct from measures of effect because of internal dose modifiers (e.g., the delayed metabolism of some poisons because of lack of enzymes to degrade them). In addition, the mathematical characteristics of a dose may vary, depending on whether a peak dose, a geometric or arithmetic mean dose, or an integral under the dose curve is used.

Because humans often cannot be exposed in experimental conditions, most toxicological literature is based on animal studies. Recent studies suggest that it is not easy to extrapolate between dose level effects from animals to man. Isolated animal systems, such as

homogenized rat livers, purified enzyme systems, or other isolated living tissues, may be used to study the impact of chemicals.

## MOLECULAR BIOLOGY

Molecular biology is the branch of science that studies the chemical and physical structure of biological macromolecules. (DNA, proteins, carbohydrates, etc.). It is interested in processes on a molecular level, identifying actual mechanisms of effect or toxicity, rather on the level of cells.

## CELLULAR BIOLOGY

Cellular biology is the branch of science that studies cellular organelles, activities, and processes. Little indoor air quality related research has been done at this mechanistic level, but it offers the final evidence in postulated cause-and-effect relationships.

## GENETICS

Genetics is a branch of science that examines heredity and variation among organisms at population, individual, and chromosomal levels. Newer studies in genetics appear to indicate that some individuals are more susceptible to or are at greater risk from certain exposures than the rest of the population. This susceptibility would explain why not all individuals react the same way to the same exposure or lifestyle.

## INDUSTRIAL HYGIENE

Industrial hygiene is the science of anticipating, recognizing, evaluating, and controlling workplace conditions that may cause worker illness or injury. Important aspects of industrial hygiene included under these principles are (1) identification of toxic chemicals; (2) evaluation of the importance of the physical state and size of airborne particle to absorption by the lungs; (3) evaluation of the importance of airborne particle size to absorption by the lungs and the physical state of individuals; (4) evaluation of the importance of skin absorption and ingestion to exposure and absorption; (5) identification of chemicals to be collected and analyzed; (6) determination of methods for collection of air samples; (7) identification of analytic methods to be used or collaboration with a chemist to develop methods to be used; (8) evaluation of results of measurements; (9) identification of physical stressors, including noise, heat stress, ionizing radiation, nonionizing radiation, ergonomics, and illumination; and (10) development of control measures. In addition to examining the environment, interpreting collected data, and implementing control measures, the industrial hygienist has responsibilities related to creating regulatory standards for the work environment, preparing programs to comply with regulations, and collaborating in epidemiologic studies to document exposures and potential exposures to help determine occupation-related illness.

## Hazard Recognition

Occupational hazards generally fall into one of four classes of environmental stressors: chemical, biological, physical, and ergonomic.

**Chemical Hazards.** Airborne chemical hazards exist as concentrations of mists, vapors, gases, fumes, or solids. Some are toxic through inhalation, some can irritate the skin on contact, some can be toxic by absorption through the skin or through ingestion, and some are corrosive to living tissue. The degree of risk from exposure to any given substance depends on the nature and potency of the toxic effects and the magnitude and duration of exposure. Air contaminants represent a very important subclass of chemical hazards due to their mobility and the ease of exposure through the lungs when they are inhaled. Air contaminants are commonly classified as either particulate or gaseous. Common particulate contam-

Table 1 Diseases Related to Buildings

Disease	History and Physical Examination	Laboratory Testing	Linkage	Causes
Rhinitis Sinusitis	Stuffy/ runny nose, post-nasal drip, pale or erythematous mucosa	Anterior and posterior rhinomanometry, acoustic rhinometry, nasal lavage, biopsy, rhinoscopy, RAST or skin prick testing	Immunologic skin prick or RAST testing, bracketed physiology	Direct occupational exposures; molds in the workplace; specific occupational factors (laser toners, carbonless copy paper, cleaning agents), secondary occupational exposures; pet (e.g., cat) danders brought from home
Asthma	Coughing, wheezing, episodic dyspnea, wheezing on examination, chest tightness, temporal pattern at work	Spirometry before and after work on Monday, peak expiratory flow diary, methacholine challenge	Immunologic: skin prick or RAST testing Physiologic: related to work*	See rhinitis/sinusitis
Hypersensitivity pneumonitis	Cough, dyspnea, myalgia, weakness, rales, clubbing, feverishness	DLCO, FVC, TLC, CXR, lung biopsy	Immunologic: IgG ab to agents present, challenge testing Physiologic (in acute forms): spirometry, DLCO	Molds, moisture
Organic dust toxic syndrome	Cough, dyspnea, chest tightness, feverishness	DLCO, TLC	Temporal pattern related to work	Gram-negative bacteria
Contact dermatitis (allergic)	Dry skin, itching, scaling skin	Scaling rash, eczema biopsy	Patch testing	Molds, carbonless copy paper, laser toners
Contact urticaria	Hives	Inspection biopsy	Provocative testing	Office products (carbonless copy paper)
Eye irritation	Eye itching, irritation, dryness	Tear-film break-up time, conjunctival staining (fluorescein)	Temporal pattern	Low relative humidity, volatile organic compounds (allergic conjunctivitis), particulates
Nasal irritation	Stuffy, congested nose, rhinitis	Acoustic rhinometry, posterior and anterior rhinomanometry, nasal lavage, nasal biopsy	Temporal pattern	Low relative humidity, volatile organic compounds (allergic conjunctivitis), particulates
Central nervous system symptoms	Headache, fatigue, irritability, difficulty concentrating	Neuropsychological testing	Temporal pattern (epidemiology)	Volatile organic compounds, noise, lighting, work stress, carbon monoxide, cytokines from bioaerosol exposure
Legionnaires' disease	Pneumonic illness	History, <i>Legionella</i> culture from biopsy fluids	1) Organism isolated from patient and source, 2) immunologic watch	Aerosols from contaminated water sources, shower heads, water faucet aerators, humidifiers at home and at work, potable water sources (hot water heaters, etc.)

\* (1) 10% decrement in FEV<sub>1</sub> across workday,  
 (2) peak flow changes suggestive of work relatedness, and  
 (3) methacholine reactivity resolving after six weeks away from exposure  
 RAST = radio allergen sorbent test  
 DLCO = single breath carbon monoxide diffusing capacity

FVC = forced vital capacity  
 TLC = total lung capacity  
 CXR = chest X-ray  
 IgG = class G immune globulins  
 FEV<sub>1</sub> = forced expiratory volume in the first second

inants include dusts, fumes, mists, aerosols, and fibers. Gaseous contaminants exist as vapors or gases. More background information on these is given in Chapter 12. Air contaminants are of concern in both industrial and nonindustrial environments. Table 1 summarizes diseases that have been associated with specific aspects of indoor environments, mostly in nonindustrial environments. For these diseases, diagnostic criteria may be used to distinguish between presence or absence of disease. These diseases come about because of the presence of an exposure, a susceptible host, and a vector of transmission.

**Biological Hazards.** These include bacteria, viruses, fungi, and other living or nonliving organisms that can cause acute and chronic infections by entering the body either directly or through breaks in the skin. In addition, some biological agents can cause allergic reactions or be toxic. Wastes, body parts, etc., of these organisms can also cause illness and allergic reactions.

**Physical Hazards.** These include excessive levels of ionizing and nonionizing electromagnetic radiation, noise, vibration, illumination, temperature, and force.

**Ergonomic Hazards.** These include tasks that involve repetitive motions, require excessive force, or must be carried out in awkward

postures, all of which can result in damage to muscles, nerves, and joints.

## Hazard Evaluation

Hazard evaluation determines the sources of potential problems. Safety and health professionals research, inspect, and analyze how the particular hazard affects worker health. Assessment of such exposures relies on qualitative, semiquantitative, or quantitative approaches. In many situations, air sampling will determine whether a hazardous condition exists. An appropriate sampling strategy must be used to ensure the validity of collected samples, determining worst-case (for compliance) or usual (average) exposures. Air sampling can be conducted to determine **time-weighted average** (TWA) exposures, which would cover an entire work shift; or **short-term exposures**, which would determine the magnitude of exposures to materials that are acutely hazardous. Samples may be collected for a single substance or a multicomponent mixture. Hazard evaluation also characterizes the workplace with respect to potential skin absorption or ingestion hazards. Analysis of bulk material samples and surface wipe samples could determine whether hazardous conditions exist. Physical agent characterization

may require direct-reading sampling methods. After collection and analysis, the industrial hygienist must interpret the results and determine appropriate control strategies.

### Hazard Control

The principles for controlling the occupational environment are substitution, isolation, ventilation, and air cleaning. Not all of these principles may be applied to all types of hazards, but all hazards can be controlled by using one of these principles. Engineering controls, work practices controls, administrative controls, and personal protective equipment are used to apply these principles. Source removal or substitution are customarily the most effective measure, but are not always feasible. Engineering controls such as ventilation and air cleaning may be effective for a range of hazards, but usually consume energy. Local exhaust ventilation is more effective for controlling point-source contaminants than is general ventilation. A building HVAC system is an example of a general ventilation system.

## AIR CONTAMINANTS

Many of the same air contaminants cause problems in industrial and nonindustrial indoor environments. These include nonbiological particles (synthetic vitreous fibers, combustion nuclei, nuisance dust, and others); bioaerosols; and gases and vapors that may be generated due to industrial processes, by building materials, furnishings, and equipment, by occupants and their activities in a space, or brought in from the outdoors. In industrial environments, contaminants are usually known from the type of process, and exposures may be determined relatively easily by air sampling. Airborne contaminants in nonindustrial environments may (1) occur from emissions and/or shedding of building materials and systems, (2) originate in outside air, and/or (3) be from building operating and maintenance programs and procedures and conditions that may foster growth of biological organisms. In general, in nonindustrial environments, there are many more contaminants that may contribute to problems, they are more difficult to identify, and they are usually present in much smaller concentrations. More information on contaminant types, characteristics, typical levels, and measurement methods can be found in Chapter 12.

### PARTICULATE MATTER

Particulate matter includes airborne solid or liquid particles. Typical examples of particulates include dust, smoke, fumes, and mists. Dusts range in size from 0.1 to 25  $\mu\text{m}$ , smoke particulate is typically around 0.25  $\mu\text{m}$ , and fumes are usually less than 0.1  $\mu\text{m}$  in diameter (Zenz 1988). Bioaerosols and particles produced from abrasions are usually smaller than 1.0  $\mu\text{m}$ .

### Units of Measurement

The quantity of particulate matter in the air is frequently reported as the mass or the particle count in a given volume of air. Mass units are milligrams per cubic metre of air sampled ( $\text{mg}/\text{m}^3$ ) or micrograms per cubic metre of air sampled ( $\mu\text{g}/\text{m}^3$ ).  $1 \text{ mg}/\text{m}^3 = 1000 \mu\text{g}/\text{m}^3$ . Mass units are widely used in industrial environments as these units are used to express occupational exposure limits.

Particle counts are usually quoted for volumes of 1 cubic foot, 1 litre, or 1 cubic metre and are specified for a given range of particle diameter. Particle count measurements are useful in less contaminated environments such as office buildings and industrial clean rooms.

### Particles in Industrial Environments

Particulates found in the work environment are generated as a result of work-related activities (i.e., adding batch ingredients for a manufacturing process, applying asphalt in a roofing operation, or

drilling an ore deposit in preparation for blasting). The engineer must recognize sources of particulate generation in order to appropriately address exposure concerns.

The engineer or industrial hygienist determining worker exposure should assess particulate release by the activity, local air movement caused by makeup air and exhaust, and worker procedures for a complete evaluation (Burton 2000).

**Health Effects of Exposure.** The health effects of airborne particulates depend on several factors that include particle dimension, durability, dose, and toxicity of the materials in the particle. A particulate must first be inhalable to be potentially hazardous. Respirable particulates vary in size from  $< 1$  to 10  $\mu\text{m}$  (Alpaugh and Hogan 1988) depending on the source of the particulate. Methods for measuring particulates are discussed in Chapter 12. Durability, or how long the particle can live in the biological system before it dissolves, can determine relative toxicity. Lastly, the dose or the amount of exposure encountered by the worker must be considered. In some instances, very small exposures can cause adverse health effects (hazardous exposures) and in others, seemingly large exposures may not cause any adverse health effects (nuisance exposures).

Safety and health professionals are primarily concerned with particles smaller than 2  $\mu\text{m}$ , since this is the range of sizes most likely to be retained in the lungs (Morrow 1964). Particles larger than 8 to 10  $\mu\text{m}$  in aerodynamic diameter are primarily separated and retained by the upper respiratory tract. Intermediate sizes are deposited mainly in the conducting airways of the lungs, from which they are rapidly cleared and swallowed or coughed out. About 50% or less of the particles in inhaled air settle in the respiratory tract. Submicrometre particles penetrate deeper into the lungs, but many do not deposit and are exhaled.

### Dusts

Dusts are coarse solid particles generated by handling, crushing, or grinding. Their size range is typically 1 to 100  $\mu\text{m}$ . They may become airborne during the generation process or through handling. Any industrial process that produces dust fine enough to remain in the air long enough to be inhaled or ingested (size about 10  $\mu\text{m}$ ) should be regarded as hazardous until proven otherwise.

Fibers are solid particles whose length is several times greater than their diameter, such as asbestos, man-made mineral fibers, synthetic vitreous fibers, and refractory ceramic fibers.

**Mechanisms of Health Effects.** A disease associated with the inhalation of particulates in industrial settings is pneumoconiosis, a fibrous hardening of the lungs caused by the irritation created from the inhalation of dust. The most commonly known pneumoconioses are asbestosis, silicosis, and coal worker's pneumoconiosis.

**Asbestosis** results from the inhalation of asbestos fibers (chrysotile, crocidolite, amosite, actinolite, anthophyllite, and tremolite) found in the work environment. The onset of symptomatic asbestosis is uncommon under exposures encountered in the last 45 years before at least 20 to 30 years of exposure (Selikoff et al. 1965, Smith 1955). The asbestos fibers cause fibrosis (scarring) of the lung tissue, which clinically manifests itself as dyspnea (shortness of breath) and a nonproductive, irritating cough. Asbestos fiber is both dimensionally respirable as well as durable in the respiratory system.

**Silicosis** is probably the most common of all industrial occupational diseases of the lung. The hazard is created by inhalation of silica dust. The worker with silicosis usually is asymptomatic, and even the early stages of massive fibrosis are not associated with signs and symptoms (Leathart 1972). It is not considered a problem in nonindustrial indoor environments.

**Coal worker's pneumoconiosis (CWP)** results from the inhalation of dust generated in coal mining operations. The dust is composed of a combination of carbon and varying percentages of silica (usually  $< 10\%$ ) (Alpaugh and Hogan 1988). Due to the confined underground work environment, exposures have the potential to be

**Table 2 OSHA Permissible Exposure Limits (PELs) for Particulates (29 CFR 1910.1000, 29 CFR 1926.1101)**

Substance	CAS #	PEL
Cadmium	7440-43-9	0.05 mg/m <sup>3</sup>
Manganese fume	7439-96-5	1.0 mg/m <sup>3</sup>
Plaster of Paris	Nuisance	10.0 mg/m <sup>3</sup>
Emery	Nuisance	10.0 mg/m <sup>3</sup>
Grain dust	Nuisance	10.0 mg/m <sup>3</sup>
Crystalline silica (as quartz)	14808-60-7	0.1 mg/m <sup>3</sup>
Asbestos	1332-21-4	0.1 fibers/cm <sup>3</sup>
Total dust	Nuisance	15.0 mg/m <sup>3</sup>
Respirable dust	Nuisance	5.0 mg/m <sup>3</sup>

very high at times, thus creating very high doses. Data meanwhile show that workers may develop CWP at exposure below the current dust standard of 1 mg/m<sup>3</sup>.

**Exposure Control Strategies.** Particulate or dust control strategies include source elimination or enclosure, local exhaust, general ventilation, wetting, filtration, and the use of personal protective devices such as respirators.

The most effective means of controlling exposures to a particulate is to totally eliminate it from the work environment. The best dust-control method is a total enclosure of the dust-producing process. A negative pressure is maintained inside the entire enclosure by exhaust ventilation (Alpaugh and Hogan 1988). This control strategy is typically found in manufacturing operations.

Local exhaust ventilation as an exposure control strategy is most frequently used where particulate is generated either at large volumes or with high velocities (i.e., lathe and grinding operations). In this situation, high-velocity air movement captures the particulate and removes it from the work environment. A number of recent studies show that push/pull methodology enhances the capture efficiency, but requires care in not “pushing” contaminants into the work environment. Counter airflow situations in source capture applications should be avoided.

General ventilation control of the work environment is defined as a dilution approach to reducing exposures. This type of ventilation is used when particulate sources are numerous and widely distributed over a large area. In this control strategy, the work environment is exhausted outside and resupplied with fresh air, thus diluting the work environment. Unfortunately this strategy is the least effective means of control and very costly because conditioned (warm or cold) air is exhausted and nonconditioned air is introduced.

Recirculation of indoor air through filters can be an effective method of reducing indoor particle concentrations. Filtration costs are often lower than costs of general ventilation.

The least desirable strategy used to control exposures is the use of personal protective equipment—a respirator. Respirators are appropriate as a primary control during intermittent maintenance or cleaning activities when fixed engineering (local or general ventilation) controls may not be feasible. Respirators can also be used as a supplement to good engineering and work practice controls to increase employee protection and comfort (Alpaugh and Hogan 1988).

**Exposure Standards and Criteria.** In the United States, the Occupational Safety and Health Administration (OSHA) has established Permissible Exposure Limits (PELs), which are published in the Code of Federal Regulations (CFR 1989a,b) under the authority of the Department of Labor. Table 2 lists PELs for several particulates commonly encountered in the workplace.

### Synthetic Vitreous Fibers

**Exposures and Exposure Sources.** A fiber can be defined as a slender, elongated structure with substantially parallel sides. These

parameters distinguish this form of particulate from a dust, which is more spherical. Synthetic vitreous fibers (SVFs) comprise a large number of important manufactured products, such as textile fibers; insulation and ceiling tile wool, including glass fibers, slag, and rock wool fibers; refractory ceramic fibers; and certain specialty glass fibers.

Exposures to SVFs primarily occur during manufacture, fabrication and installation, and demolition. Simultaneous exposures to other dusts (asbestos during manufacture, demolition products and bioaerosols during demolition) may be important as well. Facilities generally manufacture only one form. Generally, only spun glass and refractory ceramic fibers are in the respirable range. Manufacturing operations are most easily designed to assure a clean work environment, while product application operations are more difficult to control. Data on exposure likely to occur in buildings show that background levels are almost uniformly below 0.0001 fibers/cm<sup>3</sup>.

**Health Effects of Exposure.** The possible effects of SVFs on health include the following:

**Cancer.** Respirable SVFs are considered to have the potential to cause carcinogenic and noncarcinogenic health effects. Although implantation studies have suggested the potential for carcinogenesis, this route of exposure is generally not pertinent for humans. Therefore, although SVFs are often classified as potential human carcinogens by regulatory and professional agencies and organizations, reviews of epidemiology studies generally fail to find convincing evidence that they are associated with excess rates of human cancer. Some mortality studies have identified mild excesses of respiratory cancer. These have been attributed to concurrent asbestos exposure and to smoking. Only refractory ceramic fibers are currently considered likely to represent true human carcinogens, although other very hard fibers are likely to have similar effects.

**Nonmalignant respiratory disease.** Cross-sectional surveys have suggested that few measurable adverse health effects are attributable to SVFs alone. The strongest evidence suggests that SVFs may exacerbate smoking-induced obstructive lung disease; some authors consider fiberglass, no different than any other dust, to cause excess rates of chest symptoms.

**Dermatitis.** SVFs may cause an irritant contact dermatitis through embedding in the skin or conjunctivae with local inflammation. Resin binders sometimes used to tie fibers together have, on rare occasions, been associated with allergic contact dermatitis.

**Exposure Control Strategies.** As with other particulates, SVF control strategies include source exclusion or enclosure, local exhaust, and the use of personal protective devices such as respirators. In indoor environments, SVFs may be identified in surface wipe samples. Appropriate intervention strategies focus on source control.

**Exposure Standards and Criteria.** At present, SVFs are regulated by OSHA as a “nuisance dust” with an 8-hour time-weighted average of 15 mg/m<sup>3</sup> for total dust and 5 mg/m<sup>3</sup> for respirable dust.

### Combustion Nuclei

**Exposures and Exposure Sources.** Combustion nuclei can be defined as the particulate products of the combustion process. Combustion products from a material include water vapor, carbon dioxide, heat, oxides of carbon and nitrogen, and particulates known as combustion nuclei. In many situations combustion nuclei can be hazardous. They may contain potential carcinogens such as polycyclic aromatic hydrocarbons (PAHs).

Polycyclic aromatic compounds (PACs) are the nitrogen-, sulfur-, and oxygen-heterocyclic analogs of PAH and other related PAH derivatives. Depending on their relative molecular mass and vapor pressure, PACs are distributed between vapor and particulate phases. In

general, combustion particulates are smaller than dusts generated by mechanical means.

Typical sources of combustion nuclei are tobacco smoke (cigarettes, pipes, and cigars), fossil-fuel-based heating devices such as unvented space heaters and gas ranges, and flue gas from improperly vented gas- or oil-fired furnaces and wood-burning fireplaces or stoves. Infiltration of outdoor combustion contaminants can also be a significant source of such contaminants in indoor air. Combustion nuclei are thus important in both industrial and non-industrial settings.

**Exposure Standards and Criteria.** OSHA has established exposure limits for several of the carcinogens categorized as combustion nuclei (benzo(a)pyrene, cadmium, nickel, benzene, *n*-nitrosodimethylamine). These limits are established for industrial work environments and are not directly applicable to indoor air situations. Underlying atherosclerotic heart disease in individuals may be exacerbated by carbon monoxide (CO) exposures.

**Exposure Control Strategies.** Exposure control strategies for combustion nuclei are in many ways similar to those applied for other particles. For combustion nuclei derived from heating spaces, air contamination can be avoided by proper installation and ventilation of equipment to ensure that these contaminants cannot enter the work or personal environment. Proper equipment maintenance is also essential to minimize exposures to combustion nuclei. Changing makeup air availability, through the addition of enclosures, may be equally important.

### Particles in Nonindustrial Environments

In the nonindustrial indoor environment, the indoor aerosol will be affected greatly by the outdoor particle environment. Indoor particulate sources may include cleaning, resuspension of particles from carpets and other surfaces, construction and renovation debris, paper dust, deteriorated insulation, office equipment, and combustion processes including cooking stoves and fires and environmental tobacco smoke. In general, source control is the preferred method. If a dust problem is identified, characterization of the nature of the dust will allow the development of an appropriate intervention strategy.

Although asbestos is encountered in insulation in many buildings, it generally does not represent a respiratory hazard except to individuals who actively disturb it in the course of maintenance and construction. School custodians, therefore, are recognized to be at risk for asbestos-related changes. Anderson et al. (1991) and Lillienfeld (1991) raise questions about risk to teachers.

The combustion nuclei of environmental tobacco smoke (ETS) consists of exhaled mainstream smoke from the smoker and sidestream smoke that is emitted from the smoldering tobacco. ETS consists of between 70 and 90% sidestream smoke and has a somewhat different chemical composition from mainstream smoke. More than 4700 compounds have been identified in laboratory-based studies, including known human toxic and carcinogenic compounds such as carbon monoxide, ammonia, formaldehyde, nicotine, tobacco-specific nitrosamines, benzo(a)pyrene, benzene, cadmium, nickel, and aromatic amines. Many of these toxic constituents are more concentrated in sidestream than in mainstream smoke (Glantz and Parmley 1991). In studies conducted in residences and office buildings with tobacco smoking, ETS was a substantial source of many gas and particulate PACs (Offermann et al. 1991).

**Health Effects of Exposure.** The health effects of exposure to combustion nuclei depend on many factors, including concentration, toxicity, and individual susceptibility or sensitivity to the particular substance. Polycyclic aromatic compounds generated by combustion processes include many PAHs and nitro-PAHs that have been shown to be carcinogenic in animals (NAS 1983). Other PACs are biologically active as tumor promoters and/or cocarcinogens. Mumford et al. (1987) reported high exposures to PAH

and aza-arenes for a population in China with very high lung cancer rates.

ETS has been shown to be causally associated with lung cancer in adults (NRC 1986, DHHS 1986), and respiratory infections, asthma exacerbations, middle ear effusion (NRC 1986, DHHS 1986), and low birth mass in children (Martin and Bracken 1986). The U.S. Environmental Protection Agency classifies ETS as a known human carcinogen (EPA 1992). Health effects can also include headache and irritation. ETS is also a cause of sensory irritation and annoyance (odors and eye irritation).

Control of ETS is somewhat different in that it has been done primarily through regulatory mandates controlling the practice of tobacco smoking. Most states in the United States have passed laws to control tobacco smoking in public places such as restaurants and workplaces, and airlines have prohibited tobacco smoking on flights lasting 6 h or less. Where tobacco smoking is allowed, appropriate local and general ventilation can be used for control. OSHA has proposed that tobacco smoke in indoor environments be controlled through the use of separately ventilated and exhausted smoking lounges. These lounges are kept under negative pressure relative to all adjacent and communicating indoor spaces.

### BIOAEROSOLS

Aerobiology is the study of airborne microorganisms or other biologically produced particles and the effects of these aerosols on other living organisms (people, animals, vegetation, etc.). Bioaerosols are airborne microbiological particulate matter derived from viruses, bacteria, fungi, protozoa, algae, mites, plants, insects, and their cellular or cell mass components. Bioaerosols are present in both indoor and outdoor environments. For the indoor environment, locations that provide appropriate temperature and humidity conditions for reproduction and a food source to support growth may become problematic.

### Sources

Floors and floor coverings in hospitals can be reservoirs for organisms that are subsequently resuspended into the air. Carpet cleaning may even promote resuspension (Cox 1987). Some viruses may persist up to 8 weeks on nonporous surfaces (Mbithi et al. 1991).

Nonpotable water is a well-known source of infective agents, even by aerosolization. Baylor et al. (1977) demonstrated the sequestering of small particles by foam and their subsequent dispersal through a bubble burst phenomenon. Such dispersal may take place in surf, river sprays, or man-made sources such as whirlpools.

People are an important source of bacteria and viruses in indoor air. Contagious diseases occur when living organisms overcome the defense of the host and establish an infection in the host that may in turn infect another human. Infected humans are the primary sources for contagious disease and primary disseminators as well. Virulent agents can also be released from human skin when disease produces skin lesions, or dispersed from respiratory tract infection during coughing, sneezing, or talking. Other means for release directly from infected humans include sprays of saliva and other respiratory secretions during dental and respiratory therapy procedures. Blood sprays that occur during dental and surgical procedures are of potential concern for aerosol transmission of bloodborne diseases, including HIV and hepatitis viruses. Large droplets can transmit infectious particles to those close to the disseminator, while smaller particles can remain airborne for short or very long distances (Moser et al. 1979).

Both the physical and biological properties of the bioaerosols need to be understood. For a microorganism to cause a building-related illness, it must be transported in sufficient dose to the breathing zone of a susceptible occupant. Airborne infectious par-

ticles behave physically in the same way as any other aerosol-containing particles with similar size, density, electrostatic charge, etc. The major difference with bioaerosols is that they must remain viable to cause infection, although nonviable particles may promote an immunological response. An organism that does not remain virulent in the airborne state cannot cause infection, regardless of how many units of organisms are deposited in the human respiratory tract. Virulence depends on such factors as relative humidity, temperature, oxygen, pollutants, ozone, and ultraviolet light (Burge 1995). The effect of any one factor on survival and virulence can be different for different organisms.

Although microorganisms are normally present in indoor environments, the presence of abundant moisture and nutrients in interior niches amplifies the growth of some microbial agents. Thus certain types of humidifiers, water spray systems, and wet porous surfaces can be reservoirs and sites for growth of fungi, bacteria, protozoa, algae, or even nematodes (Strindehag et al. 1988, Arnov et al. 1978, Morey et al. 1986, Morey and Jenkins 1989). Excessive air moisture (Burge 1995) and floods (Hodgson et al. 1985) may cause the proliferation of microorganisms indoors. The turbulence associated with the start-up of air-handling unit plenums may also elevate concentrations of bacteria and fungi in occupied spaces (Yoshizawa et al. 1987).

### Health Effects

Exposure to airborne fungal spores, hyphal fragments, or metabolites can cause a variety of respiratory diseases. These range from allergic diseases including allergic rhinitis, asthma, and hypersensitivity pneumonitis to infectious diseases such as histoplasmosis, blastomycosis, and aspergillosis. In addition, acute toxicosis and cancer have been ascribed to respiratory exposure to mycotoxins (Levetin 1995). A large body of literature supports an association between moisture indicators in the home and symptoms of coughing and wheezing (Spengler et al. 1992, Miller and Day 1997).

The presence of microorganisms in indoor environments may cause infective and/or allergic building-related illnesses (Morey and Feeley 1988, Burge 1989). Some microorganisms under certain conditions may produce volatile chemicals (Hyppel 1984) that are malodorous.

The diseases produced by the *Legionella* genus of bacteria are collectively called legionellosis. Presently more than 34 species of the *Legionella* family have been identified, of which over 20 have been isolated from both environmental and clinical sources. The diseases produced by *Legionella pneumophila* include the pneumonia form, Legionnaires' disease, and the flu-like form, Pontiac fever. *L. pneumophila* serogroup 1 is the most frequently isolated from nature and most frequently associated with disease. It has also been suggested that the host relationship affects the virulence of *Legionella* spp.

The fungal genus *Aspergillus* is widely distributed and is common in the soil and on decaying vegetation, dust, and other organic debris (Levetin 1995). The small spores are buoyant and remain airborne for long periods (Streifel et al. 1989). Most opportunistic fungal infections are caused by *Aspergillus fumigatus*. The literature on aspergillosis is extensive, particularly for hospitals, and in many cases the environmental source of the infection has been identified.

Histoplasmosis, an infective illness caused by the fungus *Histoplasma capsulatum*, has occurred (rarely) as a building-related illness among individuals involved in the removal of bat or bird droppings in abandoned buildings (Bartlett et al. 1982) and among chicken coop cleaners. Presumably asexual spores (conidia) from this fungus were inhaled by workers who removed the droppings without adequate respiratory protection.

Outbreaks of infective illness in the indoor air may be caused by other types of microorganisms, such as viruses. For example, most

of the passengers in an airline cabin developed influenza following exposure to one acutely ill person (Moser et al. 1979). In this case, the plane had been parked on a runway for several hours with the ventilation system turned off.

Allergic respiratory illness may develop due to inhalation of particulates containing microorganisms or their components, such as spores, enzymes, mite excreta, and cell wall fragments. Numerous cases of allergic respiratory illness (humidifier fever, hypersensitivity pneumonitis) report affected people manifesting acute symptoms such as malaise, fever, chills, shortness of breath, and coughing (Edwards 1980, Morey 1988). In buildings, these illnesses may occur as a response to microbiological contaminants originating from HVAC system components, such as humidifiers and water spray systems, or other mechanical components that have been damaged by chronic water exposure (Hodgson et al. 1985, 1987). Affected individuals usually experience relief only after having left the building for an extended period in contrast to occupants with sick building syndrome, where relief is relatively rapid.

Crandall and Sieber (1996) showed that 47 of 104 problem buildings evaluated had water damage in occupied building areas. Other studies suggest that microorganisms in indoor air are important (Burge et al. 1987, Brundage et al. 1988, Burge 1995).

### Guidelines

At present, numerical guidelines for bioaerosol exposure in indoor environments are not available for the following reasons (Morey 1990):

- Incomplete data on concentrations and types of microbial particulates indoors, especially as affected by geographical, seasonal, and type-of-building parameters
- Absence of data relating bioaerosol exposure to building-related illness
- Enormous variability in kinds of microbial particulates including viable cells, dead spores, toxins, antigens, and viruses
- Large variation in human susceptibility to microbial particulates, making estimates of health risk difficult

However, even in the absence of numerical guidelines, bioaerosol sampling data can be interpreted based on such factors as

- Rank order assessment of the kinds (genera/species) of microbial agents present in complainant and control locations (ACGIH 1989)
- Medical or laboratory evidence that a building-related illness is caused by a microorganism (ACGIH 1989)
- Indoor/outdoor concentration ratios for various microbial agents (Morey and Jenkins 1989, ACGIH 1989)

For a microorganism to cause a building-related illness, it must be transported in sufficient dose to the breathing zone of a susceptible occupant. Thus, the concepts of reservoir, amplifier, and disseminator need to be considered in interpreting data. Reservoirs allow microorganisms to survive, amplifiers allow microorganisms to proliferate, and disseminators effectively distribute bioaerosols. Some factors and systems may be all or only one of these. A cooling tower is all three for *Legionella*; that is, a cooling tower can harbor microorganisms in scale, allow them to proliferate, and generate an aerosol.

### GASEOUS CONTAMINANTS

This category of indoor contaminants includes both true gases (which have boiling points less than room temperature) and vapors of liquids with boiling points above normal indoor temperatures. It also includes both volatile organic compounds (VOCs) and inorganic air contaminants.

Volatile organic compounds include 4- to 16-carbon alkanes, chlorinated hydrocarbons, alcohols, aldehydes, ketones, esters, terpenes, ethers, aromatic hydrocarbons (such as benzene and toluene), and heterocyclic hydrocarbons. Also included are chlorofluorocarbons (CFCs) and hydrochlorofluorocarbons (HCFCs) used as refrigerants. More information on classifications, characteristics and measurement methods can be found in Chapter 12.

Inorganic gaseous air contaminants include ammonia, nitrogen oxides, ozone, sulfur dioxide, carbon monoxide, and carbon dioxide. Although the last two contain carbon, they are by tradition regarded as inorganic chemicals.

The most common units of measurement for gaseous contaminants are parts per million by volume (ppm) and milligrams per cubic metre ( $\text{mg}/\text{m}^3$ ). For smaller quantities, parts per billion (ppb) and micrograms per cubic metre ( $\mu\text{g}/\text{m}^3$ ) are used. The relationship between all of these is explained in Chapter 12.

### GASEOUS CONTAMINANTS IN INDUSTRIAL ENVIRONMENTS

The Occupational Safety and Health Administration (OSHA) sets Permissible Exposure Limits (PELs), which are the only workplace regulatory standards in the United States. These are published yearly in the *Code of Federal Regulations* (29 CFR 1900, Part 1900.1000 ff) and intermittently in the *Federal Register*. Most of the levels were recommended by the American Conference of Governmental Industrial Hygienists (ACGIH) and the American National Standards Institute (ANSI). The health effects on which these standards were based can be found in their publications (ACGIH 1989). ACGIH reviews data on a regular basis and publishes Threshold Limit Values (TLVs) yearly.

The National Institute for Occupational Safety and Health (NIOSH) is charged with researching toxicity problems, and it influences the legally required levels. NIOSH publishes the *Registry of Toxic Effects and Chemical Substances* (RTECS) as well as numerous Criteria for Recommended Standard for Occupational Exposure to (compound). Some compounds not in the OSHA list are covered by NIOSH literature, and their Recommended Exposure Limits (RELs) are sometimes lower than the legal requirements set by OSHA. The NIOSH Pocket Guide to Chemical Hazards (NIOSH 1990) is a condensation of these references and is convenient for engineering purposes.

The harmful effects of gaseous pollutants on a person depend on both short-term peak concentrations and the time-integrated exposures received by the person. OSHA has defined three periods for concentration averaging and has assigned allowable levels that may exist in these categories in workplaces for over 490 compounds, mostly gaseous contaminants. The abbreviations for concentrations for the three averaging periods are

AMP = acceptable maximum peak for a short exposure

ACC = acceptable ceiling concentration, not to be exceeded during an 8-h shift, except for periods where AMP applies

TWA8 = time-weighted average, not to be exceeded in any 8-h shift of a 40-h week.

In non-OSHA literature, AMP is sometimes called STEL (short-term exposure limit), and TWA8 is sometimes called TLV (threshold limit value.) NIOSH (1990) also lists values for the toxic limit IDLH—immediately dangerous to life and health.

Table 3 lists values of the various exposure limits defined above for a selection of common gaseous industrial contaminants. Other countries have also issued standards for industrial exposure.

It is of interest to compare standards for industrial and nonindustrial environments. A Canadian National Task Force developed guideline criteria for residential indoor environments. Similarly, the World Health Organization has published indoor

**Table 3 Characteristics of Selected Gaseous Air Pollutants**

Pollutant	Allowable Concentration, $\text{mg}/\text{m}^3$			
	IDLH <sup>a</sup>	AMP <sup>a</sup>	ACC <sup>a</sup>	TWA8 <sup>a</sup>
Acetaldehyde	18 000			360
Acetone	4 800		3 200	2 400

air quality guidelines for Europe. Table 4 compares these guidelines with occupational criteria for selected contaminants.

### GASEOUS CONTAMINANTS IN NONINDUSTRIAL ENVIRONMENTS

The gaseous contaminants that are of concern in nonindustrial environments are volatile organic compounds and inorganic gases.

Table 4 Comparison of Standards Pertinent to Indoor Environments

	Canadian	WHO/Europe	NAAQS/EPA <sup>f</sup>	NIOSH REL	OSHA	ACGIH	MAK <sup>g</sup>
Aldehydes							
Acrolein	0.02 ppm <sup>a</sup>			0.1 ppm 0.25 ppm (15 min)	0.1 ppm 0.3 ppm (15 min)	0.1 ppm 0.3 ppm (15 min)	0.1 ppm 0.2 ppm (15 min)

<sup>g</sup>German Maximale Arbeitsplatz Konzentrationen

The alternative Indoor Air Quality Procedure specified in ASHRAE *Standard 62* sets limits for concentrations of several contaminants in nonindustrial environments and cautions that contaminants whose toxicity is well-known should be kept at or below one-tenth of the threshold limit value (TLV) specified by ACGIH (annual). When outdoor air quantities are reduced, the actual gaseous contaminant concentrations must be measured to ensure that *Standard 62* is met.

### Health Effects of Volatile Organic Compounds

Adverse health effects potentially caused by VOCs in nonindustrial indoor environments are not well understood, but may include (1) irritant effects, including perception of unpleasant odors, mucous membrane irritation, and exacerbation of asthma; (2) systemic effects, such as fatigue and difficulty concentrating; and (3) toxic, chronic effects, such as carcinogenicity (Girman et al. 1989).

The chronic adverse health effects due to VOC exposure are of concern because some VOCs commonly found in indoor air are human (benzene) or animal (chloroform, trichloroethylene, carbon tetrachloride, *p*-dichlorobenzene) carcinogens. Some other VOCs are also genotoxic. Theoretical risk assessment studies suggest that chronic exposure risk due to VOCs in residential indoor air is greater than that associated with exposure to VOCs in the outdoor air or in drinking water (McCann et al. 1987, Tancrede et al. 1987).

Carbon tetrachloride (CCl<sub>4</sub>) causes central nervous system (CNS) depression and significant liver and kidney damage. CCl<sub>4</sub> has also been shown to be an animal carcinogen and is classified as a potential human carcinogen.

A biological model for acute human response to low levels of VOCs indoors is based on three mechanisms: sensory perception of

the environment, weak inflammatory reactions, and environmental stress reaction (Molhave 1991). A growing body of literature summarizes measurement techniques for the effects of VOCs on nasal (Koren 1990, Koren et al. 1992, Meggs 1994, Ohm et al. 1992, Molhave et al. 1993) and ocular (Kjaergard et al. 1991, Kjaergard 1992, Franck et al. 1993) mucosa. It is not well known how different sensory receptions to VOCs are combined into perceived comfort and the sensation of air quality. This perception is apparently interrelated to stimulation of the olfactory sense in the nasal cavity, to the gustatory sense on the tongue, and the common chemical sense (Molhave 1991, Cain 1989).

Cometto-Muñiz and Cain (1994a,b) addressed the independent contribution of the trigeminal and olfactory nerves to the detection of airborne chemicals. The sense of smell is experienced through receptors in the nose of the olfactory nerve. Nasal pungency, described as common chemical sensations including prickling, irritation, tingling, freshness, stinging, and burning among others, is experienced through the nonspecialized receptors of the trigeminal nerve in the face. Odor and pungency thresholds follow different patterns related to chemical concentration. Odor is often detected at much lower levels. A linear correlation between pungency thresholds of homologous series—of alcohols, acetates, ketones, and alkylbenzenes, relatively nonreactive agents—suggests that nasal pungency relies on a physicochemical interaction with a susceptible biophase within the cell membrane. It is postulated that through this nonspecific mechanism, low, subthreshold levels of a wide variety of VOCs—as found in many polluted indoor environments—can be additive in their sensory impact to produce noticeable sensory irritation.

Formaldehyde is a very reactive small molecule that requires different analytical techniques than those usually employed in VOC assessment. Primary sources include urea-formaldehyde resin-based particle and chipboard products used in indoor spaces. It is frequently encountered in indoor spaces in concentrations between 0.04 ppm, a frequently encountered lower limit of detection, and 0.1 ppm (Liu et al. 1991, Ritchie and Lehnen 1987). Many studies have demonstrated its ability to trigger mucous membrane irritation at levels below the ACGIH TLV, and even at levels below 0.1 ppm.

### Standards for Volatile Organic Compounds

No standards for exposure to VOCs relevant to nonindustrial indoor environments are in place. NIOSH, OSHA, and the ACGIH have published regulatory standards or recommended limits for industrial occupational exposures (NIOSH 1992, ACGIH annual). With few exceptions, concentrations observed in nonindustrial indoor environments fall well below (100 to 1000 times lower) these published pollutant-specific occupational standards or recommended exposure limits. However, standards for the industrial workplace are higher than would be appropriate for the general population, which includes the elderly, children, and people who are more sensitive to VOCs than the average industrial worker.

Total VOC (TVOC) concentration has previously been used as an indicator of the potency of VOCs to cause health effects. This approach is no longer recommended since the toxicities of individual VOCs vary very widely, and concentrations differ depending on the measurement method used (Hodgson 1995). In controlled exposure experiments, odors are significant at 3 mg/m<sup>3</sup>. At 5 mg/m<sup>3</sup>, objective effects were seen in addition to the subjective irritation. Exposures for 50 min to 8 mg/m<sup>3</sup> of synthetic mixtures of 20 VOCs lead to significant irritation of mucous membranes in the eyes, nose, and throat.

Both OSHA and the ACGIH have set 8 h standards for formaldehyde as a ceiling level. California issued a residential air quality guideline of 0.1 ppm. In the setting of occupant complaints, the target guideline is 0.05 ppm.

### Health Effects of Refrigerants

ASHRAE *Standard* 34 assigns **refrigerants** to one of two toxicity classes (A or B) based on allowable exposure. Fatalities have been reported following acute exposure to fluorocarbon refrigerants. Inhalation exposures to CFCs can cause cardiotoxicity at chronic, low-level exposures. Some are thought to be cardiac sensitizers to epinephrine and put occupants at risk for arrhythmias. Central nervous system (CNS) depression has been found at very high concentrations along with asphyxia. Proctor and Hughes (1991) found that volunteers exposed to 200 000 ppm of R-12 experienced significant eye irritation and CNS effects. Chronic exposure to 1000 ppm for 8 h per day for up to 17 days caused no subjective symptoms or changes in pulmonary function.

A significant hazard exists when chlorinated hydrocarbons (R-11, for example) are used in the vicinity of open flame or heated surfaces. Phosgene gas (carbonyl chloride), an extreme irritant to the lungs, and halogen acids may be generated when chlorinated or fluorinated solvents or gases decompose in the presence of heat.

CFC-containing systems may only be serviced by certified technicians. Controls for preventing exposures include selection and use of appropriate fittings and valves and insuring that compressed gas cylinders are secured when in use, in transport, and in storage. When repairs are made to leaking or defective components in HVAC equipment, adequate dilution ventilation should be provided to the work area. CFCs should never be used in the vicinity of open flame or heated materials due to the potential for the formation of phosgene gas. ASHRAE *Standard* 15 establishes specific requirements for designing, installing, operating, and servicing mechanical refrigeration equipment.

### Health Effects of Inorganic Gases

**Carbon monoxide** is a chemical asphyxiant. Inhalation of CO causes a throbbing headache brought about because CO has a competitive preference for hemoglobin (about 240 times that of oxygen) and also a shift in the oxygen dissociation curve. Carbon monoxide inhibits oxygen transport in the blood through the formation of carboxyhemoglobin and inhibition of cytochrome oxidase at the cellular level. Deaths and adverse health effects from overexposures are attributed primarily to motor vehicles. Cobb and Etzel (1991) suggested that CO poisoning at home represented a major preventable disease. Moolenaar et al. (1995) subsequently identified similar data and suggested that motor vehicles and home furnaces were primary causes of mortality. Girman et al. (1996) identified both fatal outcomes and episodes. Respectively, 35.9% and 30.6% resulted from motor vehicles, 34.8% and 39.9% from appliance combustion, 4.5% and 5.2% from small appliances, 2.2% and 2.3% from camping equipment, 5.6% and 5.0% from fires, 13.4% and 13.3% from grills and hibachis, and the remainder were unknown.

**Carbon dioxide** can become dangerous not as a toxic agent but as a secondary asphyxiant. When concentrations exceed 35 000 ppm, central breathing receptors are triggered and cause the sensation of shortness of breath. At progressively higher concentrations, central nervous system dysfunction begins due to simple displacement of oxygen. Concentrations of CO<sub>2</sub> in the nonindustrial environment (office buildings and schools) are often measured in the range of 400 to 1500 depending on occupant density, ventilation distribution, and amount of outside air supplied to the occupied spaces.

Inhalation of **nitric oxide** (NO) causes the formation of methemoglobin, which adversely affects the body by interfering with oxygen transport at the cellular level. NO exposures of 3 ppm have been compared to carbon monoxide exposures of 10 to 15 ppm (Case et al. 1979 in EPA 1991).

**Nitrogen dioxide** (NO<sub>2</sub>) is a corrosive gas with a pungent odor, the odor threshold of which is reported to be between 0.11 and 0.22 ppm (WHO 1987). NO<sub>2</sub> has a low water solubility and therefore can be inhaled into the deep lung where it causes a delayed inflammatory response. Increased airway resistance has been reported at 1.5 to 2 ppm (Bascom 1996). NO<sub>2</sub> is reported to be a potential carcinogen by way of free radical production (Burgess and Crutchfield 1995). At high concentrations, NO<sub>2</sub> causes lung damage directly by its oxidant properties and may cause health effects indirectly by increasing host susceptibility to respiratory infections. Health effects from exposures to ambient outdoor concentrations or in residential situations show inconsistency, especially studies relating to exposures from gas cooking stoves (Samet et al. 1987). Indoor concentrations of NO<sub>2</sub> often exceed ambient concentrations due to the presence of strong indoor sources and a trend toward more energy efficient (tighter) homes. Acute toxicity is seldom seen from NO<sub>2</sub> produced by unvented indoor combustion because of the insufficient quantities of NO<sub>2</sub> produced. Chronic pulmonary effects from exposure to combinations of low-level combustion pollutants are possible, however (Bascom et al. 1996).

**Sulfur dioxide** (SO<sub>2</sub>) is a colorless gas with a pungent odor detected at about 0.5 ppm (EPA 1991). Because SO<sub>2</sub> is quite soluble in water, it can react with moisture in the upper respiratory tract to produce irritant effects on the upper respiratory mucosa. Concomitant exposure to fine particulates, an individual's depth and rate of breathing, and the presence of preexisting disease can influence the degree of SO<sub>2</sub> toxicity.

**Ozone** is a pulmonary irritant and causes changes in human pulmonary function at concentrations of approximately 0.12 ppm (Bates 1989). Exposure to ozone at 60 to 80 ppb causes inflammation, bronchoconstriction, and increased airway responsiveness.

**Table 5 Inorganic Gas Comparative Criteria**

Contaminant	OSHA/NIOSH TWA <sup>a</sup>	EPA NAAQS 1 Std.
Nitric oxide	1 h 2 ppm (5 mg/m <sup>3</sup> ) 24 h 25 ppm (30 mg/m <sup>3</sup> )	None
Nitrogen dioxide	1 h 5 ppm (9 mg/m <sup>3</sup> ) 24 h 1 ppm (1.8 mg/m <sup>3</sup> )	0.053 ppm (100 µg/m <sup>3</sup> )
Sulfur dioxide	1 h 5 ppm (13 mg/m <sup>3</sup> ) 24 h 2 ppm (5 mg/m <sup>3</sup> )	0.014 ppm (365 µg/m <sup>3</sup> )
Ozone	1 h 0.1 ppm (0.2 mg/m <sup>3</sup> ) 24 h 0.1 ppm (0.2 mg/m <sup>3</sup> )	0.12 ppm (235 µg/m <sup>3</sup> )

<sup>a</sup>The values listed are the annual arithmetic mean unless otherwise listed. The first value listed is the 24 h average and the second value is the maximum 1 h average. (TWA = time weighted average)

Inhalation exposures to the gaseous oxides of nitrogen, sulfur (NO<sub>x</sub> and SO<sub>2</sub>) and ozone (O<sub>3</sub>) can and do occur in residential and commercial buildings. These air pollutants are of considerable concern due to the potential for acute and chronic respiratory tract health effects in exposed individuals, particularly individuals with preexisting pulmonary disease.

**Standards for Inorganic Gases**

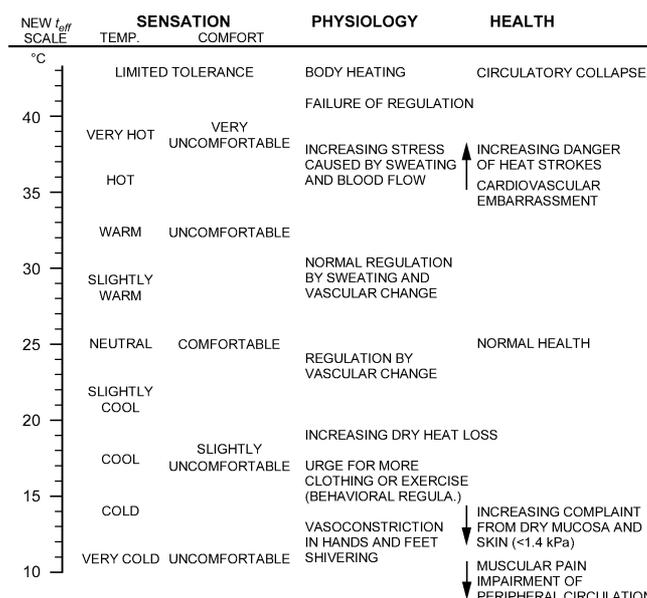

Currently, there are no specific United States government standards relative to nonindustrial occupational exposures to air contaminants. Occupational exposure criteria are health-based; that is, they consider healthy workers in an environment, and not necessarily individuals who may be unusually responsive to the effects of chemical exposures. The EPA National Ambient Air Quality Standards (NAAQS) (see Chapter 12) are also health-based standards designed to protect the general public health from the effects of hazardous airborne pollutants. However, there is a debate as to whether these standards truly represent health-based thresholds. Two of the six criteria, ozone and carbon monoxide, involve toxicologically based research for the development of the standards. The criteria (Table 5) are not meant to be health-based guidelines for the evaluation of exposures to inorganic gasses in the indoor environment. Table 5 is included for comparative use and consideration by investigators of the indoor environment with the understanding that these criteria may not be completely protective to all industrial workers.

**PHYSICAL AGENTS**

Physical factors in the indoor environment include thermal conditions (temperature, moisture, air velocity, and radiant energy), mechanical energy (noise and vibration), and electromagnetic radiation [ionizing (radon) and nonionizing (light, radio-frequency, and extremely low frequency magnetic and electric fields)]. Physical agents can act directly upon building occupants, interact with indoor air quality factors, or affect the way humans respond to the indoor environment. Physical agents, while not categorized as indoor air quality factors, often affect human perception of the quality of indoor air.

**THERMAL ENVIRONMENT**

The thermal environment affects human health in that it affects body temperatures, both internally and externally (of the skin). In the normal, healthy, resting adult, internal or core body temperatures are very stable, with variations seldom exceeding 0.5 K. The internal temperature of a resting adult, measured orally, averages about 37°C; measured rectally, it is about 0.5 K higher (Guyton 1972). The temperature of the core is carefully modulated by an elaborate physiological control system. In contrast, the temperature of the skin is basically unregulated and can vary from about 31 to 36°C in normal environments and activities and also varies over different parts of the skin, with the greatest variation in the hands and feet.

**Fig. 1 Related Human Sensory, Physiological, and Health Responses for Prolonged Exposure**

**Range of Healthy Living Conditions**

The environmental conditions for thermal comfort are those that minimize the effort of the physiological control systems to maintain the internal temperature. The control system regulates the internal body temperature by varying the amount of blood flowing to different skin areas, thus increasing or decreasing heat lost to the environment, by secreting and evaporating sweat from the skin in warm or hot environments, and by increasing the metabolic heat production by shivering in the cold. For a resting person wearing trousers and a long-sleeved shirt, thermal comfort is experienced in a still air environment at 24°C. A zone of comfort extends about 1.5 K above and below this optimum level. An individual can minimize the need for physiological (involuntary) responses to the thermal environment that are generally perceived as uncomfortable, by a variety of behavioral responses. In a cool or cold environment, such responses include increased clothing, increased activity, or seeking or creating an environment that is warmer. In a warm or hot environment, the amount of clothing can be reduced, the level of physical activity can be reduced, or an environment that is more conducive to increased heat loss can be created. Some of the human responses to the thermal environment are shown in Figure 1.

Cardiovascular and other diseases and the inevitable processes of aging can reduce the capacity or ability of physiological processes to maintain internal body temperature through the balancing of heat gains and heat losses. Thus, some persons are less able to deal with thermal challenges and deviations from comfortable thermally neutral conditions. Metabolic heat production tends to decrease with age, as a result of decreasing basal metabolism together with decreased physical activity. Metabolic heat production at age 80 is about 20% less than that at 20 years old, for comparable size and mass. Persons in their eighties, therefore, prefer an environmental temperature about 1.5 K warmer than persons in their twenties. In any given environment near thermally neutral temperature, an older person is likely to have a lower core and skin temperature. Older people may have reduced capacity to secrete and evaporate sweat and to increase their skin blood flow and are therefore more likely to experience greater strain in warm and hot conditions as well as in cool and cold conditions.

## Hyperthermia

Hyperthermia refers to the condition where body temperatures are above normal. A deep body temperature increase of 2 K above the normal range does not generally impair body function. For example, it is not unusual for runners to have rectal temperatures of 40°C after a long race. An elevated body temperature increases metabolism. Central nervous system function deteriorates at deep body temperatures above 41 to 42°C. Convulsions may occur above such temperatures and cells may be damaged. This condition is particularly dangerous for the brain, because lost neurons are not replaced. Thermoregulatory functions of sweating and peripheral vasodilation cease at about 43°C, after which body temperatures tend to rise rapidly if external cooling is not imposed.

## Seasonal Patterns

Ordinary seasonal changes in temperate climates are temporally associated with the prevalence of illness. Many acute and several chronic diseases vary in frequency or severity with time of year, and some are present only in certain seasons. Minor respiratory infections, such as colds and sore throats, occur mainly in fall and winter. More serious infections, such as pneumonia, have a somewhat shorter season in winter. Intestinal infections, such as dysentery and typhoid fever, are more prevalent in summer. Diseases transmitted by insects such as encephalitis and endemic typhus are limited to summer since insects are active in warm temperatures only.

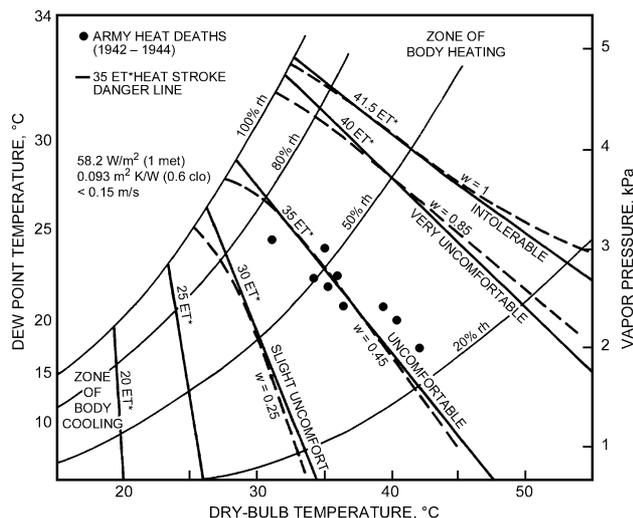

Martinez et al. (1989), Hryhorczuk et al. (1992), and others describe a correlation between weather and seasonal illnesses; but such correlations do not necessarily establish a causal relationship. Daily or weekly mortality and heat stress in heat waves have a strong physiological basis directly linked to outdoor temperature. In indoor environments which are well controlled with respect to temperature and humidity, such temperature extremes and the possible adverse effects on health are strongly attenuated.

## Increased Deaths in Heat Waves

The role of ambient temperature extremes produced by weather conditions in producing discomfort, incapacity, and death has been studied extensively (Katayama 1970). Military personnel, deep mine workers, and other workers occupationally exposed to extremes of high and low temperature have been studied, but the importance of thermal stress affecting both the sick and healthy is not sufficiently appreciated. Collins and Lehmann (1953) studied weekly deaths over many years in large cities in the United States and demonstrated the impact of heat waves in producing conspicuous periods of excess mortality. Excess mortality due to heat waves was of the same amplitude as that due to influenza epidemics, but tended to last one week instead of the 4 to 6 weeks duration of influenza epidemics.

Ellis (1972) reviewed heat wave related excess mortality in the United States. Mortality increases of 30% over background are commonly seen, especially in heat waves that occur early in the summer. Much of the increase occurs in the population over age 65, more of it in women than in men, and many deaths are due to cardiovascular and cerebrovascular causes. Oeschli and Buechley (1970) studied heat-related deaths in Los Angeles heat waves of 1939, 1955, and 1963. Kilbourne et al. (1982) suggested that the same risk factors (i.e., age, low income, and African-American derivation) persist in the heat death epidemics that continue to occur.

Hardy (1971) showed the relationship of health data to comfort on a psychrometric diagram (Figure 2). The diagram contains ASHRAE effective temperature  $ET^*$  lines and lines of constant skin moisture level or skin wettedness  $w$ . Skin wettedness is defined as that fraction of the skin covered with water to account for the observed evaporation rate. The  $ET^*$  lines are loci of constant physiological strain, and also correspond to constant levels of physiological discomfort—slightly uncomfortable, comfortable, and very

**Fig. 2 Isotherms for Comfort, Discomfort, Physiological Strain, Effective Temperature ( $ET^*$ ), and Heat Stroke Danger Threshold**

comfortable (Gonzalez et al. 1978). Skin wettedness, as an indicator of strain (Berglund and Gonzalez 1977, Berglund and Cunningham 1986) and the fraction of the skin wet with perspiration, is fairly constant along an  $ET^*$  line. Numerically  $ET^*$  is the equivalent temperature at 50% rh that produces the strain and discomfort of the actual condition. The summer comfort range is between an  $ET^*$  of 23 and 26°C. In this region, skin wettedness is less than 0.2. Heat strokes occur generally when  $ET^*$  exceeds 34°C (Bridger and Helfand 1968). Thus, the  $ET^*$  line of 35°C is generally considered dangerous. At this point, skin wettedness will be 0.4 or higher.

The black dots in Figure 2 correspond to heat stroke deaths of healthy male U.S. soldiers assigned to sedentary duties in midwestern army camp offices (Shickele 1947). It is to be expected that older persons respond less well to thermal challenges than do healthy soldiers. This was apparently the case in the Illinois heat wave study mentioned earlier, where the first wave with a 33% increase in death rate and an  $ET^*$  of 29.5°C affected mainly the over 65-year-old group. The studies suggest that the “danger line” represents a threshold of significant risk for young healthy people, and that the danger tends to move to lower values of  $ET^*$  with increasing age.

## Effects of Thermal Environment on Specific Diseases

Cardiovascular diseases are largely responsible for excess mortality during heat waves. For example, Burch and DePasquale (1962) found that the heart disease cases in whom decompensation is present are extremely sensitive to high temperatures and particularly to moist heat. However, both cold and hot temperature extremes are associated with increased coronary heart disease deaths and anginal symptoms (Teng and Heyer 1955).

Both acute and chronic respiratory diseases often increase in frequency and severity during extreme cold weather. No increase in these diseases has been noted in extreme heat. Additional studies of hospital admissions for acute respiratory illness show a negative correlation with temperature after removal of seasonal trends (Holland 1961). The symptoms of patients with chronic respiratory disease (bronchitis, emphysema) increase in cold weather. This is thought to be due to reflex constriction of the bronchi, adding to the obstruction already present. Greenberg (1964) revealed evidence of cold sensitivity in asthmatics; emergency room treatments for asthma increased abruptly in local hospitals with early and severe autumn cold spells. Later cold waves with even lower temperatures produced no such effects, and years without early extreme cold had no asthma

epidemics of this type. Patients with cystic fibrosis are extremely sensitive to heat because their diminished sweat gland function greatly diminishes their ability to cope with increased temperature (Kessler and Anderson 1951).

Itching and chapping of the skin is influenced by (1) atmospheric factors, particularly cold and dry air, (2) frequent washing or wetting of skin, and (3) low indoor humidities. Although itching of the skin is usually a winter cold climate illness in the general population, it can be caused by excessive summer air conditioning (Susskind and Ishihara 1965, Gaul and Underwood 1952).

People suffering from chronic illness (heart disease) or serious acute illnesses that require hospitalization often manage to avoid serious thermal stress. Katayama et al. (1970) found that countries with the most carefully regulated indoor climates (such as the Scandinavian countries and the United States) have had only small seasonal fluctuations in mortality in recent decades, while countries with less space heating and cooling exhibit greater seasonal swings in seasonal mortality. For example, mandatory air conditioning in homes for the aged in the southwest United States has virtually eliminated previously observed mortality increases during heat waves.

Summer cooling reduces heat stress by removing both sensible and latent heat from the occupied space, but winter heating has a mixed effect. It reduces cold stress, but it usually does not increase the low water vapor pressure that occurs outdoors during the winter. This results in very low relative humidity in the heated space, which can contribute to dehydration and discomfort and cause injury to skin, eyes, nose, throat, and mucous membranes. These dry tissues may be less resistant to infection. Animal experiments also show that infection rates increase with low levels of either ventilation or relative humidity (Schulman and Kilbourne 1962).

In various tests conducted under identical conditions except humidity level, mechanical humidification raised the relative humidity in one space above that in the matched space; no humidified room was higher than 50% rh (Green 1979 and 1982, Gelperin 1973, Serati and Wuthrich 1969). In each investigation, the humidified rooms showed a reduction in absenteeism and upper respiratory infection—49% reduction in kindergarten children, 6% and 18% in office workers, and 8% and 18% in army recruits. Since occupants in each pair of spaces were subject to the same outdoor conditions and the same indoor air temperature, reductions were attributed to differences in humidity or a related factor (e.g., reduced dust levels and coughing). Therefore, while low humidity does not have a direct pathological effect, it is a factor contributing to disease. A more direct effect has been indicated among users of contact lenses on long airline flights in cabins at low humidity. Here, dehydration of the eyes has been blamed for causing irritation and corneal edema or even ulceration of the corneal epithelium (Laviana et al. 1988).

### Injury from Hot and Cold Surfaces

The skin has cold, warm, and pain sensors to feed back thermal information about surface contacts. When the skin temperature rises above 45°C or falls below about 15°C, sensations from the skin's warm and cold receptors are replaced by those from the pain receptors to warn of thermal injury to the tissue (Guyton 1968). The temperature of the skin depends on the temperature of the contact surface, its conductivity, and the contact time. Table 6

**Table 6 Approximate Surface Temperature Limits to Avoid Pain and Injury**

Material	Contact Time				
	1 s	10 s	1 min	10 min	8 h
Metal, water	149°F	133°F	124°F	118°F	109°F
Glass, concrete	176°F	151°F	129°F	118°F	109°F
Wood	248°F	190°F	140°F	118°F	109°F

gives approximate temperature limits to avoid pain and injury when contacting three classes of conductors for various contact times (CEN).

### ELECTRICAL HAZARDS

Electrical current can cause burns, neural disturbances, and cardiac fibrillation (Billings 1975). The threshold of perception is about 5 mA for direct current, with a feeling of warmth at the contact site. The threshold is 1 mA for alternating current, which causes a tingling sensation.

The resistance of the current pathway through the body is a combination of core and skin resistance. The core is basically a saline volume conductor with very little resistance; therefore, the skin resistance provides the largest component of the resistance. The skin resistance decreases with moisture. If the skin is moist, voltages as low as 2 V (ac) or 5 V (dc) are sufficient to be detected, and voltages as low as 20 V (ac) or 100 V (dc) can cause a 50% loss in muscular control.

The dangerous aspect of alternating electrical current is its ability to cause cardiac arrest by ventricular fibrillation. If a weak alternating current (100 mA for 2 s) passes through the heart (as it would in going from hand to foot), the current can force the heart muscle to fibrillate and lose the rhythmic contractions of the ventricles necessary to pump blood. Unconsciousness and death will soon follow if medical aid cannot rapidly restore normal rhythm.

### MECHANICAL ENERGIES

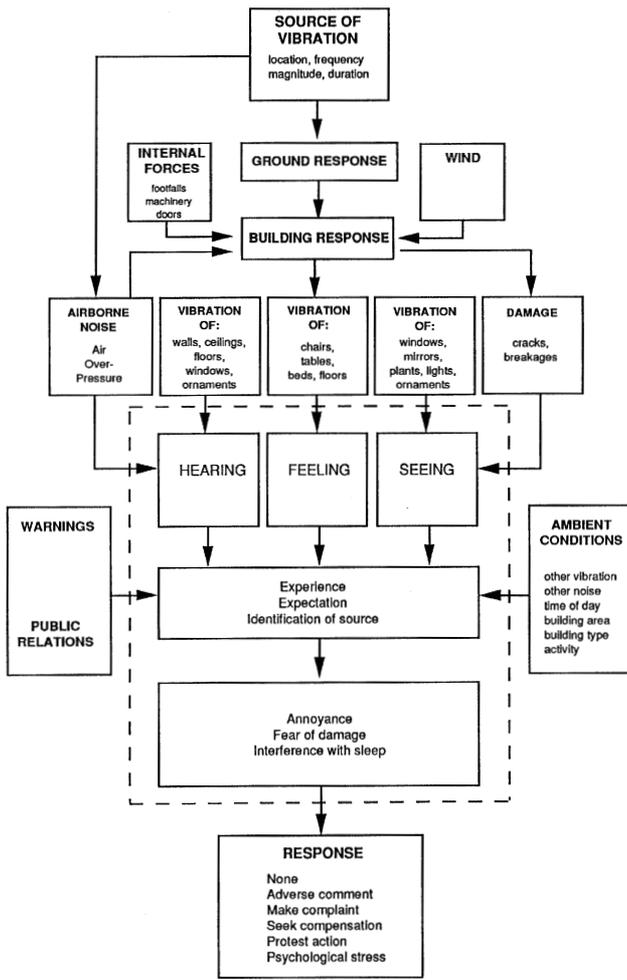

#### Vibration

Vibration in a building originates from both outside and inside the building. Sources outside a building include blasting operations, road traffic, overhead aircraft, underground railways, earth movements, and weather conditions. Sources inside a building include doors closing, foot traffic, moving machinery, elevators, HVAC systems, and other building services. Vibration is an omnipresent, integral part of the built environment. The effects of the vibration on building occupants depend on whether it is perceived by those persons and on factors related to the building, the location of the building, and the activities of the occupants in the building, and the perceived source and magnitude of the vibration. Factors influencing the acceptability of building vibration are presented in Figure 3.

The combination of hearing, seeing, or feeling vibration determines human response. Components concerned with hearing and seeing are part of the visual environment of a room and can be assessed as such. The perception of mechanical vibration by feeling is generally through the cutaneous and kinesthetic senses at high frequencies, and through the vestibular and visceral senses at low frequencies. Because of this and the nature of vibration sources and building responses, building vibration may be conveniently considered in two categories—low-frequency vibrations less than 1 Hz and high-frequency vibrations of 1 to 80 Hz.

**Measurement and Assessment.** Human response to vibration depends on the vibration of the body. The main vibrational characteristics are vibration level, frequency, axis (and area of the body), and exposure time. A root-mean-square (rms) averaging procedure (over the time of interest) is often used to represent vibration acceleration ( $m/s^2$  rms). Vibration frequency is measured in cycles per second (Hz), and the vibration axis is usually considered in three orthogonal, human-centered translational directions (up-and-down, side-to-side, and fore-and-aft). Although the coordinate system is centered inside the body, in practice, vibration is measured at the human surface and measurements are directly compared with relevant limit values or other data concerning human response.

Rotational motions of a building in roll, pitch, and yaw are usually about an axis of rotation some distance from the building

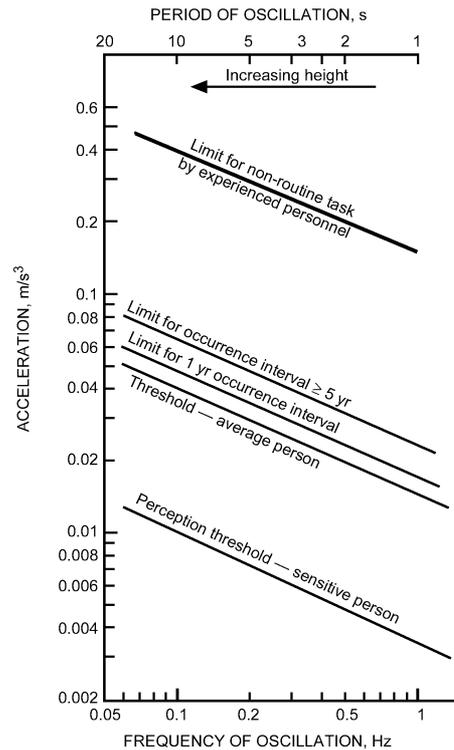

**Fig. 3 Factors Affecting Acceptability of Building Vibration**

occupants. For most purposes, these motions can be considered as the translational motions of the person. For example, a roll motion in a building about an axis of rotation some distance from a seated person will have a similar effect as side-to-side translational motions of that person, etc.

Most methods assess building vibrations with rms averaging and frequency analysis. However, human response is related to the time-varying characteristics of vibration as well. For example, many stimuli are transient, such as those caused by a train passing a building. The vibration event builds to a peak, followed by a decay in level over a total period of about 10 s. The nature of the time-varying event and the number of occasions it occurs during a day are important factors that might be overlooked if data are treated as steady-state and continuous.

**Standard Limits**

**Low-Frequency Motion (1 Hz).** The most commonly experienced form of slow vibration in buildings is building sway. This motion can be alarming to occupants if there is fear of building damage or injury. While occupants of two-story wood frame houses accept occasional creaks and motion from wind storms or a passing heavy vehicle, such events are not as accepted by occupants of high-rise buildings. Detected motion in tall buildings can cause discomfort and alarm. The perception thresholds of normal sensitive humans to low-frequency horizontal motion are given in Figure 4

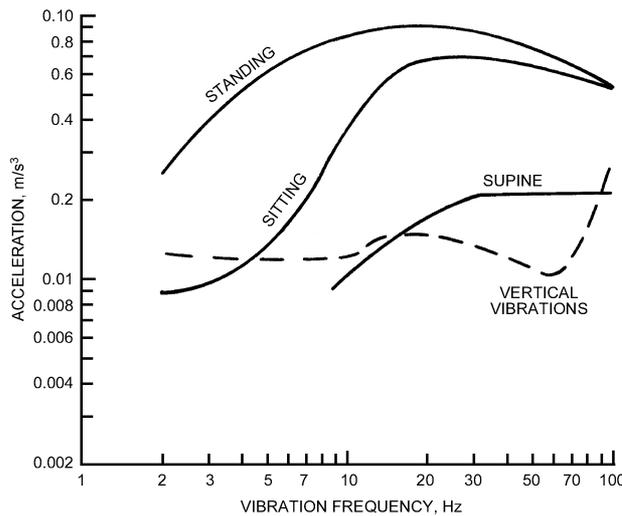

**Fig. 4 Acceleration Perception Thresholds and Acceptability Limits for Horizontal Oscillations**

(ISO 1984, Chen and Robertson 1972). The frequency range is from 0.06 to 1 Hz or, conversely, for oscillations with periods of 1 to 17 s. The natural frequency of sway of the Empire State Building in New York City, for example, has a period of 8.3 s (Davenport 1988). The thresholds are expressed in terms of relative acceleration, which is the actual acceleration divided by the standard acceleration of gravity ( $g = 9.8 \text{ m/s}^2$ ). The perception threshold to sway in terms of building accelerations decreases with increasing frequency and ranges from 50 to 20  $\text{mm}^2/\text{s}$ .

For tall buildings, the highest horizontal accelerations generally occur near the top at the building's natural frequency of oscillation. Other parts of the building may have high accelerations at multiples of the natural frequency. Tall buildings always oscillate at their natural frequency, but the deflection is small and the motion undetectable. In general, short buildings have a higher natural frequency of vibration than taller ones. However, strong wind forces energize the oscillation and increase the horizontal deflection, speed, and accelerations of the structure.

ISO (1984) states that building motions are not to produce alarm and adverse comment from more than 2% of the building's occupants. The level of alarm depends on the interval between events. If noticeable building sway occurs for at least 10 min at intervals of 5 years or more, the acceptable acceleration limit is higher than if this sway occurs annually (Figure 4). For annual intervals, the acceptable limit is only slightly above the normal person's threshold of perception. Motion at the 5 year limit level is estimated to cause 12% to complain if it occurred annually. The recommended limits are for purely horizontal motion; rotational oscillations, wind noise, and/or visual cues of the building's motion exaggerate the sensation of motion, and, for such factors, the acceleration limit would be lower.

The upper line in Figure 4 is intended for offshore fixed structures such as oil drilling platforms. The line indicates the level of horizontal acceleration above which routine tasks by experienced personnel would be difficult to accomplish on the structure.

**Fig. 5 Median Perception Thresholds to Horizontal (Solid Lines) and Vertical (Dashed Line) Vibrations**

**Table 7 Acceptable to Threshold Vibration Level Ratios**

Place	Time	Continuous or Intermittent Vibration	Impulse or Transient Vibration Several Times per Day
Critical work areas	Day or night	1	1
Residential	Day/Night	2 to 4 / 1.4	30 to 90 / 1.4 to 20
Office	Day or night	4	60 to 128
Workshop	Day or night	8	90 to 128

*Note:* The ratios for continuous or intermittent vibration and repeated impulse shock are in the range of 0.7 to 1.0 for hospital operating theaters (room) and critical working areas. In other situations, impulse shock can generally be much higher than when the vibration is more continuous.

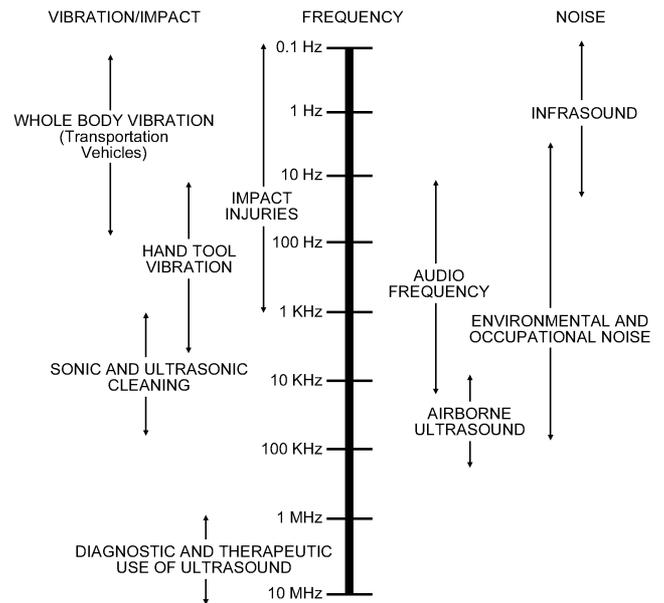

**High-Frequency Motion (1 to 80 Hz).** Higher frequency vibrations in buildings are caused by machinery, elevators, foot traffic, fans, pumps, and HVAC equipment. Further, the steel structures of modern buildings are good transmitters of high-frequency vibrations. The sensitivity to these higher frequency vibrations is indicated in Figure 5 (Parsons and Griffin 1988). Displayed are the median perception thresholds to vertical and horizontal vibrations in the 2 to 100 Hz frequency range. The average perception threshold for vibrations of this type is from 10 to 90 mm/s<sup>2</sup>, depending on the frequency and on whether the person is standing, sitting, or lying down.

People detect horizontal vibrations at lower acceleration levels when lying down than when standing. However, a soft bed decouples and isolates a person fairly well from the vibrations of the structure. The threshold to vertical vibrations is nearly constant at approximately 12 mm/s<sup>2</sup> for both sitting and standing positions from 2 to 100 Hz. This agrees with earlier observations by Reiher and Meister (1931).

Many building spaces with critical work areas (surgery, precision laboratory work) are considered unacceptable if vibration is perceived by the occupants. In other situations and activities, perceived vibration may be acceptable. Parsons and Griffin (1988) found that accelerations twice the threshold level would be unacceptable to occupants in their homes. A method of assessing vibrational acceptability in buildings is to compare the vibration with perception threshold values (Table 7).

**Sound and Noise**

When the vibration of an object is transmitted to air particles, making them vibrate, a variation in normal atmospheric pressure is

**Fig. 6 Mechanical Energy Spectrum**

created. When this disturbance spreads to the eardrum, it is vibrated, and this vibration is translated into the sensation called “sound.” In general terms, sound in the physical sense is the vibration of particles in a gas, a liquid, or a solid. The entire mechanical energy spectrum includes infrasound and ultrasound as well as audible sound (Figure 6).

**Health Effects.** Hearing loss is generally considered the most undesirable effect of noise exposure, although there are other effects. Tinnitus, a ringing in the ears, is really the hearing of sounds that do not exist. It often accompanies hearing loss. Paracusis is a disorder where a sound is heard incorrectly; that is, a tone is heard, but has an inappropriate pitch. Speech misperception occurs when an individual mistakenly hears one sound for another; for example, when the sound for “t” is heard as a “p.”

Hearing loss can be categorized as conductive, sensory, or neural. Conductive hearing loss results from a general decrease in the amount of sound transmitted to the inner ear. Excessive ear wax, a ruptured ear drum, fluid in the middle ear, or missing elements of the bone structures in the middle ear are all associated with conductive hearing loss. These are generally not occupationally related and are generally reversible by medical or surgical means. Sensory hearing losses are associated with irreversible damage to the inner ear. Sensory hearing loss is further classified as (1) presbycusis, loss caused as the result of aging; (2) noise-induced hearing loss (industrial hearing loss and sociacusis, which is caused by noise in everyday life); and (3) nosacusis, losses attributed to all other causes. Neural deficits are related to damage to higher centers of the auditory system.

Noise-induced hearing loss is believed to occur, in the most sensitive individuals, in those exposed for 8 h per day over a working lifetime at levels of 75 dBA and for most people similarly exposed to 85 dBA.

**ELECTROMAGNETIC RADIATION**

Radiation energy is emitted, transmitted, or absorbed in wave or particulate form. This energy consists of electric and magnetic forces which, when disturbed in some manner, produce electromagnetic radiation. Electromagnetic radiation is grouped into a spectrum arranged by frequency and/or wavelength. The product of frequency and wavelength is the speed of light ( $3 \times 10^8$  m/s). The

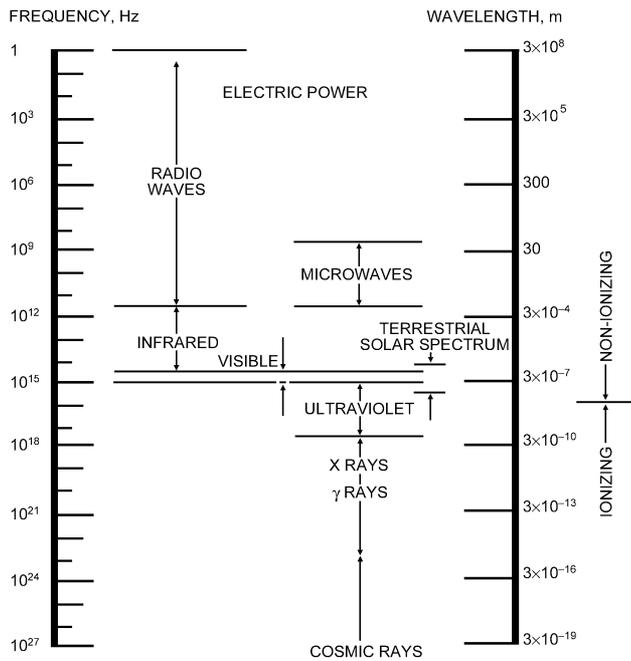

Fig. 7 Electromagnetic Spectrum

spectrum includes ionizing, ultraviolet, visible, infrared, micro-wave, radio-frequency, and extremely low frequency (Figure 7). Table 8 presents these electromagnetic radiations by their range of energies, frequencies, and wavelengths. The regions are not sharply delineated from each other and, in fact, often overlap. It is convenient to divide these regions as listed in Table 8, due to the nature of the physical and biological effects.

**Ionizing Radiation**

Ionizing radiation is that part of the electromagnetic spectrum that has very short wavelengths and high frequencies, and it has the ability to ionize matter. Such ionizations tend to be very damaging to living matter. Background radiation that occurs naturally in the environment is from cosmic rays and naturally occurring radionuclides. It has not been established whether exposure at the low dose rate of average background levels is harmful to humans.

The basic standards for permissible air concentrations of radioactive materials are those of the National Committee on Radiation Protection, published by the National Bureau of Standards as *Handbook No. 69*. Industries operating under licenses from the U.S. Nuclear Regulatory Commission or state licensing agencies must meet requirements of the *Code of Federal Regulations*, Title 10, Part 20. Some states have additional requirements.

An important naturally occurring radionuclide is radon (<sup>222</sup>Rn), a decay product of uranium in the soil (<sup>238</sup>U). Radon, denoted by the symbol Rn, is chemically inert. Details of units of measurement, typical radon levels, measurement methods and control strategies can be found in Chapter 12.

**Health Effects of Radon.** Studies of workers in uranium and other underground mines form the principal basis for knowledge about health risks due to radon. The radioactive decay of radon produces a series of radioactive isotopes of polonium, bismuth, and lead. Unlike their chemically inert radon parent, these progeny are chemically active. They can attach to airborne particles that subsequently deposit in the lung or deposit directly in the lung without prior attachment to particles. Some of these progeny, like radon, are alpha-particle emitters, and the passage of these alpha particles through lung cells can lead to cellular changes that may initiate lung cancer (Samet 1989). Thus, adverse health effects

Table 8 Energy, Wavelength, and Frequency Ranges for Electromagnetic Radiation

Radiation Type	Energy Range	Wavelength Range	Frequency Range
Ionizing	> 12.4 eV	< 100 nm	> 3.00 PHz
Ultraviolet (UV)	12.40 – 3.10 eV	100 – 400 nm	3.00 PHz – 0.75 PHz
Visible	3.10 – 1.63 eV	400 – 760 nm	750 THz – 395 THz
Infrared (IR)	1.63 – 1.24 meV	760 nm – 1 mm	395 THz – 0.30 THz
Microwave (MW)	1.24 meV – 1.24 eV	1 mm – 1 m	300 GHz – 300 MHz
Radio-frequency (RF)	1.24 eV – 1.24 peV	1 m – 1 Mm	300 MHz – 300 Hz
Extremely low frequency (ELF)	< 1.24 peV	> 1 Mm	< 300 Hz

Table 9 Action Levels for Radon Concentration Indoors

Country/Agency	Action Level	
	Bq/m <sup>3</sup>	pCi/L
Australia	200	5.4
Austria	400	10.8
Belgium	400	10.8
CEC	400	10.8
Canada	800	21.6
Czech Republic	400	10.8
P.R. China	200	5.4
Finland	400	10.8
Germany	250	6.7
ICRP	200	5.4
Ireland	200	5.4
Italy	400	10.8
Norway	400	10.8
Sweden	400	10.8
United Kingdom	200	5.4
United States	148	4.0
World Health Organization	200	5.4

Source: DOE (1995).

associated with radon are due to exposures to radon decay products, and the amount of risk is assumed to be directly related to the total exposure. Even though it is the radon progeny that present the possibility of adverse health risks, radon itself is usually measured and used as a surrogate for progeny measurements because of the expense involved in accurate measurements of radon progeny.

**Standards.** Many countries besides the United States have established standards for exposure to radon. International action levels are listed in Table 9.

About 6% of homes in the United States (5.8 million homes) have annual average radon concentrations exceeding the action level of 148 Bq/m<sup>3</sup> (4 pCi/L) set by the U.S. Environmental Protection Agency (Marcinowski et al. 1994).

**Nonionizing Radiation**

Ultraviolet radiation, visible light, and infrared radiation are components of sunlight and of all artificial light sources. Microwave radiation and radio-frequency radiation are essential in a wide range of communication technologies and are also in widespread

use for heating as in microwave ovens and heat sealers, and for heat treatments of a variety of products. Power frequency fields are an essential and unavoidable consequence of the generation, transmission, distribution, and use of electrical power.

**Optical Radiation.** Ultraviolet (UV), visible, and infrared (IR) radiation compose the optical radiation region of the electromagnetic spectrum. The wavelengths range from 100 nm in the UV to 1 mm in the IR, with 100 nm generally considered to be the boundary between ionizing and nonionizing. The UV region wavelengths range from 100 to 400 nm, the visible region from 400 to 760 nm, and the IR from 760 nm to 1 mm.

Optical radiation can interact with a medium by reflection, absorption, or transmission. The skin and eyes are the organs at risk in humans. Optical radiation from any of the spectral regions can cause acute and/or chronic biologic effects given appropriate energy characteristics and exposure. These effects include tanning, burning (erythema), premature “aging,” and cancer of the skin; and dryness, irritation, cataracts, and blindness in the eyes.

The region of the electromagnetic spectrum visible to humans is known as light. There can be biological, behavioral, psychological, and health effects from exposure to light. Assessment of these effects depends on the purpose and application of the illumination. Individual susceptibility varies, with other environmental factors (air quality, noise, chemical exposures, and diet) acting as modifiers. It is difficult, therefore, to generalize potential hazards. Light pollution results from the presence of unwanted light.

Light penetrating the retina not only allows the exterior world to be seen, but, like food and water, it is used in a variety of metabolic processes. Light stimulates the pineal gland to secrete melatonin, which regulates the human biological clock. This, in turn, influences reproductive cycles, sleeping, eating patterns, activity levels, and moods. The color of light affects the way the objects appear. The distortion of color rendition may result in disorientation, headache, dizziness, nausea, and fatigue.

As the daylight shortens, the human body may experience a gradual slowing down, loss of energy, and a need for more sleep. It becomes harder to get to work, and depression or even withdrawal may take place. This type of seasonal depression, brought on by changes in light duration and intensity, is called seasonal affective disorder (SAD). Sufferers of this syndrome also complain of anxiety, irritability, headache, weight gain, and lack of concentration

and motivation. Treatment of this problem is through the manipulation of environmental lighting (exposure to full-spectrum lighting for extended periods, 12 h/day).

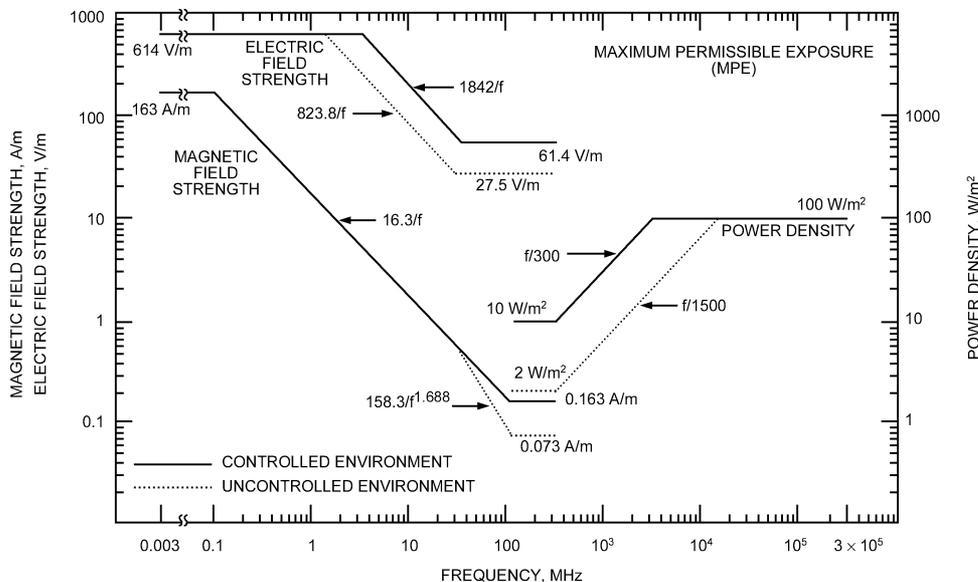

**Radio-Frequency Radiation.** Just as the body absorbs infrared and light energy, which can affect thermal balance, it can also absorb other longer wavelength electromagnetic radiation. For comparison, visible light has wavelengths in the range 0.4 to 0.7  $\mu\text{m}$  and infrared from 0.7 to 10  $\mu\text{m}$ , while the wavelength of K and X band radar is 12 and 28.6 mm. The wavelength of radiation in a typical microwave oven is 120 mm. Infrared is absorbed within 1 mm of the surface (Murray 1995).

The heat of the absorbed radiation raises the skin temperature and, if sufficient, is detected by the skin’s thermoreceptors, warning the person of the possible thermal danger. With increasing wavelength, the radiation penetrates deeper into the body. The energy can thus be deposited well beneath the skin’s thermoreceptors, making the person less able or slower to detect and be warned of the radiation (Justesen et al. 1982). Physiologically, these longer waves only heat the tissue and, because the heat may be deeper and less detectable, the maximum power density of such waves in occupied areas is regulated (ANSI 1991) (Figure 8). The maximum permitted power densities are less than half of sensory threshold values.

**ERGONOMICS**

Ergonomics may be defined as the scientific study of the relationship between man and his work environment to achieve optimum adjustment in terms of efficiency, health, and well-being. Ergonomic designs of tools, chairs, etc., help workers interact more comfortably and efficiently with their environment. In jobs that were ergonomically designed, productivity typically increased and the worker enjoyed a healthier working experience. More recently, researchers have distinguished intrinsic ergonomics from extrinsic, or traditional, ergonomics. Intrinsic ergonomics considers how the interface between an individual and the environment affects and relies on specific body parts (i.e., muscles, tendons, and bones) and work practices such as force of application, relaxation intervals, styles, and strength reserves that are not adequately considered in simple analyses of the physical environment.

The goal of ergonomic programs ranges from making work safe and humane, to increasing human efficiency, to creating human

**Fig. 8** Maximum Permissible Levels of Radio Frequency Radiation for Human Exposure

well-being. The successful application of ergonomic factors is measured by improved productivity, efficiency, safety, and acceptance of the resultant system design. The design engineer uses not only engineering skills, but also the sciences and principles of anatomy, orthopedics, physiology, medicine, psychology, and sociology to apply ergonomics to a design.

Implementing ergonomic principles in the workplace helps minimize on-the-job stress and strain, and prevents cumulative trauma disorders or CTDs. These disorders are subtle injuries that can affect the muscles, tendons, and nerves at body joints, especially the hands, wrists, elbows, shoulders, neck, back, and knees. Carpal tunnel syndrome is an example of a CTD. CTDs most frequently occur as a result of strain from performing the same task on a continuous or repetitive basis. This strain can slowly build over time, until the worker experiences pain and difficulty using the injured part of the body. Higher risks of developing CTDs are encountered when the work task requires repetitive motions, excessive force, or awkward postures. The ergonomics engineer addresses these risk factors by analyzing the task thoroughly and minimizing the repetitive motion, excessive force, and awkward posture.

**T**HERMAL conditions, air quality, lighting, noise, ion concentration, and crowding are important in designing structures for animals and plants. Thermal environment influences heat dissipation by animals and chemical process rates in plants. Lighting influences photoperiodism in animals and plants, and photosynthesis and regulation in plants. Air quality, noise, ion concentrations, and crowding can affect the health and/or productivity of animals or plants. This chapter summarizes the published results from various research projects and provides a concept of the physiological factors involved in controlling the environment.

### ANIMALS

Animal performance (growth, egg or milk production, wool growth, and reproduction) and their conversion of feed to useful products are closely tied to the thermal environment. For each homeothermic species, an optimum thermal environment permits necessary and desirable body functions with minimum energetic input (Figure 1A). The optimal thermal environment—in terms of an effective temperature that integrates the effects of dry-bulb temperature, humidity, air movement, and radiation—is less important to the designer than the range of conditions that provides acceptable animal performance, efficiency, well-being, and economic return for a given species. Figure 1A depicts this range as the **zone of nominal losses**, selected to limit losses in performance to a level acceptable to the livestock manager. Researchers have found that the zone of nominal losses corresponds to the welfare plateau (i.e., welfare is enhanced by maintaining environmental conditions within the zone of nominal losses). Milk and egg production by mature animals also shows an optional thermal environment zone, or zone of nominal losses (Figure 2).

Developed from actual measurements of swine growth, Figure 1B shows the relationships of energy, growth, and efficiency with air temperature. In the case of growing pigs in Figure 1B, the range of temperatures from 15 to 22°C, which includes both optimal productivity and efficiency levels, represents acceptable design conditions to achieve maximum performance and efficiency. Even beyond that temperature range, performance and efficiency do not markedly decline in the growing pig until near the lower critical temperature (LCT) or upper critical temperature (UCT), and potential performance losses within the temperature range from 10 to 25°C may be acceptable. Response

relationships, as shown in Figure 1B, allow environmental selection and design criteria to be based on penalties to performance (i.e., economic costs) and animal well-being—particularly when used with climatological information to evaluate risks for a particular situation (Hahn et al. 1983). Choosing housing requires caution, because research indicates that factors such as group versus individual penning, feed intake, and floor type can affect the LCT by 5 K.

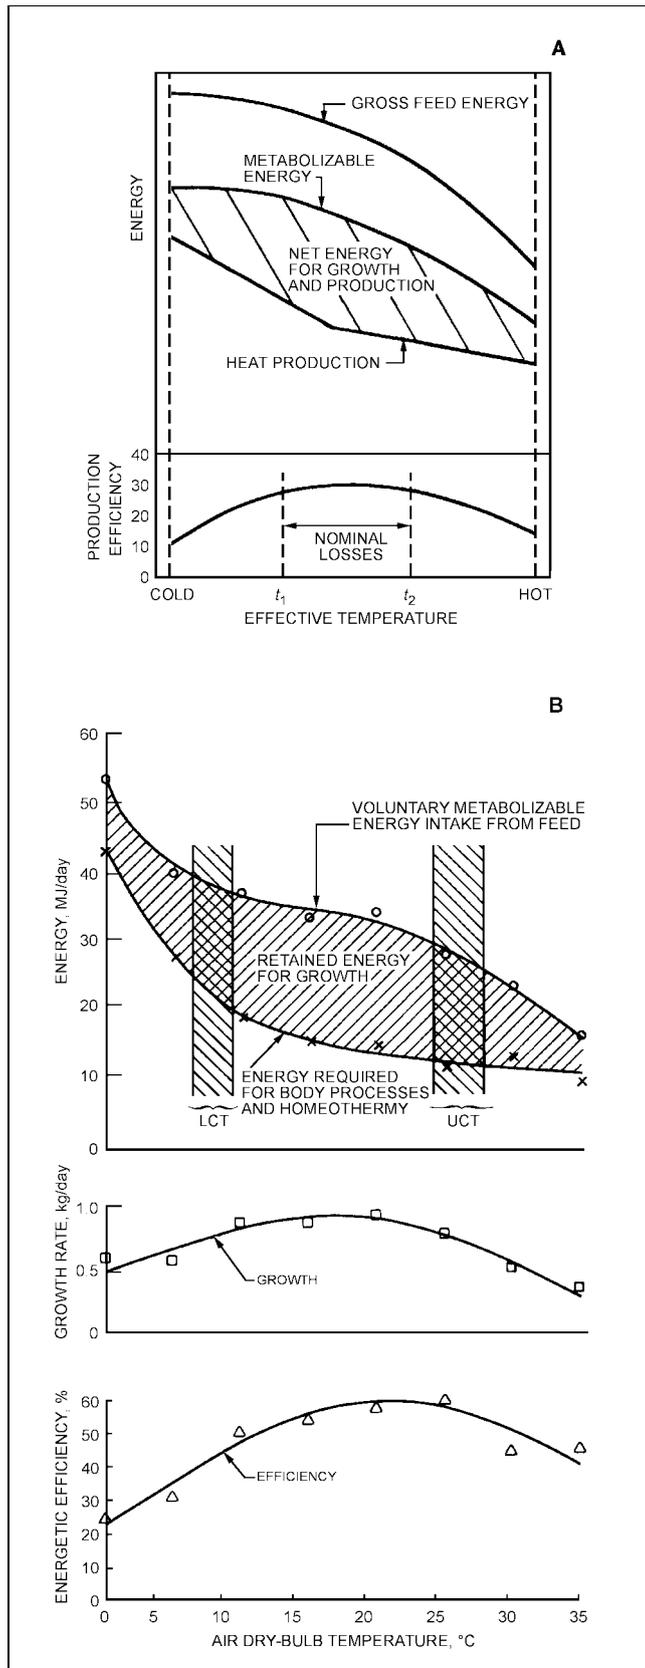

The limits of acceptable values of the LCT and UCT depend on such effects as the species, breed, genetic characteristics of an individual animal's age, mass, sex, level of feeding and type of feed, prior conditioning, parasites, disease, social factors such as space allocation, lactation or gestation, and physical features of the environment. The LCT and UCT vary among individuals; data reported are for group means. As a result, the limits become statistical values based on animal population and altered by time-dependent factors.

Acceptable conditions are most commonly established based on temperature because an animal's sensible heat dissipation is largely influenced by the temperature difference between the animal's surface and ambient air. Humidity and air movement are sometimes included as modifiers for an effective temperature. This has been a logical development. Air movement is a secondary but influential factor in sensible heat dissipation. The importance of air velocities is species and age dependent (e.g., swine under 8 weeks of age experience slower gains and increased disease susceptibility when air velocity is increased from 125 to 250 mm/s).

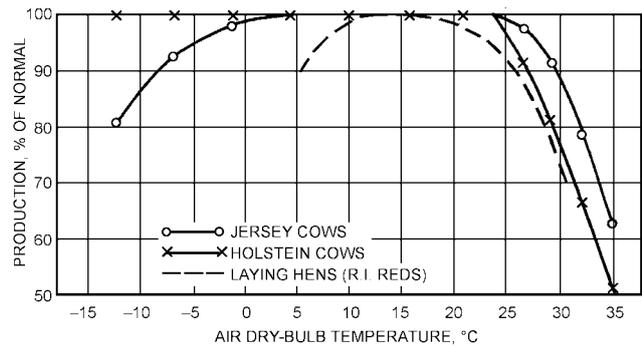

With warm or hot ambient temperature, elevated humidity can restrict performance severely. Relative humidity has little effect on the animal's heat dissipation during cold temperatures, and it is usually only moderately important to thermal comfort during moderate temperatures. (Information is limited on such interactions, as well as on the effects of barometric pressure, air composition, and thermal radiation.)

Animals housed in a closed environment alter air composition by reducing oxygen content and increasing carbon dioxide and vapor content. Decomposing waste products add methane, hydrogen sulfide, and ammonia. Animal activities and air movement add microscopic particles of dust from feed, bedding, and fecal material. Generally, a ventilation rate sufficient to remove water vapor adequately controls gases. However, improper air movement patterns, certain waste-handling methods, and special circumstances (e.g., disease outbreak) may indicate that more ventilation is necessary. In many cases, ventilation is not as effective for dust control as for gas control. Alternative dust control strategies may be needed.

The preparation of this chapter is assigned to TC 2.2, Plant and Animal Environment, with cooperation of Committees SE-302 and SE-303 of the American Society of Agricultural Engineers.

**Fig. 1 Energetic and Performance Relationships Typical for Animals as Affected by Effective Environmental Temperatures**  
(Hahn et al. 1983)

**Fig. 2 Comparative Effect of Air Temperature in Mature Animal Production**  
(Hahn et al. 1983, Tienhoven et al. 1979)

**ANIMAL CARE/WELFARE**

Animal facilities that facilitate good animal care and welfare must be designed considering a wide range of environmental factors beyond thermal conditions. These include space requirements, flooring type, lighting, feed and water requirements, animal handling, and waste management. Facilities that meet animal care and welfare needs vary considerably by purpose, animal species, and geographic location. For additional information and guidelines for designing animal facilities to meet animal care and welfare needs, see the section on Bibliography.

**PHYSIOLOGICAL CONTROL SYSTEMS**

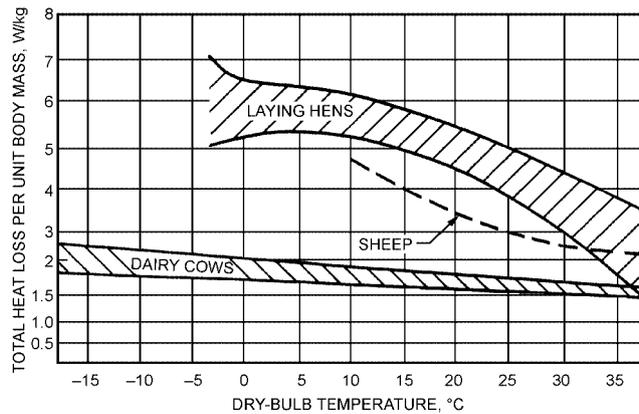

An animal has a phenomenally stable control system. Despite wide variations in environmental, nutritional, or pathological conditions, animals can control blood pressure and composition, body temperature, respiration, and cardiac output without conscious effort. Physiological control systems react to unfavorable conditions to ensure survival of the animal at the expense of production or reproduction.

One physiological control system important for air-conditioning design is the homeothermic system—the means by which an animal adapts to its thermal environment. The animal strives to control body temperature by adjusting both heat production in the tissues and transfer of heat to the environment from exposed surfaces. The homeothermic system in domestic animals is a closed-loop system and can be analyzed like any closed-loop control system.

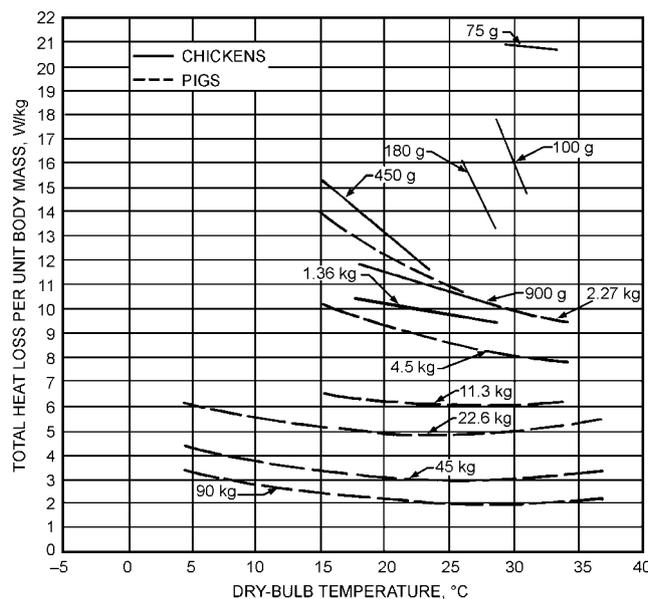

**Heat Production**

Heat production data have been measured for many farm animals (Yeck and Stewart 1959, Longhouse et al. 1960, 1968, Bond et al. 1959). Much of the early data were obtained for a basal condition (i.e., all life processes at a minimum level). Heat production under conditions of normal metabolic activity is more useful to the engineer. Such data are now available for most farm animals (Figures 3 and 4). Where possible, the data show total or sensible and latent heat for animals fed in a typical housing situation. Thus, the sensible heat used to evaporate urine moisture (assuming no other moisture) appears as latent heat. For design purposes, such data are better reflections of total heat partitioning than metabolic heat production obtained by calorimetry. Scott et al. (1983) provide additional information on specific situations.

The rate of heat production is primarily a function of temperature, animal species, and animal size. Heat production varies diurnally, depending on animal activity and eating times, and may change dramatically under special circumstances (e.g., when animals are disease-stressed). Building type and waste-handling system can affect the conversion of sensible to latent heat by more than 50%. Heat and moisture production of animals changes with other

**Fig. 3 Comparative Heat Loss of Mature, Producing Animals**  
(Tienhoven et al. 1979)

**Fig. 4 Comparative Heat Loss of Growing Animals**  
(Bond et al. 1959)

variables such as their genotype and growth rate. For example, a broiler chicken grows to 4 kg in 7 weeks compared to 12 weeks 30 years ago. Faster growth rate is usually associated with higher heat production, so updated data is needed. Therefore, the ranges of ventilation require careful analysis.

**Heat Transfer to Environment**

An animal can control, to some extent, the amount of heat transferred from its body by chemical and physical regulations. In a cold environment, the animal’s metabolism increases, which increases the amount of heat production, offsetting heat transfer to the environment. (The principal result of such chemical regulation is inefficient feed utilization.) Physical regulation is also used in a cold environment; blood circulation to subcutaneous capillaries decreases, hair or feathers are erected, and animals huddle together in an attempt to reduce sensible heat loss. In a hot environment, opposite physical and physiological responses generally occur to enable transfer to the environment of heat associated with necessary and productive life processes. In addition, as sensible heat dissipation becomes more

difficult, evaporative heat loss increases and air moisture content becomes a factor in heat loss. Since the production of heat is a necessary by-product of growth and useful production, environmental limits to dissipating this heat cause a decrease in feed consumption and subsequent decrease in growth and production.

Most sensible heat of domestic animals is dissipated through the skin. Birds, sheep, and swine transfer most of their latent heat through the respiratory tract; cattle and horses transfer most of their latent heat through the skin. Blood transfers the heat produced by metabolism to the skin or to the lung surfaces, where it is dissipated by evaporation from the mucous layer coating the inside of the alveoli. Inspired air reaching the alveoli is heated almost to body temperature and may become nearly saturated with moisture. Expired air may not be saturated at body temperature—especially during periods of heat stress—because it is a combination of air, some of which has not reached deeply into the lungs. Minor amounts of heat are also transferred by ingestion of feed and water and through excretion.

Design factors affecting animal heat loss are (1) air temperature; (2) air vapor pressure; (3) air movement; (4) configuration, emissivity, absorptivity, and surface temperature of the surrounding shelter; and (5) temperature and conductivity of surfaces (e.g., floors with which the animal may be in contact).

**Cyclic Conditions**

The physiologic sensing elements respond both to environmental conditions and to changes in those conditions. Cycles of temperature, pressure, light, nutrients, parasites, magnetic fields, ionization, and other factors frequently occur with little engineering control.

Light is perhaps the earliest discovered and most important controlled environmental variable affecting reproductive processes (Farner 1961). However, the effects vary widely among animal species and age. Some animals grow and remain healthy with or without light (e.g., growing swine), while for others, lighting management is important. Studies have shown that (1) short photoperiods induce or accelerate estrus development in sheep; (2) day length affects semen production in sheep and horses (Farner 1961); (3) continuous white incandescent light during incubation caused White Leghorn eggs to hatch from 16 to 24 h earlier than eggs incubated in darkness (Shutze et al. 1962); and (4) red, yellow, or blue lights gave comparable results. Use of lights for only one of the three weeks also reduced the time required for hatching, but differences were not as marked. Percent hatchability was not affected by lighting treatments.

Light is used to delay sexual maturity in hens, which enhances subsequent production. This is done by gradually decreasing day length from hatching to 22 weeks of age or by abruptly decreasing day length to 9 h at 14 to 16 weeks of age. If pullets have previously been exposed to an increasing day length, the change should take place at 14 weeks of age; if exposed to a constant or decreasing schedule, a change at 16 weeks is adequate. Light intensities of 10 to 20 lx measured at bird height were adequate in all cases. Light can then be abruptly increased at 21 weeks of age to 14 or 16 h of light. The economic value of increasing day length beyond 14 h in a windowless poultry house, and 16 h in an open poultry house, has not been proved. Photoperiods such as 8 h of light (L), 10 h of darkness (D), 2 L and 4 D, and other cycles have improved feed utilization, egg production, and poultry growth (Buckland 1975, Riskowski et al. 1977).

Continuous light from hatching through 20 to 21 weeks of age markedly depressed subsequent egg production and caused a severe eye abnormality, but did not depress egg mass. (Light intensity was 10 to 30 lx, measured at bird height.)

Temperature cycles have been studied in cattle (Brody et al. 1955, Kibler and Brody 1956), swine (Bond et al. 1963, Nienaber et al. 1987), and poultry (Squibb 1959). The results differ somewhat among animals. Heat loss from cattle and swine can usually

be calculated from average daily environmental temperatures with sufficient accuracy for design load calculation.

Productivity is only slightly different for averaged temperatures when cyclic conditions with a range less than 10K are experienced (Squibb 1959). Above that range, productivity is depressed below that expected from the averaged temperature as determined in constant temperature tests, but under diurnally varying air conditions (15 to 25°C temperature and widely varying humidities), near-normal egg production is maintained.

### Air Composition and Contaminants

The major contaminants in livestock housing are (1) respirable dusts from feed; manure; and animal skin, hair, and feathers; (2) microbes, both pathogenic and nonpathogenic, hosted in the respiratory tracts, animal wastes, or feed; and (3) several noxious gases of various concentrations. Respirable dust particles have diameters between approximately 0.5 and 5 µm. Gases are produced from the metabolic processes of animals, from the anaerobic microbial degradation of wastes, and from combustion processes. The gases of most concern are ammonia, hydrogen sulfide, carbon monoxide, and methane.

Dust levels in animal housing are high enough to create a nuisance in and near animal buildings, increase labor requirements for building and equipment maintenance, and interfere with the performance of heating and ventilating equipment. Dust has been implicated in poultry building fires. Dust is generated primarily by feed handling and increases with animal activity and air movement causing reentrainment of settled dust.

Contaminants are a concern because they predispose animals to disease and poorer performance and affect operator health. Animals experiencing stress (e.g., newborns, hot or cold, nutritionally limited, and sick animals) are more sensitive, and the presence of low levels of contaminants can have adverse effects on them.

Particulates (dust, endotoxins, live and dead microorganisms) and gases (ammonia, carbon dioxide, and hydrogen sulfide) in swine buildings (Zejda et al. 1993, Senthilselvan et al. 1997) have been implicated as contributors to the increased incidence of respiratory disorders among livestock producers compared to grain farmers and non-farm workers (Donham et al. 1989, Dosman et al. 1988). Young farmers may be at particular risk of developing chronic bronchitis, coughing, wheezing, toxic organic dust syndrome, and/or occupational chronic pulmonary disease (Zejda et al. 1994). For example, 33% of pork producers in Europe suffer chronic respiratory symptoms related to poor indoor air quality (Van't Klooster 1993). In the Netherlands, 10% of swine producers had to change jobs due to severe respiratory problems caused by poor air quality (Preller et al. 1992). In cold climates, the problems appear to be more serious because of (1) larger building size and longer working hours and (2) lower air exchange rates due to cold climates and energy conservation concerns.

Particle size is most commonly described using aerodynamic diameter, which is defined in terms of its aerodynamic behavior rather than its geometric properties. Aerodynamic diameter is a function of its equivalent geometric diameter, density, and a shape factor. The aerodynamic diameter of a particle is the diameter of a spherical water droplet having the same settling velocity as the particle of concern. Size distribution of dust particles influences the dust transportation and its effect on a human respiratory system. The human eye can only see a particle larger than 50 µm under normal light. For evaluating animal buildings, particle size is often divided into the following categories:

- Total dust = all sizes of particles suspended in the air
- Inhalable dust = all sizes of particles that are inhaled by a sampling instrument
- Respirable dust = particles smaller than 10 µm

In animal facilities, ultrafine particles (< 0.5 µm) are usually excluded from the evaluation because they are primarily background dust and not the concern of the indoor environment. If the dust concentration is measured in counts rather than mass, the ultrafine particles can dominate over the counts of the other particle sizes and cause large errors (Zhang et al. 1994).

Dust in animal buildings is different from other types of buildings in at least three aspects. First, animal building dust is biologically active in that it contains a variety of bacteria, microorganisms, and fungi (Martin et al. 1996, Wiegard and Hartung 1993). Second, its concentration is high, typically more than ten times higher than office buildings and residential buildings. Third, it is an odor carrier. Dust sources and flora are summarized in Table 1. Of those microbes, some are transmittable to people. For example, *Listeria monocytogenes* and *Streptococcus suis* are zoonotic agents that have caused fatal diseases in people (Fachlam and Carey 1985, Bor-tolussi et al. 1985).

**Table 1 Dust Sources and Flora in Swine Buildings**

<b>Dust Sources</b>	
Feed particles:	Grain dust Antibiotics Growth promoters
Swine protein:	Urine Dander Serum
Other agents:	Swine feces Mold Pollen Grain mites, insect parts Mineral ash Gram-negative bacteria Endotoxin Microbial proteases Ammonia adsorbed to particles Infectious agents

Gram-positive cocci:	<i>Staphylococcus</i> species (coagulase-negative) <i>Staphylococcus haemolyticus</i> <i>Staphylococcus hominis</i> <i>Staphylococcus simulans</i> <i>Staphylococcus sciuri</i> <i>Staphylococcus warneri</i> <i>Micrococcus</i> species <i>Aerococcus</i> species <i>Streptococcus equines</i> <i>Streptococcus suis</i> (presumptive) <i>Enterococcus durans</i>
Gram-positive bacilli:	<i>Corynebacterium</i> species <i>Corynebacterium xerosis</i> <i>Bacillus</i> species
Gram-negative bacilli:	<i>Acinetobacter calcoaceticus</i> Nonfermentative gram-negative bacillus: <i>Enterobacter calcoaceticus</i> <i>Pasteurella</i> species <i>Vibrio</i> species
Fungi:	<i>Alternaria</i> species <i>Cladosporium</i> species <i>Penicillium</i> species

Source: Zhang (1995, 1996).

Threshold limit values for different types of exposure are available (Table 2). These limit values are likely additive. For example, someone exposed to 75% of maximum ammonia level may be exposed to no more than 25% of the maximum for any other contaminant or combination of contaminants. Due to its biological nature, a lower limit for animal building dust may be warranted. For example, Donham et al. (1989) proposed a more stringent threshold TWA value of 0.23 mg/m<sup>3</sup> respirable dust for farm animal buildings.

Airborne dust and microbes have been linked to respiratory disease in cattle, poultry, swine, horses, and laboratory animals. Infectious diseases, such as viral pneumonia and diarrhea, in calf barns have caused mortality rates between 20 and 80%, with the highest mortality occurring in enclosed barns that were underventilated during cold weather. Many respiratory diseases of poultry have been found to be transmitted via pathogenic microbes that can travel over 50 km and remain infectious for months (Siegmond 1979). Respiratory diseases are also costly to the swine industry—the incidence of enzootic pneumonia in pigs has ranged from 30 to 75%.

Gaseous ammonia is frequently a contaminant causing serious problems in swine and poultry housing. Ammonia levels of 50 ppm have been shown to reduce body mass gain rates of swine (Curtis 1983), and many researchers suspect that adverse health effects begin at levels below 25 ppm (18 mg/kg). Some physiologists and veterinary science researchers suggest that the level is between 5 and 10 ppm (3.5 and 7 mg/kg) (Donham 1987). Ammonia at concentrations greater than 60 ppm (45 mg/kg) has been implicated in reduced body mass and feed consumption, and in increased ocular and respiratory problems with broiler chickens (Carr and Nicholson 1980). Ammonia levels are influenced by animal diet, the ventilation rate, sanitation practices, and the waste-handling system. Ventilating for moisture control is usually adequate to control ammonia below 10 ppm (7 mg/kg) in buildings sanitized monthly, where wastes are not allowed to accumulate for more than two weeks and where manure solids are covered by water.

Hydrogen sulfide is produced mainly from the wastes and is present at toxic levels that usually cause problems only when liquid wastes are agitated or pumped and emitted gases can filter into the animal occupied area. Hydrogen sulfide production can rise to lethal levels when manure in a pit below the animals is agitated, so extra precautions are necessary to ensure that ventilation is sufficient to remove the contamination.

Carbon monoxide is usually produced by malfunctioning fuel-burning heaters and internal combustion engines used for spray washing equipment. Many heaters are unventilated, which, when combined with the corrosive environment in livestock housing, makes this equipment susceptible to failure. Heaters should be vented to the outdoors or sensors should be installed to ensure complete combustion.

## PRINCIPLES FOR AIR CONTAMINANT CONTROL

Reducing dust concentration by 85% or reducing dust inhalation by wearing a respirator improves human respiratory responses significantly (Senthilselvan et al. 1997, Zhang et al. 1998, Barber et al. 1999). Air contaminant control strategies include source suppression, air cleaning, and effective ventilation.

### Source Suppression

Spreading (e.g., spraying, sprinkling, or fogging) a small quantity of oil, water, emulsifier or mixture of these can reduce dust concentration in the air (Takai et al. 1993, Zhang et al. 1995, 1996). Adding oil or fat to feed (Heber and Martin 1988) reduces emission of large feed dust particles. Other management practices, such as wet feeding, power washing, and maintaining sani-

**Table 2 Gas and Dust Threshold Values for People Exposure**

Contaminant	Specific Density <sup>a</sup>	Odor	TWA <sup>b</sup>	STEV <sup>b</sup>	FEV <sup>c</sup>
<b>Toxic gases (ppm in volume)</b>					
Ammonia	0.6	sharp, pungent	25	35	300

<sup>c</sup>From Canada Plan Service, M-8710 (1985), M-9707 (1992).

n/a = currently not available

TWA = time-weighted average, for 40 hours per week

STEV = short-term exposure value for not exceeding 30 minutes

FEV = fatal exposure values

tation in the facility also reduces the production and emission of air contaminants.

### Air Cleaning

Generally, air contaminants can be removed mechanically, electrically, chemically, or biologically. **Mechanical air cleaning** includes filtration, scrubbing, and aerodynamic separation (cyclones or dust separators). Existing mechanical air cleaning methods, including fiber filters, require large quantities of airflow through the filtration media. For many dusty environments such as found in animal buildings, this type of cleaner requires frequent maintenance.

**Cyclones** use centrifugal force to separate particles from the main air stream. But a high pressure drop (typically higher than 500 Pa) across the cyclone is required to create the cyclone effect. This high pressure requires a large amount of power and creates high turbulence, which reduces the particle separation efficiency. Carpenter (1986) concluded that it is impractical to separate particles smaller than those that cause health concerns in animal buildings.

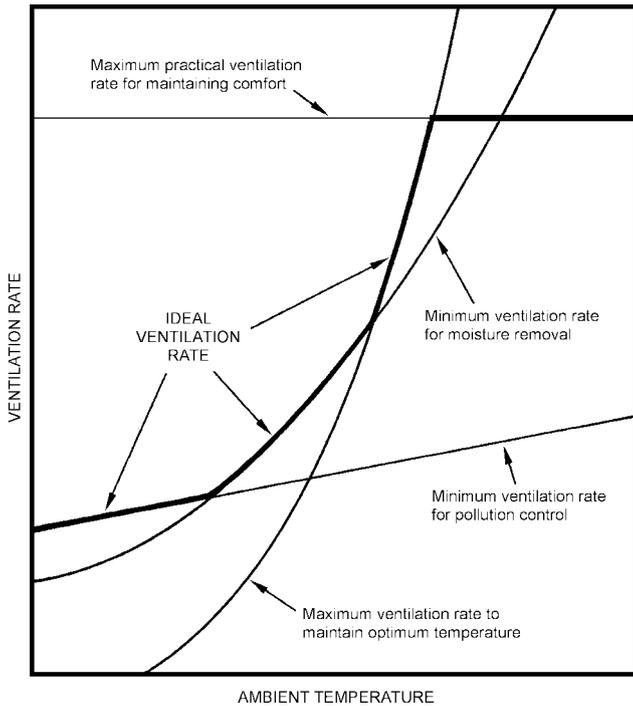

**Electrical air cleaning** includes ionization, electrostatic precipitation, and ozonation. The principle of the three technologies is to charge a dust particle with polarized electrical particles (ions or electrons) so that the charged dust particles can be attracted to a neutrally or opposite charged surface. Challenges of the ionization technology for livestock buildings include dust removal efficiency, initial and maintenance costs, and a potential problem of static electricity when used under cold and dry weather conditions.

The air cleaning efficiency of an electrostatic precipitator is proportional to the airflow rate through the precipitator. A large airflow rate in an airspace can reentrain a large amount of settled dust and thus create a high dust concentration in the air. Dust reduction efficiency, airflow rate, and power consumption of the air delivery through the precipitator must be balanced for optimum performance. Similar to air filters, an electrostatic precipitator requires frequent cleaning and maintenance. When dust particles accumulate on the precipitation surfaces of the device, the air cleaning efficiency rapidly decreases.

**Ozone** can effectively reduce airborne microorganisms in an animal building. Care must be taken to maintain an appropriate concentration because ozone is a potential irritant to humans and animals.

### Ventilation Requirement

Ventilation is the primary method for controlling air quality in confinement buildings as it brings in fresh air to dilute the contaminants. The logic of ventilation is illustrated in Figure 5. Unlike res-

**Fig. 5 Logic for Selecting the Appropriate Ventilation Rate in Livestock Buildings**  
(Christianson and Fehr 1983)

idential or office buildings, the minimum ventilation for animal buildings is often determined by humidity or contaminant (such as ammonia) balances. Therefore, ventilation requirements must be calculated for sensible heat, humidity, and a given contaminant to determine the minimum ventilation for an animal building.

Volumetric ventilation requirement for sensible heat balance  $V_s$ , moisture balance  $V_w$ , and contaminant balance  $V_c$  (in  $\text{m}^3/\text{s}$ ) can be calculated as follows:

$$V_s = \frac{q_n v}{(h_s - h_{s_o})} \quad (1)$$

$$V_w = \frac{W_n v}{(w - w_o)} \quad (2)$$

$$V_c = \frac{M_c v}{(c - c_o)} \quad (3)$$

where

- $v$  = specific volume of air,  $\text{m}^3/\text{kg}$
- $q_n$  = net heat transfer rate through the building shelter, kW
- $h_s$  = sensible heat content of room air, kJ/kg
- $h_{s_o}$  = sensible heat content of outside air or supply air, kJ/kg
- $w$  = moisture content of room air, kg/kg of air
- $w_o$  = moisture content of outside air, kg/kg of air
- $W_n$  = production rate of moisture within the room, kg/s
- $c$  = contaminant concentration of room air, kg/kg of air
- $c_o$  = contaminant concentration of outside or supply air, kg/kg of air
- $M_c$  = production rate of the contaminant in the room, kg/s

### Ventilation Effectiveness

Two terms are often used to evaluate a ventilation system: ventilation efficiency and ventilation effectiveness. **Ventilation efficiency** is a criterion for energy and fan performance; it is not

directly related to ventilation effectiveness and air quality control. Ventilation efficiency refers to the mass of air delivered per unit of power consumed by the ventilation system at a given pressure. The more air delivered per unit of power, the more efficient the ventilation system. It is also called the **ventilation efficiency ratio (VER)** or **energy efficiency ratio (EER)** (Pratt 1983).

Zhang et al. (2000) proposed a **ventilation effectiveness factor (VEF)** to quantitatively describe the ventilation effectiveness for controlling indoor air quality. The VEF can be defined as the ratio of two contaminant concentration differentials:

$$\text{VEF} = \frac{C_x - C_s}{C_m - C_s} \quad (C_m > C_s \text{ and } C_x > C_s) \quad (4)$$

where  $C_x$  is the contaminant concentration under complete mixing conditions, which can be determined based on the mass balance of the contaminant of concern. For a ventilated airspace at steady state, the amount of contaminant removed by the exhaust air must equal the sum of the amount of contaminant brought in by the supply air plus the contaminant produced in the airspace, regardless of complete or incomplete mixing conditions. The contaminant concentration of the exhaust air  $C_e$  can be measured. Under complete mixing conditions,  $C_e$  is the same as the  $C_x$ ; thus,

$$C_x = C_e \quad (5)$$

$C_s$  is the contaminant concentration of the supply air,  $C_m$  is the mean contaminant concentration of the airspace at  $n$  measured locations.

$$C_m = \frac{1}{N} \sum_{i=1}^N C_i \quad (6)$$

Substituting Equations (5) and (6) into Equation (4), ventilation effectiveness factor becomes

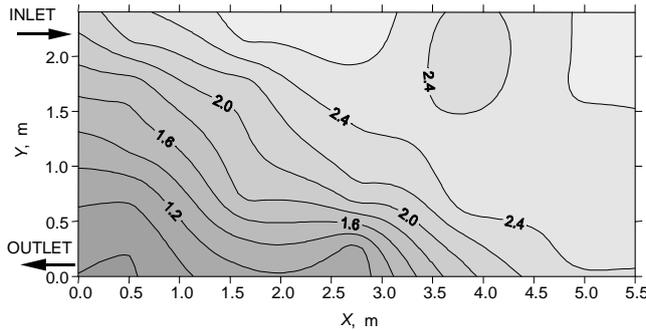

$$\text{VEF} = \frac{N(C_e - C_s)}{\sum_{i=1}^N C_i - N C_s} \quad (C_e > C_s) \quad (7)$$

The ventilation effectiveness factor is nondimensional and independent of the ventilation rate. The higher the value of the factor, the more effective the ventilation system for contaminant removal. When  $C_e < C_s$ , the airspace becomes a settling chamber or an air cleaner and the air cleaning efficiency  $\xi = 1 - C_e/C_s$  should be used to evaluate the system. When the contaminant concentration of supply air is negligible, i.e.,  $C_s \approx 0$ , the ventilation effectiveness factor becomes

$$\text{VEF} = \frac{C_e}{C_m} \quad (8)$$

One useful feature of VEF is that the system being evaluated can be its own control. This feature is particularly valuable for evaluating or troubleshooting in the field. From Equation (4) and Equation (8), the VEF compares the actual contaminant concentration with its own concentration under complete mixing conditions in the same airspace. The existing methods of evaluating ventilation effectiveness often require comparing two systems. In practice, it is usually difficult to find an identical system for comparison.

A ventilation effectiveness map (VEM) such as shown in Figure 6 is a useful tool for design, analysis, and modification of a ventilation system. It is a contour plot of the ventilation effectiveness factors calculated using Equation (8) for the entire airspace. Dust mass was measured concurrently at several locations throughout the building cross section and the VEF values were calculated from that

**Fig. 6 Typical Ventilation Effectiveness Map for a Room**  
(Room is 5.5 m long by 3.7 m wide by 2.4 m high with slot air inlet at top of one wall and air outlet near bottom of same wall.)

data. The higher the VEF values in the map, the more effective the ventilation system is in that area.

Improved ventilation effectiveness is an important strategy to reduce contaminant concentration in animal buildings. It is very expensive to clean large quantities of air and it is difficult to move the air through central cleaning equipment without creating drafts. Incomplete mixing ventilation such as **displacement** and **zonal ventilation** has great potential in creating a cleaner zone in a dusty airspace without changing the overall ventilation rates.

**Interactive Stressors**

Thermal (air temperature, air humidity, air velocity, and surrounding surface temperatures) and air quality (relative absence of dust, microbes, and contaminant gases) are the two stressors of most concern to ventilating a livestock structure. However, health status, animal age, stage of production, nutrition, and social conditions interact with the thermal and air quality conditions to determine animal health and performance.

Whether stressors are linearly additive or otherwise is an important research area. McFarlane (1987) found that ammonia, heat, acoustic noise, disease, and beak-trimming stressor effects on chickens were linearly additive in effect on the feed efficiencies and daily gain rates.

**Comparing Individual Animal and Room Heat Production Data**

Liquid wastes from urine, manure, waterer spillage, and cleaning affect the sensible and latent heat fraction in a room (ASAE 1991). More water on the floors requires more thermal energy from the animals or the building heating system to evaporate the moisture. This evaporated moisture must then be removed by ventilation to prevent condensation on building surfaces and equipment and minimize adverse health effects, which can occur when humidities exceed 80%.

Floor flushing or excessive water spillage by animals can increase latent heat production by one-third from animal moisture production data, with a corresponding reduction in sensible heat production on a per-animal basis (ASAE 1991). Partially slatted floors with underfloor storage of wastes reduce the room moisture production by approximately 35%, compared to solid floor systems. Rooms with slatted floors throughout the building may have moisture production rates as much as 50% lower than solid floors. Therefore, slatted floors reduce the ventilation rate required for moisture removal, while excessive water spillage increases the moisture removal ventilation rate.

**Influence of Genetic Change and Breed on Heat Production**

Researchers have noted significant genetic correlations with performance. For example, swine breeds with high fat content characteristics outgained low fat content breeds, but the low fat content lines used feed more efficiently (Bereskin et al. 1975). Barrows (male hogs castrated before sexual maturity) ate 6% more than gilts (young sows that have not farrowed) to sustain a 7% faster growth rate.

Genetic improvements within breeds suggest that performance data should be updated periodically. Between 1962 and 1977, for example, the average gain rate for swine increased 70 g per day, and feed efficiency improved 15% for Missouri hogs (Thomeczek et al. 1977).

**CATTLE**

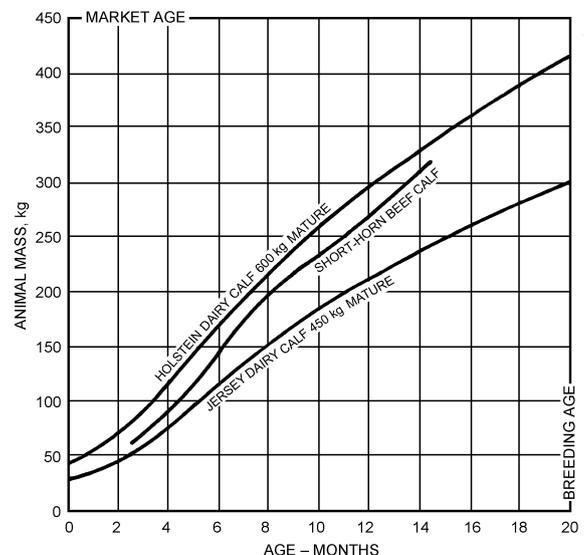

**Growth**

Figure 7 shows the general growth rate for both beef and dairy breeds. Efficiency of beef calf growth is of economic importance; the dairy calf is developed for adult productive and reproductive capacity. Fattening calves and yearlings could be fed increasing amounts of grain and hay, with an expected gain of about 0.9 kg per day. Figure 8 shows the effect of temperature on the growth rate of several breeds of beef calves.

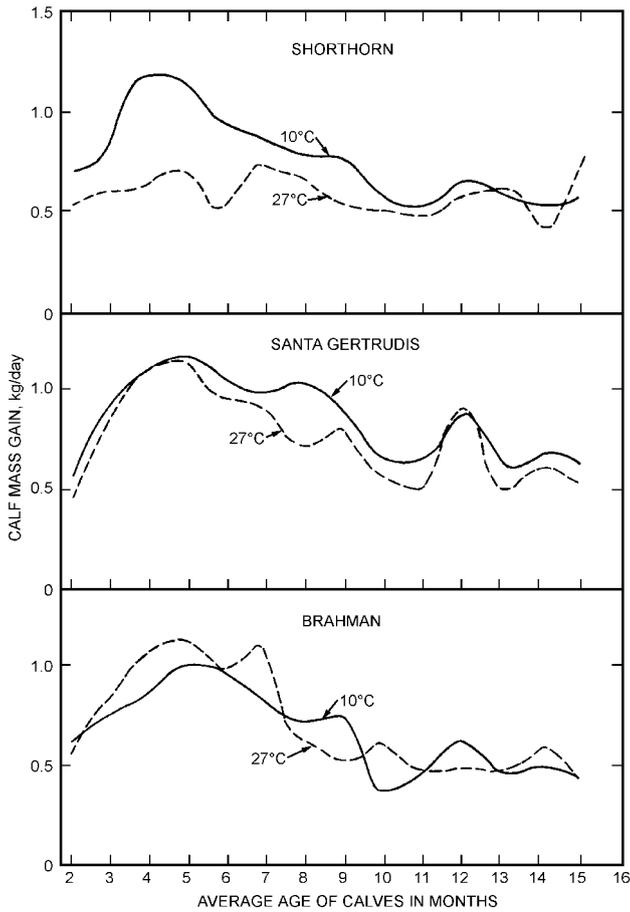

Food and energy requirements for growth can be computed by taking the difference between the energy in the available ration consumed and the energy required for maintenance and growth. Energy requirements for maintenance at an air temperature of 20°C has been reported to be 9.13 kJ/h per kilogram of body mass (Blaxter and Wood 1951), 8.42 kJ/h (Bryant et al. 1967), and 8.80 kJ/h (Gebremedhin et al. 1983). Using 3413 kJ/kg body tissue for conversion of feed energy to body tissue (Brody 1945), the growth rate of a calf at 21°C (0.54 g/h gain per kilogram of body mass) can be nearly 30 times that of a calf being kept at 3°C [18 mg/(h·kg)]. Alternatively, to get the same growth rate at 3°C as at 21°C, the same ration must be fed at the rate of 11.6% of body mass each day, a 16% increase (Gebremedhin et al. 1981).

**Lactation**

Figure 9 illustrates the effect of high temperature on the milk production of one Holstein in a test designed to study the combined

**Fig. 7 General Growth Curves for Calves Fed Grain**  
(Johnson et al. 1958, Ragsdale 1960)

**Fig. 8 Daily Mass Gain of Beef Calves**  
(Longhouse et al. 1960)

effects of temperature and humidity. The dotted line represents the normal decline in milk production (persistency) from an advancing stage of lactation.

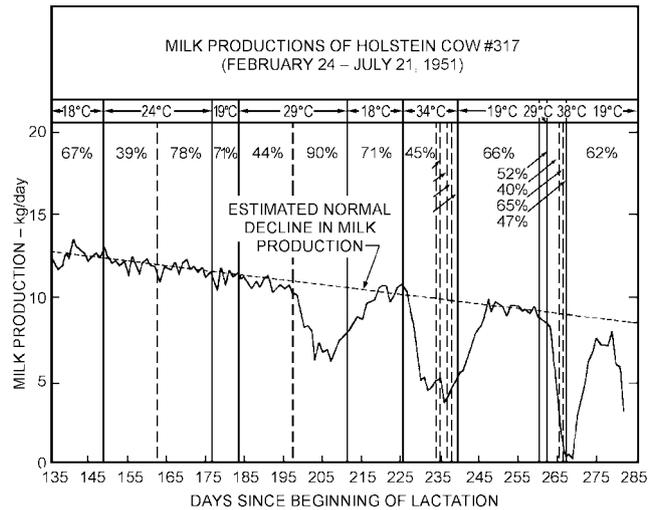

The ideal environment for Holstein cattle should not exceed 24°C. Jerseys are somewhat more heat tolerant, and their limit can be 27°C (Yeck and Stewart 1959). At the lower end of the temperature scale, production decreases may be expected at -1°C for Jerseys and below -12°C for Holsteins and Brown Swiss.

A temperature-humidity index (THI) expresses the relationship of temperature and humidity to milk production. Temperature-humidity indexes have a greater effect on cows with a genetic potential for high milk production than for those with a lower potential (Figure 10).

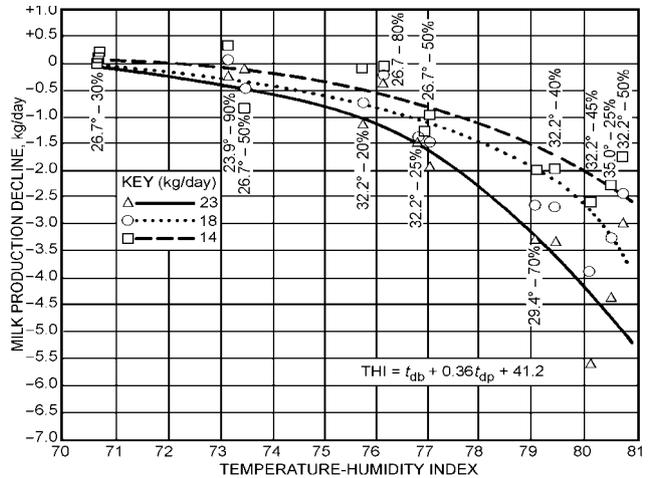

Under high temperatures, a cooling system can help maintain milk production and reproductive function. In field studies conducted by Bucklin and Turner (1991) in both warm and hot, humid climates, a system providing evaporative cooling by forced air movement and direct sprinkling of lactating cows increased milk production by a range of 7 to 15% over cows not exposed to cooling.

**Reproduction**

Prolonged low temperatures, even those well below freezing, do not affect the reproductive performance of farm livestock, but breeding efficiency of both sexes decreases under summer conditions. Sustained temperatures above 30°C may decrease fertility, sperm production, and semen quality of males, and increase anestrus and embryonic death in females. In bulls, temperatures above 24°C decrease spermatogenesis, and long exposures at 30°C or above cause temporary sterility. The extent of the reaction depends on temperature rise and exposure duration.

**Fig. 9 Milk Production Decline of One Holstein During Temperature-Humidity Test**  
(Yeck and Stewart 1959)

**Fig. 10 Effect of Milk Production Level on Average Decline in Milk Production, Versus Temperature-Humidity Index**  
(Johnson et al. 1962)

In females, Guazdauskas (1985) observed that conception rates decreased from a range of 40 to 80% conception in thermoneutral environments (10 to 22°C) to a range of 10 to 51% conception in hot environments (>27.5°C). A cooling system involving a cooled shade and artificially induced air movement increased breeding efficiency by approximately 100% in a hot climate (Wiersma and Stott 1969).

**Heat and Moisture Production**

Sensible and latent heat production from individual animals (Figure 11) differ from the stable heat and moisture production of animals (Figures 12 and 13). The data in Figures 12 and 13 were obtained while ambient conditions were at constant temperatures and relative humidities were between 55 and 70%. The effects of evaporation from feces and urine are included in these data.

The rate of cutaneous water loss is very small at colder temperatures but rises sharply above 18°C. Cutaneous evaporation as a means of heat loss in calves becomes increasingly important as the air temperature rises above 24°C. As the air temperature rises, the

proportion of nonevaporative cooling decreases. Above 30°C, about 80% of the heat transferred is by evaporative cooling. Gebremedhin et al. (1981) observed that cutaneous water loss from calves varied between 0.06 and 0.4 g/h per kilogram of body mass for air temperatures between 0 and 18°C and increases steadily beyond 18°C (Figure 14). Water loss by respiration, the other avenue of loss, is shown in Figure 15.

breed. Hampshires often gain more than 0.5 kg per day, and lambs can be fed to have a mass over 90 kg while still under a year old.

Variations exist among breeds and strains of sheep in their ability to adjust to environmental changes. Temperature effects on sheep growth suggest a lower rate at elevated temperatures. A South African study shows that lack of shade in warm climates reduces growth rate. Australian studies indicate that Merino lambs survive for only about 2 h in an air temperature of 38°C.

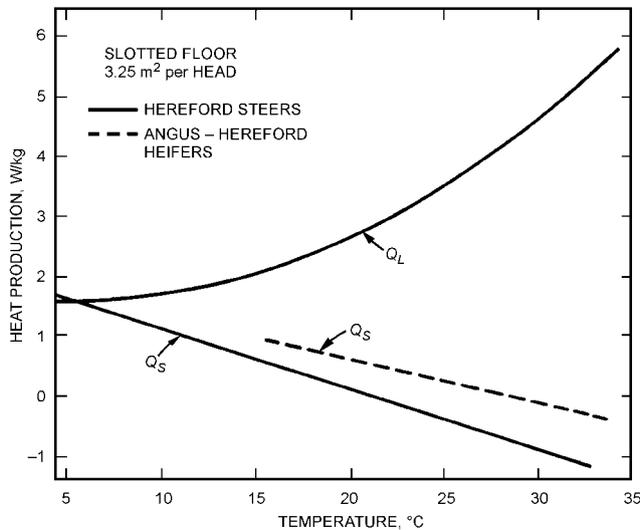

**SHEEP**

**Growth**

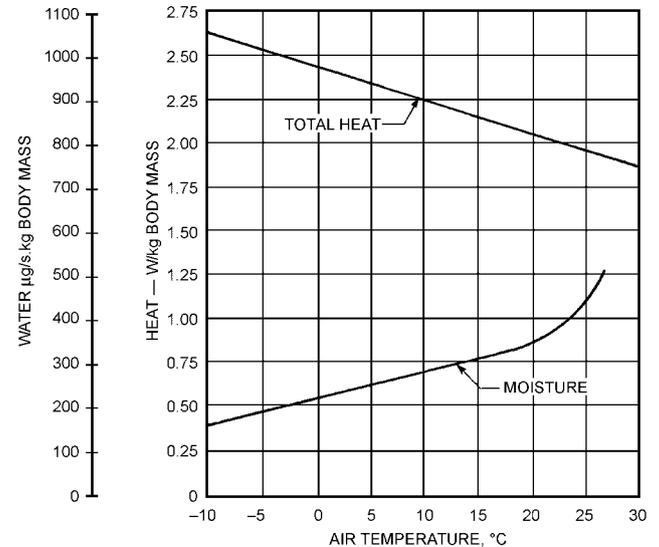

In normal environments, an average daily gain of 0.25 kg per day can be expected of lambs marketed at 40 to 60 kg, depending on

**Wool Production**

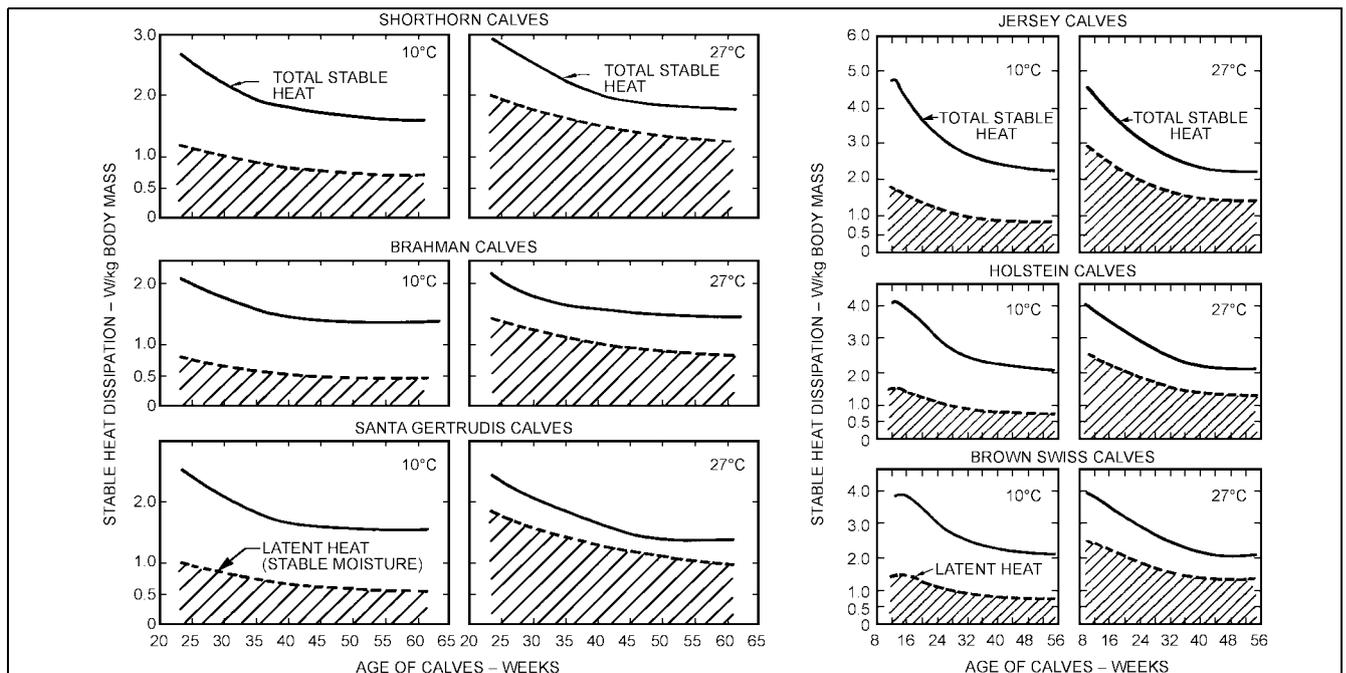

The amount and quality of wool produced varies considerably among breeds, ranging from about 1.4 kg of poor quality wool from

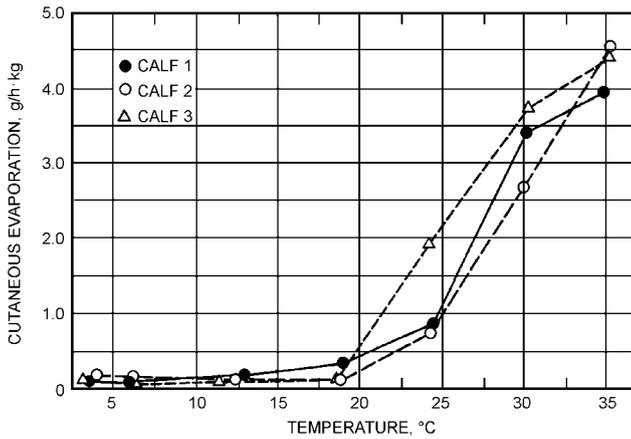

**Fig. 11 Sensible and Latent Heat Production per Unit Livestock Mass**

(Gebremedhin et al. 1981)

Dorset ewes (a breed developed primarily for mutton) to well over 4.5 kg of high quality fleece from dual-purpose breeds. Rambouillet, Merino, and Columbia-Southdale breeds supplied 3.2 kg per year, and about 2.0 kg was grown by a Hampshire, where monthly shearing increased wool production by about 0.5 kg per year.

Environmental factors such as photoperiod, nutritional level, and temperature also affect wool growth. Skin temperature is considered a dominant factor; high wool growth is associated with high skin temperatures. In a related study, low subcutaneous blood circulation limited wool growth. A thick fleece appears to limit radiant heat loads.

**Reproduction**

Sheep mate only during certain periods of the year, but they can sometimes be induced to mate outside the normal season if the natural environment is modified. Ewes may breed if exposed to an air temperature of 7°C before mating is attempted.

In studies on the effects of high temperatures on sheep reproduction, air temperature was reported to affect the spermatogenesis rate. Rams kept at 32°C environmental temperature showed a reduced rate of spermatogenesis, although a 3-week period at 21°C effected recovery to the normal rate. Later reports suggest that high air temperatures may cause lowered fertility for other reasons. Sub-

jecting ewes to 38°C just before mating causes fertilization failure because of some form of ovum structure degeneration.

Under practical conditions, early embryonic death appears to be the greatest loss in potential offspring conceived in a high-temperature environment. Degree of susceptibility to high temperature is greatest near mating time but generally decreases as the length of time after mating increases. A temperature of 32°C and 65% rh at mating kills most embryos at an early age. The same conditions applied later in gestation do not cause death, but do cause the birth of small, weak lambs. The longer the high-temperature period, especially during the last third of gestation, the greater the number of weak lambs born. All reproductive processes appear to be more adversely affected by high air temperature when accompanied by high relative humidity.

**Heat Production**

Only a few heat-production tests have been conducted, mostly for correlation with other physiological data. A lamb's ability to generate heat is important because it is normally born during the most severe climatic season. One study indicated newborn lambs were limited in heat production to 19.4 W/kg—five times the basal level. Test conditions were from -10 to 0°C with a 19 km/h wind, but lambs are capable of withstanding temperatures as low as -40°C. Table 3 provides heat production data for sheep; while the total heat production data are reliable, the latent heat proportions do not reflect the portions of sensible heat used for water and urine evaporation from flooring and bedding.

**SWINE**

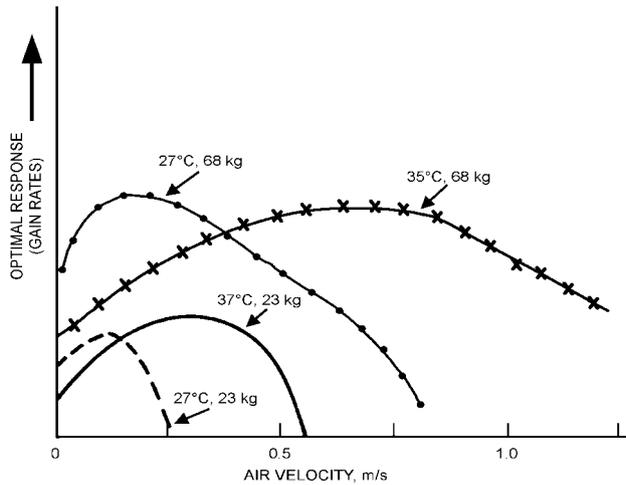

**Growth**

Ambient air temperature affects the feed conversion and daily mass of growing swine. As shown in Figure 1B, a temperature range of 16 to 21°C produces maximum rates of gain and feed use for 70 to 100 kg hogs, while a broader range of 10 to 24°C reduces performance only slightly. For 20 to 59 kg animals, the optimal and nominal loss ranges are about 17 to 23°C and 13 to 24°C, respectively (Kibler and Brody 1956). Younger animals require temperatures of 23 to 28°C for best performance, and piglets from 3 days to 2 weeks of age should have 30 to 32°C conditions (Hahn 1983).

Daily air temperature cycles of more than 5 K on either side of 21°C result in reduced daily gain by pigs and an increased feed requirement per unit of gain (Nienaber et al. 1987). Reasonably constant air temperatures are desirable.

The level of air temperature in which swine grow affects deposition and retention of protein (carcass quality). Lean meat formation is reportedly highest in pigs raised between 16 and 21°C (Mount 1963). However, the ratio of protein to fat decreases at air temperatures above 16°C.

Swine gains and feed conversion rates are highly sensitive to air velocities and, in many cases, are affected adversely at velocities as low as 0.25 m/s. Swine less than 8 weeks of age should not be

**Fig. 16 Swine Response to Air Velocity**  
(Riskowski and Bundy 1986, Bond et al. 1965)

exposed to velocities greater than 0.25 m/s; a velocity lower than 0.13 m/s is preferred when temperatures are in the recommended range. Even in hot conditions, pigs are affected adversely by air velocities greater than 1 m/s (Bond et al. 1965, Gunnarson et al. 1967, Riskowski and Bundy 1991). Feed utilization and gain are much better at low air velocities (0.18 m/s) than at high (1.5 m/s) air velocities when temperatures are optimal (Figure 16).

**Reproduction**

Merkle and Hazen (1967) and Heard et al. (1986) have shown that sows benefit from some type of cooling in hot weather. In these studies, cool, dry air was directed at the sow to relieve heat stress by increasing evaporative and convective heat dissipation. Field studies of breeding problems and resultant small litters have established that both sexes suffer losses from high temperature. Sprinkling the sow during hot weather at breeding time and shortly after resulted in more live births than with unsprinkled sows. Sprinkling boars before mating also increased the number of live births per litter. Conception rate varied from about 100% of normal at 21°C to only 70% at 32°C. Breeding difficulties and a decrease in live embryos were observed in tests with controlled temperatures and relative humidities (Roller and Teague 1966). In some species, spontaneous abortion under severe heat stress may save the mother’s life; however, sows appear to die of heat prostration, due to extra metabolic heat generation in late pregnancy, before spontaneous abortion occurs.

Little information is available on the value of temperature control for sows during cold weather. Forcing sows to produce the necessary heat to maintain body temperature may require rigid nutritional management to avoid the animals from becoming overweight—a condition resulting in poorer conception and smaller litters.

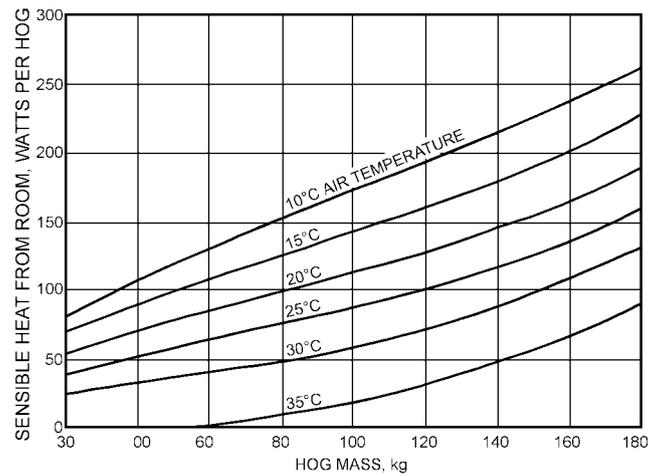

**Heat and Moisture Production**

Table 4 (Butchbaker and Shanklin 1964, Ota et al. 1982) shows heat production for piglets. Figure 17 and Figure 18 (Bond et al.

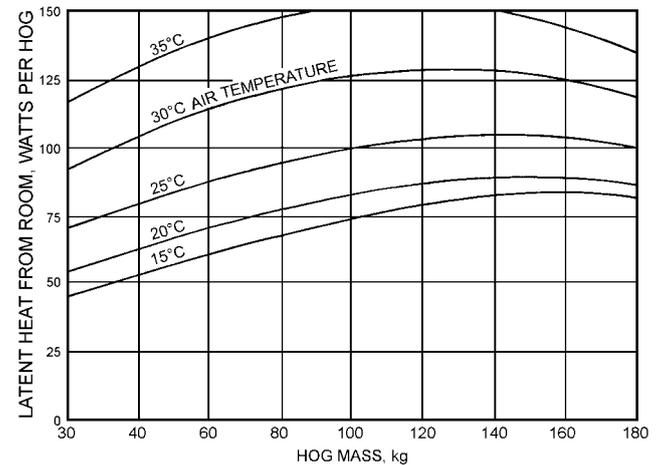

**Table 4 Heat Production of Grouped Nursery Pigs**

Source: Ota et al. (1982).

**Fig. 17 Room Sensible Heat in Hog House**  
(Bond et al. 1959)

**Fig. 18 Room Latent Heat in Hog House**  
(Bond et al. 1959)

1959) show heat and moisture that must be accounted for in ventilating or air conditioning older swine housing for swine between 20 and 180 kg, housed at temperatures from 10 to 32°C. These data are the sensible and latent heat levels measured in a room containing hogs. For design purposes, room heat data reflect swine housing conditions rather than metabolic heat production from an individual animal.

The same data can be applied even where building temperatures are cycling, if the average air temperature during the cycle is used for design. The total animal heat load and the latent load that the ventilation system must remove are greater than the values in Figure 17 and Figure 18, if the air velocity around the animals is more than about 0.25 m/s.

The lower critical temperature (the ambient temperature below which heat production increases) is about 25 to 30°C for a group of newborn pigs; for a single piglet, the critical temperature is about 34 to 35°C. As the pigs grow, the critical temperature falls—for 2 to 4 kg pigs, it is between 30 and 35°C; for 4 to 8 kg pigs, between 25 and 30°C. The floor bedding materials for growing piglets influence these critical temperatures. For a group of nine pigs averaging 40 kg, the critical temperature is 12 to 13°C on straw, 14 to 15°C on asphalt, and 19 to 20°C on concrete slabs (Butchbaker and Shanklin 1964).

**CHICKENS**

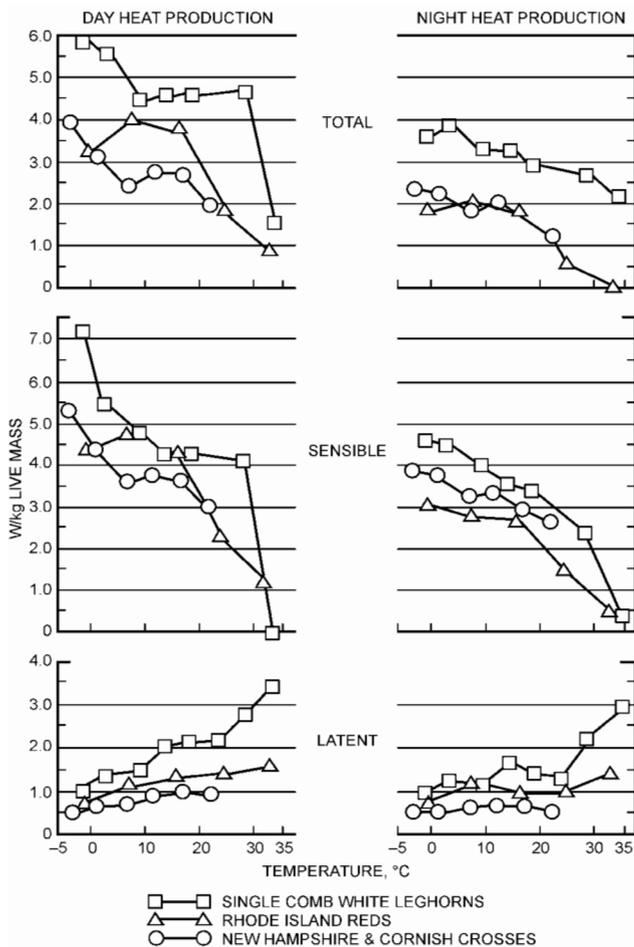

**Growth**

The tremendous worldwide production of broiler chickens is a result of improvements in genetics, nutrition, and housing. Two-kilogram broilers are produced in less than 6 weeks. Intermittent light and darkness (photoperiod) improve growth and conserve feed and energy (McDaniel and Brewer 1975).

Supplemental heat is generally needed for newly hatched chicks. Broiler strains respond well to brooding temperatures of 33°C for the first few days. Thereafter, air temperatures may be decreased at a rate of 4 K per week until 21°C is reached. Relative humidities of 65 to 70% promote good feathering and market-quality broilers. Effects of air velocity on heat dissipation of broilers is widely acknowledged, although not completely quantified, and has led to the widespread adoption of tunnel ventilation in new housing. Some benefit from increased velocity (up to 2.5 m/s) is obtained at air temperatures from 24 to 35°C (Drury 1966). High-velocity air, at a temperature above the feather temperatures, causes more, not less, heat stress. Observations showed that 28-day-old broilers rested in areas with airflow temperature combinations of 0.28 m/s at 15°C, 0.5 m/s at 21°C, and 0.75 m/s at 24°C.

**Reproduction**

Adverse effects of high thermal environments (above 29°C) on egg production include fewer eggs, reduced egg mass, and thinner

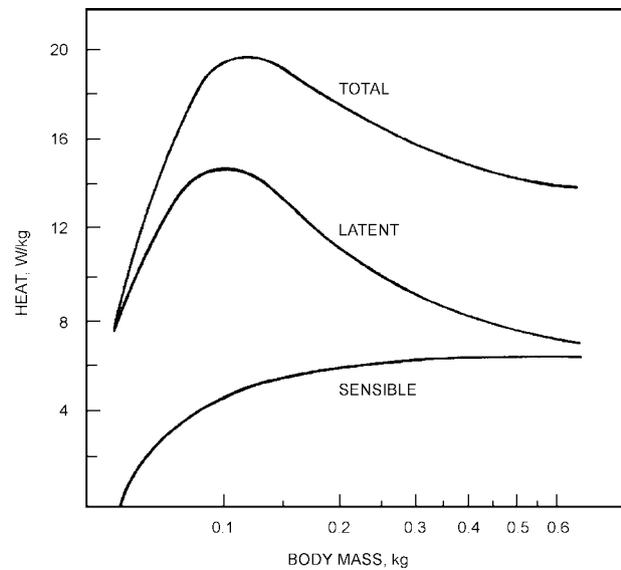

**Fig. 19 Heat and Moisture Loads for Caged Laying Hens at Various Air Temperatures**  
(Ota and McNally 1961)

shells. Hens over 1 year of age are more adversely affected by high thermal environments than younger hens. Larger hens are more adversely affected than smaller hens. Hatchability also declines as temperatures increase. Although the fertility rate is good at 21°C, it declines at 30°C. Feed requirements increase markedly below 7°C; activity and productivity decline below 0°C. The suggested ideal environment is between 13 and 24°C.

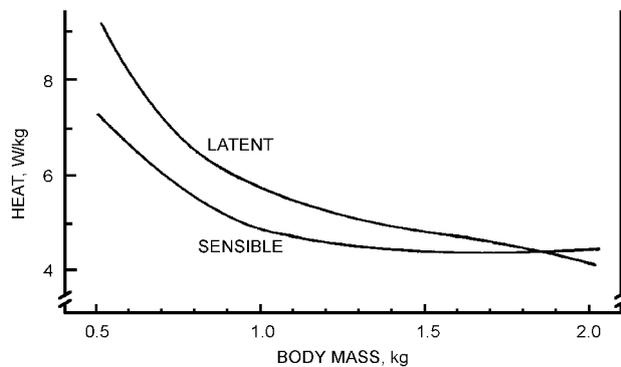

Increasing relative humidity above 80%, at 29°C dry-bulb temperature, produces an increased respiration rate and drooping wings. After 7 to 10 days, acclimatization may reduce the respiration rate, but production will still be less than optimal. Generally, relative humidity can vary from around 40% to 75% with little impact on bird performance. Lower relative humidities may be associated with dusty conditions and signal excessive minimum ventilation; higher relative humidities are conducive to mold growth and building deterioration from excess moisture.

**Heat and Moisture Production**

Figure 19 shows the total sensible and latent heat produced by laying hens during day and night at various temperatures. Figure 20

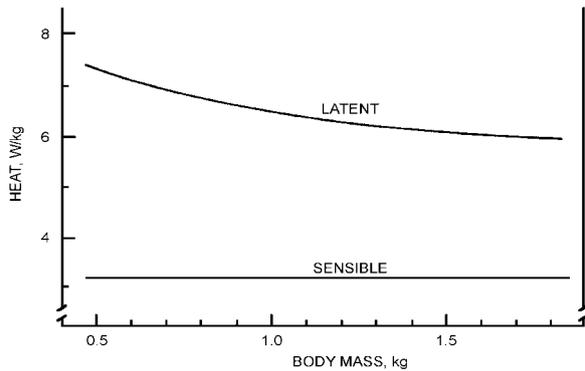

**Fig. 20 Sensible, Latent, and Total Heat for Chicks Brooded on Litter**  
(Reece and Lott 1982)

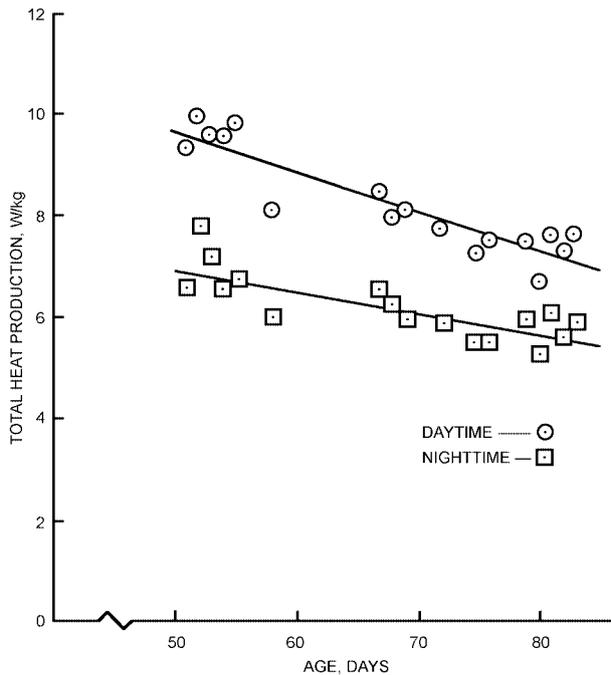

**Fig. 21 Sensible and Latent Heat for Broilers Raised at 27°C on Litter**  
(Reece and Lott 1982)

shows the same data for chicks. Figure 21 and Figure 22 show sensible and latent heat production for broilers grown on litter at typical stocking rates at two temperatures. The effects of heat and moisture absorption or release by the litter are included in these figures. (Note: modern bird growth rates have increased approximately threefold since the work reported in Figures 20, 21, and 22 was performed.)

The continued improvement in nutrition, genetics, and housing for poultry means that currently available data for heat and moisture production is outdated. Research by Gates et al. (1996) suggests that total specific heat production (i.e., expressed per kilogram of body mass) may be reasonably similar, but that partitioning between sensible and latent components has changed. In general, latent loads have increased during brooding and decreased during growout, presumably because of new water delivery systems with fewer leaks.

**Fig. 22 Sensible and Latent Heat for Broilers Raised at 27°C on Litter**  
(Reece and Lott 1982)

**Fig. 23 Total Heat Production of Medium Breed Turkeys Versus Age During Daytime and Nighttime**  
(Buffington et al. 1974)

**TURKEYS**

**Growth**

The turkey poult has the best rate and efficiency of gain at a brooder room temperature of 21 to 24°C for the first 2 weeks, and 18°C thereafter, with about 70% rh. Initial brooder temperature should be 38°C, reduced 3 K per week until room temperature is reached. Proper control of photoperiod stimulates the growth rate in turkeys. Table 5 shows weekly cumulative average live mass for both sexes (Sell 1990). Figure 23 provides heat production data for medium breed turkeys.

**Reproduction**

Mature turkeys tolerate temperature and humidity over a range of at least -7 to 32°C and 35 to 85% rh. Since mature birds are kept only for fertile egg production, lighting for off-season egg production becomes very important. The young stock are raised to 20 weeks on natural light. At 20 weeks, females are placed in a

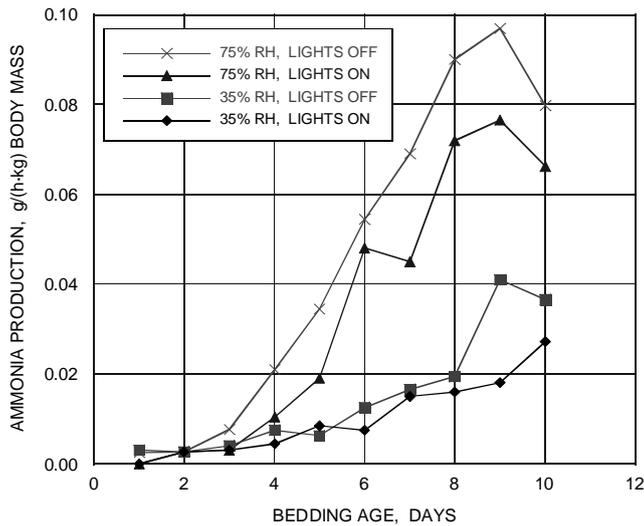

Fig. 24 Ammonia Generated by Laborator Mice

totally darkened pen and given 8 h per day illumination at an intensity of 20 to 50 lux at bird's-eye level. At 30 weeks, the sexes are mixed, and the lighting period is increased to 13 to 15 h. The breeding season then continues for 12 to 26 weeks.

### Heat and Moisture Production

Table 6 gives limited heat loss data on large breed growing turkeys (DeShazer et al. 1974); however, an estimate from data on heavy chickens, applied to turkeys on a live-mass basis, should be satisfactory for design purposes. The reduction in heat loss during the dark period of the day is 25% for large breeds (Buffington et al. 1974) and between 5 and 40% for small breeds.

The latent heat production of turkeys may be significantly higher than the 1970s data show if the growth rate or feed consumption is significantly higher in the 1990s than it was in the 1970s (see the section on Chickens, Heat and Moisture Production).

## LABORATORY ANIMALS

Significant environmental conditions for facilities that house laboratory animals include temperature, humidity, air motion, illumination, noise, and gaseous and viable particulate contaminants (Moreland 1975). Design conditions vary widely, depending on whether the animals are experiencing disease-induced stress (which alters environmental needs), subjected to test environments, or simply housed (Besch 1975, Murakami 1971, Nienaber and Hahn 1983). This fact reflects differing housing and ventilation guidelines for animals used in research (NIH 1985), compared to recommendations by the ASAE (1991) and Midwest Plan Service (MWPS 1983) for production agriculture. Little is known about the influence of disease on environmental requirements, animal performance, and well-being. Because significantly different conditions may exist between animal cages and the animal room (macroenvironment), control of cage environments is essential to ensure the animal's physiological well-being. Temperature and velocity gradient controls require low supply air-to-room air temperature differential, overhead high induction diffusion, uniform horizontal and vertical air distribution, and low return outlets.

### Heat and Moisture Production

Memarazadeh (1998) reported CO<sub>2</sub>, H<sub>2</sub>O and NH<sub>3</sub> generation rates, O<sub>2</sub> consumption rates, and heat generation rates of laboratory mice. The rates were measured at two room relative humidities

Table 7 Average Production/Consumption Rates for Laboratory Mice

Production/Consumption Rates per Kilogram of Body Mass	Light Period	Dark Period	Light/Dark Average
Total heat, W	23	27	—
Water generated, kg/h	—	—	0.08
CO <sub>2</sub> generated, kg/h	0.0068	0.0090	—
O <sub>2</sub> consumed, kg/h	0.0059	0.0066	—

Notes:

- Mice were white laboratory females in shoebox cages with chipped hardwood bedding.
- Heat production rates were calculated from O<sub>2</sub> consumption data. A mixed respiratory quotient (RQ) was assumed (RQ = 0.82), and heat production was based on a rate of 0.020 kJ/m<sup>3</sup> of O<sub>2</sub> consumed.

Pig	68	82.65	108.70	85.56	194.26
Chicken	1.82	5.47	3.78	6.42	10.20

<sup>a</sup>Based on standard metabolic rate  $M = 3.5W^{0.75}$  watt per animal (Kleiber 1961) or appropriate reference ( $W$  = animal mass, kg).

<sup>b</sup>Referenced according to availability of heat generation data. Otherwise, heat generations is calculated on basis of  $ATHG = 2.5M$  (Gordon et al. 1976). Latent heat is assumed to be 33% of total heat and sensible heat is 67% of total heat (Besch 1973, Woods et al. 1972).

<sup>c</sup>Data taken from Runkle (1964), Kleiber (1961), Besch (1973), Woods and Besch (1974), Woods et al. (1972), Bond et al. (1959), and Ota and McNally (1961).

ties (35% and 75%), and during light and dark periods. The production rate of CO<sub>2</sub> and H<sub>2</sub>O and the consumption of O<sub>2</sub> were constant over the 10 day period once the mice became acclimatized to cage conditions (Table 7). However, the generation rate of ammonia depended on the cage relative humidity, light phase, and day in the experiment (Figure 24).

Table 8 lists the approximate amount of heat released by laboratory animals at rest and during normal activity. For load calculation purposes, heat gain from all laboratory animal species can be estimated (Wood et al. 1972, Gordon et al. 1976) with an acceptable level of error from

$$ATHG = 2.5M \quad \text{where } M = 3.5W^{0.75} \quad (9)$$

and where

ATHG = average total heat gain, W per animal

$M$  = basal metabolic rate of animal, W per animal

$W$  = mass of animal, kg

Conditions in animal rooms must be maintained continuously. This requires year-round availability of refrigeration and, in some cases, dual air-conditioning facilities and emergency power for motor drives and control instruments. Chapter 21 of the 1999 ASHRAE Handbook—Applications has additional information on laboratory animal facilities.

## PLANTS: GREENHOUSES, GROWTH CHAMBERS, AND OTHER FACILITIES

Most agronomically important plant crops are produced outdoors in favorable climates and seasons. Greenhouses and other indoor facilities are used for the out-of-season production of horticultural crops for both commercial sales and research purposes, and for producing food, floricultural, and other crops in conditions that permit the highest quality by buffering the crops from the vagaries of weather. The industry that produces crops in greenhouses may be termed controlled environment agriculture (CEA).

Historically, many cold-climate commercial greenhouses were operated only from late winter into early summer, and during autumn. Greenhouses were too warm during midsummer; during winter in some cold-climate locations, light levels were too low and the day length inadequate for many crops. Mechanical ventilation, evaporative cooling, centralized heating systems, movable insulations, carbon dioxide enrichment, and supplemental lighting have extended the use of greenhouses to year-round cropping on a relatively large scale.

Growth chambers, growth rooms, and propagation units are environmentally controlled spaces used for either research or commercial crop production. Environmentally controlled chambers may include highly sophisticated facilities used for micropropagation (e.g., tissue culture), or may be simple boxes in which air temperature and lights are controlled. Indoor facilities having controlled temperature and humidity environments may be used as warehouses to hold plants and plant products prior to commercial sale. Often these are simple refrigerated storage rooms or chambers.

Primary atmospheric requirements for plant production include: (1) favorable temperatures, (2) adequate light intensity and suitable radiation spectrum, and (3) favorable air composition and circulation. Engineering design to meet these requirements typically is based on steady-state assumptions. The thermal and ventilation time constants of most greenhouses are sufficiently short that transient conditions are seldom considered.

### TEMPERATURE

#### Plant Requirements

Leaf and root temperatures are dominant environmental factors for plant growth and flowering. Factors in the energy balance of a plant canopy include air temperature, relative humidity, air movement, thermal radiation exchange, and convective exchange coefficients for sensible and latent heat. Therefore, leaf temperature is affected by such environmental factors as the type of heating and ventilating systems, supplemental lighting, light transmittance characteristics of the greenhouse cover, misting or evaporative cooling, location of the leaf on the plant, and the geometry of the surrounding leaf canopy.

Most information on plant responses to temperature is based on air temperature rather than plant temperature. Leaf temperature is difficult to measure, and one or several leaves represent neither the average nor the extreme temperatures of the plant. Since plants cannot actively regulate their cell and tissue temperatures in response to changing ambient conditions (passive regulation by opening and closing leaf stomata, which controls evapotranspiration, provides a small degree of control), their leaves and stems are usually within a few degrees of the surrounding air temperature (above during times of solar insolation, below at other times due to thermal reradiation and evapotranspiration).

All plants have minimum, optimum, and maximum temperatures for growth. Optimum temperature depends on the physiological process desired. Thermoperiodic species have different optimum day and night temperatures for each stage of growth, and each stage of plant growth may have its own unique optimum temperature

influenced by radiant flux density, the ambient carbon dioxide level, and water and nutrient availability.

Historically, plants have been grown with night temperatures lower than day temperatures. In practice, many greenhouse crops are grown at standard (blueprint) night temperatures. Day temperatures are increased from 5 to 10 K (depending on solar intensity) above night temperatures. Table 9 presents recommended ranges of night temperatures for a selection of greenhouse crops.

Night temperature (NT) and day temperature (DT) are manipulated to provide nonchemical means to control plant height and development in some greenhouse crops. The effects of both DT and NT and their difference ( $DIF = DT - NT$ ) are being investigated. Stem elongation, internode spacing and elongation, rate of elongation, photosynthesis rate, mature stem length, and fruit yield can be affected with DIF control (Jacobson et al. 1998, Neily et al. 1997, Erwin et al. 1991, Moe and Heins 1990). Typically, a negative DIF results in shorter crops. For example, Gent and Ma (1998) increased the yield of greenhouse tomatoes with a larger positive DIF (14 K) as compared to a lower positive DIF (5 K).

#### Heating Greenhouses

Heat loss from greenhouses is caused primarily by conduction through the structural cover and infiltration of outdoor air. The heating system is designed to meet the sum of the two. Perimeter heat loss is generally only a few percent of the total and is often neglected in design. When movable night insulation is used to conserve energy, heating systems are still designed to match conduction and infiltration losses without insulation because movable insulation may be opened early in the morning when outdoor air temperature is near its minimum, and excess heating capacity may be useful to melt snow in climatic regions where this occurs. Greenhouses are not designed to carry heavy snow loads.

#### Energy Balance

**Radiation energy exchange.** Solar gain can be estimated using procedures presented in Chapter 30. Not all insolation appears as sensible heat, however. As a general rule, from two-thirds to three-quarters of ambient insolation is available inside a typical commercial greenhouse. (Highly detailed models for calculating solar transmittance may be found in the literature.) If a greenhouse is filled with mature plants, approximately one-half of the available insolation (transmitted) may be converted to latent heat, one-quarter to one-third released as sensible heat, and the rest either reflected back outdoors or converted through photosynthesis (perhaps 3%).

Supplemental lighting can add significantly to the thermal load in a greenhouse. If movable night insulation is used, venting may be required during times of lighting, even during cold weather. The components of heat addition from supplemental lighting are divided between sensible and latent loads, with approximately one-quarter to one-third of the total heat load in latent form.

Reradiation heat loss from greenhouses comprises complex processes and may involve both reradiation from the structural cover and reradiation from inside the greenhouse if the cover is not thermally opaque. Glass is nearly thermally opaque, but many plastics are not. Newer plastic films may contain IR-inhibiting substances and can save a significant amount of heating energy, while adding only slightly to summer ventilation needs. Condensation on plastic films also reduces transmittance of thermal radiation, while diffusing but not seriously impairing transmittance of solar radiation. Generally, heat loss coefficients used in greenhouse design include the effects of thermal radiation exchange by the structural cover.

**Structural heat loss.** Conduction  $q_c$ , plus infiltration  $q_i$  determine total heating requirements  $q_t$ . While infiltration heat loss is most accurately calculated using enthalpy differences, in practice only air temperature changes are considered, but with the apparent specific heat of air adjusted upward to account for the latent heat component.

Table 9 Recommended Night Temperatures for Greenhouse Crops

Crop Species	Night Temperatures, °C	Remarks	Crop Species	Night Temperatures, °C	Remarks
Aster <i>Callistephus chinensis</i>	10-13	Long days during early stages of growth	Gloxinia <i>Sinningia speciosa</i>	18-21	Lower temperatures increase bud brittleness
Azalea <i>Rhododendron</i> spp.	16-18	Vegetative growth and forcing specific temperatures required for flower initiation and development	Hydrangea <i>H. macrophylla</i>	13-16 16-17 (forcing)	Specific temperature for flower initiation and development
Calceolaria <i>C. herbeohydrida</i>	16 10	Vegetative growth Flower initiation and development; initiation also occurs with long days and high temperatures if photon flux density is high	Iris <i>I. tingitana</i> (Wedgewood)	7-16 (forcing)	Forcing temperature 13 to 14°C for 10/11 bulbs; 10 to 12°C for 9/10 bulbs
Calendula <i>C. officinallis</i>	4-7		Kalanchoe <i>(K. Blossfeldiana)</i>	16	Temperatures influence rate of flower development and incidence of powdery mildew
Calla <i>Zantedeschia</i> spp.	13-16	Decrease to 13K as plants bloom	Lily <i>Lilium longiflorum</i>	16	Temperatures manipulated to alter rate of flower development; specific temperatures for flower initiation
Carnation <i>Dianthus caryophyllus</i>	10-11 winter 13 spring 13-16 summer	Night temperatures adjusted seasonally in relation to photon energy flux density	Orchida <i>Cattleya</i> spp.	16	Temperature requirement of hybrids related in parental species
Chrysanthemum <i>C. morifolium</i>	16 cut flowers 17-18 pot plants	Temperatures during flower initiation especially critical; uniform initiation very important for pot mums; cultivars classified on basis of temperature for development	Orchids <i>Phalaenopsis</i> spp. <i>Cymbidium</i> spp. <i>Cypripedium</i>	18 10 10-13	
Cineraria <i>Senecio cruentus</i>	16 9-10	Vegetative growth Flower initiation and development; plant quality best at low temperatures	Poinsettia <i>Euphorbia pulcherrima</i>	18 16-17	Vegetative growth Photoperiod requirement changes with temperature; bract development influenced by temperature
Crossandra <i>C. infundibuliformis</i>	24-27 18	Germination Growth and flowering	Roses <i>Rosa</i> spp.	16-17	
Cyclamen <i>C. indicum</i>	16-18 13 10-11	Germination Seedlings Growth and flowering	Saintpaulia <i>S. ionantha</i>	18-21	Below 16°C, growth is slow, hard and brittle
Foliage plants	18-21	Species differ in their temperature and radiant energy requirements	Snapdragon <i>Antirrhinum maias</i>	9-10 13-16	Winter Spring and Fall seedlings benefit from 16 to 18°C temperatures
Fuchsia <i>F. hybrida</i>	11-16	Long days for flower initiation	Stock <i>Matthiola incana</i>	7-10	Buds fail to set if temperatures are above 18°C for 6 h or more per day. Grown mainly as field crop
Geranium <i>Pelargonium hortorum</i>	11-16	16 to 18°C for fast crops at high radiant energy flux	Tomato	16-19	Dry temperatures from 21 to 27°C on sunny days
Gardenia <i>G. grandiflora</i> <i>G. jasminoides</i>	16-17 16-17	Lower temperatures result in iron chlorosis; higher temperatures increase bud abscission	Lettuce	13	17 to 18°C on cloudy days 21 to 26°C on sunny days
			Cucumber	18	24°C on cloudy days 27°C on sunny days

**Table 10 Suggested Heat Transmission Coefficients**

		$U, W/(m^2 \cdot K)$
Glass	Single-glazing	6.4
	Double-glazing	4.0
Plastic film	Manufacturer's Data	
	Single film <sup>a</sup>	6.8
	Double film, inflated	4.0
	Single film over glass	4.8
	Double film over glass	3.4
Corrugated glass fiber		
	Reinforced panels	6.8
Plastic structured sheet <sup>b</sup>		
	16 mm thick	3.3
	8 mm thick	3.7
	6 mm thick	4.1

<sup>a</sup>Infrared barrier polyethylene films reduce heat loss; however, use this coefficient when designing heating systems because the structure could occasionally be covered with non-IR materials.

<sup>b</sup>Plastic structured sheets are double-walled, rigid plastic panels.

**Table 11 Typical Infiltration Rates for Various Construction Types (ach)**

Metal frame and glazing system, 400 to 600 mm spacing	1.08
Metal frame and glazing system, 1200 mm spacing	1.05
Fiberglass on metal frame	1.03
Film plastic on metal frame	1.02
Film or fiberglass on wood	1.00

$$q_t = q_c + q_i \quad (10)$$

$$q_c = \sum UA\Delta t \quad (11)$$

$$q_i = c_p V \left( \frac{N}{3600} \right) \Delta t \quad (12)$$

where

- $U$  = heat loss coefficient,  $W/(m^2 \cdot K)$  (Table 10)
- $A$  = exposed surface area,  $m^2$
- $\Delta t$  = inside minus outside air temperature,  $^{\circ}C$
- $c_p$  = volumetric specific heat of air (adjusted upward to account for latent heat component),  $0.5 \text{ kJ}/(m^3 \cdot K)$
- $V$  = greenhouse internal volume,  $m^3$
- $N$  = number of air exchanges per hour (Table 11)
- $\Sigma$  = summation of all exposed surfaces of the greenhouse and perimeter heat losses

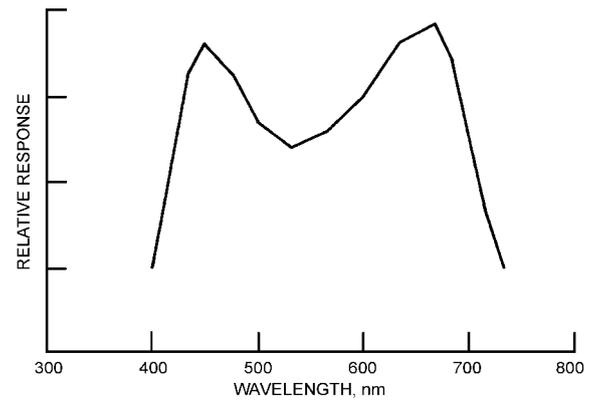

When design conditions are assumed for indoor and outdoor air temperatures and air exchange rate, the resulting heat loss may be assumed equal to the peak heating requirement for the greenhouse.

No universally accepted method exists to determine season-long heating needs for greenhouses. The heating degree-day method may be applied, but heating degree-day data must be adjusted to a base lower than  $18.3^{\circ}C$  because of the significant passive solar heating effect in greenhouses. The proper base must be determined locally to reflect the expected solar climate of the region and the expected greenhouse operating temperature. These difficulties often lead designers to obtain season-long heating data from comparable, existing greenhouses in the region, and apply them to new designs.

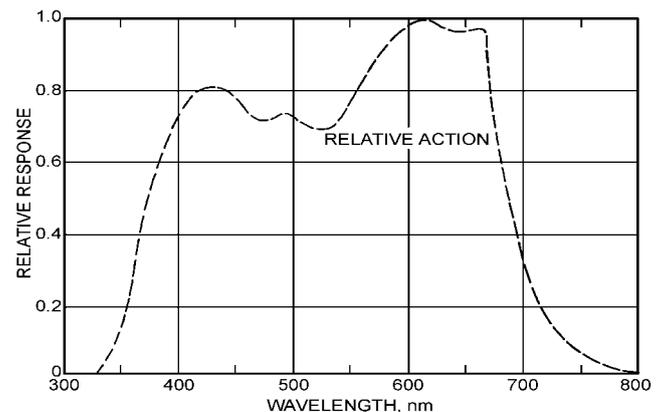

## LIGHT AND RADIATION

### Plant Requirements

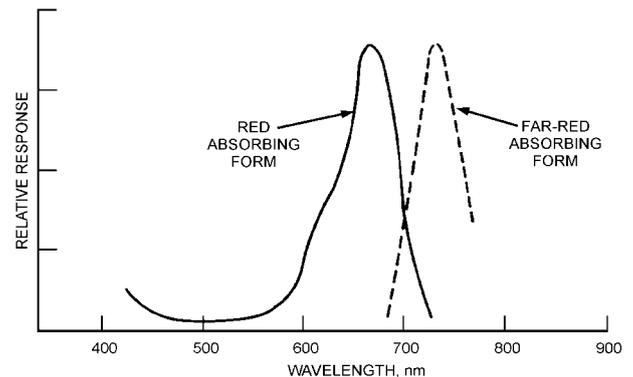

Light (400 to 700 nm) is essential for plant vegetative growth and reproduction (Figure 25 and Figure 26). Intensity integrated

**Fig. 25 Traditional Photosynthesis Action Spectra Based on Chlorophyll Absorption**

**Fig. 26 Relative Photosynthetic Response**

**Fig. 28 Phytochrome Action Spectra**

over time provides the energy for growth and development, while duration (either long or short, depending on species) may be essential for certain physiological processes such as flowering. High light intensity may exceed the ability of individual leaves to photosynthesize. However, if there is a dense canopy, excess light may be beneficial to lower leaves even when upper leaves are light saturated. The intensity at which light saturates a leaf depends on various environmental factors, such as the concentration of carbon dioxide in the ambient air, as well as biological factors (Figure 27).

Spectral distribution of light can affect plant development, but sunlight's spectral distribution need not be duplicated by artificial lighting to have suitable growth and development. Certain repro-

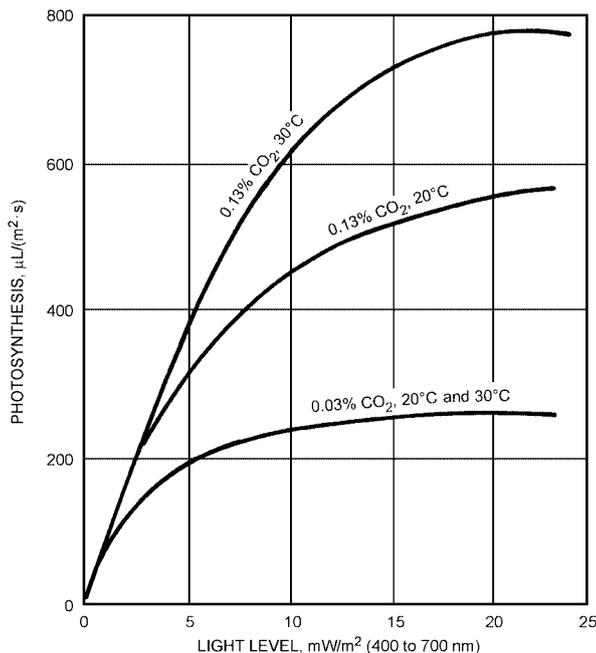

ductive changes are initiated by red (660 nm) and far red (730 nm) light (Figure 28), and excessive ultraviolet light (290 to 390 nm) may be detrimental to growth.

Plants that respond to the durations of light and dark periods are termed photoperiodic (photoperiodic effects generally relate to flowering). Some plant species are long-day obligates, some are short-day obligates, some are day length-intermediate, and others are day-neutral. Such responses are usually (relatively) independent of light intensity. Photoperiodic effects can be initiated by very low light levels (less than 1 W/m<sup>2</sup>), such as that provided to chrysanthemums by incandescent lights for a short period during the middle of the night to promote vegetative growth and inhibit flowering (until a suitable size has been attained) during the winter. Some plant species can tolerate continuous light, but others require some period of darkness for proper growth and development.

Sunlight is the most common source of photosynthetically active radiation (PAR, 400 to 700 nm). Although specially designed lamp sources may provide light similar to sunlight, no single source or combination of sources has spectral radiation exactly like the emission of the sun from 300 to 2700 nm. Table 12 summarizes the spectral distribution of various light sources. Three systems of measuring radiation are as follows:

1. Radiometric units (irradiance) in watts per square metre (W/m<sup>2</sup>), with specified wavelength intervals.
2. Quantum units as photon flux density in  $\mu\text{mol}/(\text{s}\cdot\text{m}^2)$  (at 400 to 700 nm unless otherwise specified). A mole of photons delivered in one second over a square meter may be called an einstein.
3. Photometric units (illuminance) as one lumen per square metre, or lux (lx).

Plant scientists use photosynthetic photon flux density (PPFD) in  $\mu\text{mol}/(\text{s}\cdot\text{m}^2)$  (400 to 700 nm). Engineering organizations and manufacturers of light sources use photometric and radiometric units. Because of the variation in spectral power distribution, conversion from one system of units to another must be made individually for each light source for the wavelength interval included (Table 13). To obtain comparable plant growth from different light sources, the same radiation levels (PAR) and red/far-red ratios must be maintained.

**Fig. 27 Photosynthesis of Cucumber Leaf at Limiting and Saturating Carbon Dioxide Concentrations under Incandescent Light**

**Table 12 Radiation Power Distribution of Light Sources**

Light Sources	UV	PAR + FAR	IR	Thermal	Total
	300-400 nm	400-850 nm	850-2700 nm		
FCW	2	36	1	61	100
HG/DX	3	19	18	60	100

**Radiation Levels for Plant Growth**

**Display 0.3 W/m<sup>2</sup>.** For display purposes, plants can exist at an irradiance of 0.3 W/m<sup>2</sup>. The preferred lamp has changed with technological advances in efficiency and distribution. The emphasis, however, has always been on color rendering and the type of atmosphere created in the display space. Low-wattage incandescent and fluorescent lamps are preferred. At this irradiance, plants can be displayed (seen), but little or no significant positive effect on plants can be expected. Extended holding in such low light conditions will have a negative effect on many plant species. Timing (light-dark durations) and temperature interaction are not a concern.

**Photoperiod Response 0.9 W/m<sup>2</sup> (4 to 6 h).** For a photoperiod response, plant growth can be regulated at an irradiance of 0.9 W/m<sup>2</sup> for as little time as 1 h. This irradiance is called a low light intensity system. The range of plant responses (promote or delay flowering, promote growth) that can be regulated is extensive, and this lighting is widely used by commercial growers.

**Survival 3 W/m<sup>2</sup> (8 h).** Plants can survive at an irradiance of 3 W/m<sup>2</sup> for 8 or more hours daily. This level enables many green plants to maintain their color. However, stem lengthening (etiolation) and reduction in new leaf size and thickness occur under this irradiance level. In time, the overall development of the plants falls behind that of other plants grown under higher radiation levels. Photoperiod responses do not function well at this irradiance. However, strong interactions occur between this irradiance and temperature, watering frequency, and nutrition. Cooler temperatures (less than 17°C) help conserve previously stored material, while frequent watering and fertilization aggravate stem lengthening and senescence of older foliage.

**Growth Maintenance 9 W/m<sup>2</sup> (12 h).** Plants maintain growth over many months when exposed to an irradiance of 9 W/m<sup>2</sup> of 12-h duration daily. This is the intensity at which many indoor gardeners (professional or hobbyists) grow their plants when

starting them from seeds, cuttings, or meristems. Interactions with the environment (temperature, airflow, relative humidity, and pollutants) can vary among installations. Simple facilities with good air exchange and limited lamp concentration can grow a wide range of plant species. The rate of development, particularly as the plants grow in size, can be slow compared to plants grown at higher irradiances.

**Propagation 18 W/m<sup>2</sup> (6 to 8 h).** Plants propagate rapidly when exposed to an irradiance of 18 W/m<sup>2</sup> for a minimum of 6 to 8 h daily, but they prefer 12 h. Above this level, many propagators attempt to shade their greenhouses with one or several layers of neutral filters (painted films on glazing, or movable or semipermanent plastic or other fabric shade cloth materials) to restrict light (and heat) in the propagation area.

Cuttings rooted at this intensity maintain a growth rate much like that of similar tissue on a stock plant. Stem length, branching, and leaf color, however, can be regulated by manipulating temperature, moisture, stress, and nutrients. Most plants grown for their flowers and fruits can be brought to maturity by increasing the day length to 16 to 18 h for flower initiation (or rapid growth) and then reducing the day length to 8 to 12 h for development. The growth rate, however, is relatively slow. For quickest development (leaf number, number of branches, and early flower initiation), the plants must be transferred to a higher lighting regime—24 to 50 W/m<sup>2</sup>.

**Greenhouse Supplemental Light 24 W/m<sup>2</sup> (8 to 16 h).** When natural light is inadequate, it may be supplemented up to approximately 24 W/m<sup>2</sup> for 8 to 16 h daily. When coupled with the ambient sunlight (shaded by clouds, greenhouse structures, and lamp fixtures), this irradiance simulates many of the growth responses and rates associated with growth chamber studies. Plants grown in greenhouses without supplemental lighting grow slower and flower later than lighted ones in cloudy regions or in northern areas during winter. Duration (in hours) and timing (day-night) of lighting is critical.

Supplemental lighting for 8 h, particularly during the day (0800 to 1600) may not be as cost-effective as lighting at night (2000 to 0400) if off-peak electric rates are available. Neither of these lighting regimes, however, is as effective as lighting for 16 h from morning to midnight.

Lighting short-day plants, such as chrysanthemums and poinsettias, is relatively inefficient because they can be lighted only during the 8- to 12-h day, followed by an obligatory 12- to 16-h daily dark period.

**Growth Chambers 50 W/m<sup>2</sup> (8 to 24 h).** Plants grow in growth chambers or growth rooms if the light irradiance is a minimum of 50 W/m<sup>2</sup> for 8 to 24 h daily. This irradiance is approximately one-fourth that of outdoor sunlight. Cool, white fluorescent lamps, combined with incandescent lamps, are widely used. More recently, HID lamps have been substituted for fluorescent lamps. For consistent results, all require a barrier of glass or other material between the lamp and the plants, and a separate ventilating system to remove the heat from such enclosed spaces.

Since filters cannot remove infrared completely, chambers are difficult to standardize. This often leads to confusing information on plant growth and flowering of plants grown in greenhouses and outdoors. When the total irradiance is 50 W/m<sup>2</sup> and 10 to 20% of the total radiation is provided by incandescent lamps, most kinds of plants can be grown. In typical plant forms, flowering and fruiting responses occur when the plants are subjected to the following parameters:

- Day length, 8 to 24 h
- Temperature, 10 to 35°C
- Carbon dioxide, 300 to 2000 ppm (540 to 3600 mg/m<sup>3</sup>)
- Relative humidity, 20 to 80%

## Photoperiod

Day length affects the performance of some plants. There are four basic day length plant groups:

1. *Short-day plants* flower only when the length of the daily light period is less than the critical number of hours. Daily light periods longer than the critical length inhibit flowering.
2. *Long-day plants* flower only when the daily light period is longer than the critical number of hours. They become dormant or remain vegetative when the daily light period is shorter than the critical length.
3. *Day length-intermediate plants* flower only within a narrow range of day length, usually between about 10 and 14 h. If the day length is shorter than the optimum day length for flowering, the plants stop growing.
4. *Day-neutral plants* continue in vegetative growth or flower regardless of the day length.

Continuous light inhibits flowering and promotes vegetative growth of short-day plants, but encourages continued vegetative growth and early flowering of long-day plants, blocks the flowering of day length-intermediate plants, and in many instances, increases the stem length of day-neutral plants. Plants vary in their responsiveness to light source, duration, and intensity. The technology that has evolved to control the photoperiod of plants is based primarily on the incandescent-filament lamp. Of all the light sources available, this lamp creates the regulating mechanism most similar to that of sunlight. This is because the red/far-red wavelength ratio of light from an incandescent lamp is similar to the ratio of sunlight.

The effectiveness for photoperiod response in plants peaks at wavelengths of 660 nm (red) and 730 nm (far-red). The relative order of activity in regulating photoperiod responses by lamp type is as follows: Incandescent (INC) > High-pressure sodium (HPS) >> Metal halide (MN) = Cool white fluorescent (F) = Low-pressure sodium (LPS) >> Clear mercury (Hg). Photoperiod lighting is always used in combination with daylight or another main light source. Short days (less than normal day length) are created in the greenhouse with opaque materials that surround the plants.

## RELATIVE HUMIDITY

Relative humidity affects the rate at which plants take water up, the rate of latent heat transfer, and certain diseases. Normal plant growth generally occurs at relative humidities between 20 and 80% if the plants have a well-developed root system, although relative humidities above 40% are preferred to avoid water stress conditions.

Transpiration, the movement of water vapor and gases from the plant to its surroundings, is controlled by the plant's stomatal openings. It is a function of air velocity and the vapor pressure difference between water at saturation at the leaf temperature and the actual water vapor partial pressure in the air. Generally, as relative humidity decreases, transpiration increases. Very low relative humidities (less than 20%) can cause wilting, since evaporation losses may be higher than the plant can replace, especially when light intensity is high.

High humidity provides a good environment for pathogenic organisms. Many pathogenic spores do not germinate unless relative humidity is 96% or more and many require a film of water on the leaves. Somewhat lower relative humidities may support other pathogen growth stages.

Still air surrounding a plant may be much wetter than the general atmosphere because evapotranspiration from the leaves raises the relative humidity in interfoliage air. The lower leaves, which stay moist longer, are more susceptible to disease. The upper leaves are dried by radiation and air currents.

## AIR COMPOSITION

Carbon dioxide, which comprises about 0.035% of ambient air, is essential for plant growth. There are basically three ways to obtain carbon dioxide for greenhouse enrichment: pure in solid, liquid, or gaseous form; from burning fuels such as propane, natural gas, or kerosene; and by the aerobic breakdown of organic matter. The three ways are listed in order of purity and reliability. Carbon dioxide enters plants through stomata and is converted to carbohydrates through photosynthesis. The carbon dioxide concentration in air surrounding a plant, as well as light level, affects the rate of photosynthesis. The concentration for maximum growth depends on many factors, including the stage of growth, leaf area, light intensity, temperature, and air velocity past the stomatal openings.

An important relationship exists between light level and carbon dioxide uptake (Figure 27). As light level increases, carbon dioxide concentration must increase concurrently to take maximum advantage of the greater photosynthetic potential. In plastic greenhouses, and in glass greenhouses sealed against infiltration, the carbon dioxide level can drop below 360 mg/m<sup>3</sup> when the weather is cold, light levels are moderate, and the greenhouse is not ventilated. Carbon dioxide enrichment just to maintain normal levels can then be beneficial. During times of high light levels, carbon dioxide enrichment gives maximum benefit from the available light and may even be economically desirable when greenhouse ventilation is modest. However, carbon dioxide concentrations above 2700 mg/m<sup>3</sup> are seldom recommended; levels between 1400 and 2200 mg/m<sup>3</sup> are typically used.

The effects of enrichment are not always positive. Without proper crop management, the yield, quality, or both may decrease, and timing of crop maturity may change.

### Pollutants

Plants are sensitive to atmospheric pollutants such as ethylene, ammonia, gaseous fuels, ozone, fluorides, photochemical smog, and oxidants (from nitrogen and sulfur). Pollution damage can range from small spots on leaves, to yellowing of leaves, to severe foliage burn, and, ultimately, to plant death in extreme but not rare situations. The effect occurs both outdoors and in greenhouses; however, this is more common in greenhouses, because of their closed nature. Pollutants indoors can be removed by activated charcoal filters in the ventilation system; however, these are seldom used in commercial greenhouses. Economically, the more feasible approach is to limit pollutant production within, or introduction into, the greenhouse air space.

Ethylene is produced naturally by plants and leads to flower and whole plant senescence. It is also produced by combustion of gaseous and liquid fuels and can rapidly cause plant damage. Concentrations above 230 µg/m<sup>3</sup> can have a detrimental effect on plant growth. Unvented heaters, air currents that bring vented combustion products back into the greenhouse, and burners for carbon dioxide production are common sources of ethylene injury. Liquefied carbon dioxide may be used to supplement natural levels rather than combustion, specifically to avoid introducing ethylene into the greenhouse air, but even liquefied carbon dioxide should be carefully selected to avoid residual amounts of ethylene that may be contained within it.

Nitrogen oxides, common components of air pollution, can cause serious plant damage. Greenhouse locations near highways, nearby industrial complexes, and even a truck left running for an extended time near a greenhouse air intake vent may lead to leaf damage from NO and NO<sub>2</sub>.

Sulfur dioxide, produced by the burning of sulfur containing fuels, causes injury to many plants within a short time. Sources of sulfur dioxide may be nearby, such as an industrial area, or may be within the greenhouse complex, such as the vented combustion products from a central heating facility, combustion products from

carbon dioxide burners (using kerosene as a fuel, for example), and sulfur burned for mildew control.

Ozone is widely recognized as a serious pollutant affecting the production of many agronomic crops. Although few research results exist to quantify the effect of ozone on greenhouse crops, damage is likely to occur when greenhouses are located near ozone sources.

Phenolics and certain other organic vapors are phytotoxic. Phenolics, as volatiles from certain wood preservatives (creosote and pentachlorophenol), can cause leaf and petal damage. Vapors from some paints can also be damaging. Misuse of herbicides and pesticides can lead to plant injury, either through spray drift or volatilization.

Covering and sealing greenhouses for energy conservation can increase concentrations of ethylene and other air pollutants if their sources are within the air space, since infiltration and ventilation are decreased. Sealing to reduce infiltration can also lead to rapid carbon dioxide depletion and inhibited plant growth during cold temperatures when, even with bright light, ventilation is not required.

## AIR MOVEMENT

Air movement influences transpiration, evaporation, and the availability of carbon dioxide. Air speed affects the thickness of the boundary layer at the leaf surface, which in turn influences the transport resistance between the ambient air and the leaf stomatal cavities. Air speed of 0.5 to 0.7 m/s is commonly accepted as suitable for plant growth under CEA conditions. Air speeds across the leaf of 0.03 to 0.1 m/s are needed to facilitate carbon dioxide uptake. Air speeds above 1 m/s can induce excessive transpiration, cause the stomatal guard cells to close, reduce carbon dioxide uptake, and inhibit plant growth. Air speeds above 5 m/s may cause physical damage to plants. Generally, if plants within a greenhouse move noticeably due to ventilation, air speed is excessive.

Air circulation within greenhouses may be created to reduce thermal stratification and maintain suitable levels of carbon dioxide within the leaf canopy. Horizontal air flow, produced by small propeller fans that move air around the greenhouse in a racetrack pattern, has been found to be effective. Such fans are approximately 350 mm in diameter, with approximately 0.2 kW motors, spaced at approximately 15 m intervals. Total fan capacity in metres per second (m<sup>3</sup>/s) should equal about 25% of the greenhouse volume in cubic metres.

## CHAPTER 11

# PHYSIOLOGICAL FACTORS IN DRYING AND STORING FARM CROPS

<i>Factors Determining Safe Storage</i> .....	11.1
<i>Moisture Measurement</i> .....	11.5
<i>Prevention of Deterioration</i> .....	11.6
<i>Drying Theory</i> .....	11.8
<i>Drying Specific Crops</i> .....	11.11

**T**HIS CHAPTER focuses on the drying and storage of grains, oil-seeds, hay, cotton, and tobacco. However, the primary focus is on grains and oilseeds, collectively referred to as **grain**. Major causes of postharvest losses in these products are fungi, insects, and rodents. Substantial deterioration of grain can occur in storage. However, where the principles of good grain storage are applied, losses are minimal.

Preharvest invasion of grains by storage insects is usually not a problem in the midwestern United States. Field infestations can occur in grains when they are dried in the field at warm temperatures during harvest. Preharvest invasion by storage fungi is possible and does occur if appropriate weather conditions prevail when the grain is ripening. For example, preharvest invasion of corn by *Aspergillus flavus* occurs when hot weather is prevalent during grain ripening; it is, therefore, more common in the southeastern United States (McMillan et al. 1985). Invasion of wheat, soybeans, and corn by other fungi can occur when high ambient relative humidities prevail during grain ripening (Christensen and Meronuck 1986). However, the great majority of damage occurs during storage, due to improper conditions that permit storage fungi or insects to develop.

Deterioration from fungi during storage is prevented or minimized by (1) reduction of grain moisture content to below limits for growth of fungi, (2) maintenance of low grain temperatures throughout the storage period, (3) chemical treatment to prevent the development of fungi or to reduce the rate of fungal growth while the grain moisture content is being lowered to a safe level, and (4) airtight storage in which initial microbial and seed respiration reduces the oxygen level so that further activity by potentially harmful aerobic fungi is reduced.

Reduction of moisture by artificial drying is the most commonly used technique. The longer grain is stored, the lower its storage moisture should be. Some of the basic principles of grain drying and a summary of methods for predicting grain drying rate are included in the section on Drying Theory.

Reduction of grain temperature by aeration is practical in temperate climates and for grains that are harvested during cooler seasons. Fans are operated when ambient temperature is lower than grain temperature. Basic information on aeration is summarized in the section on Drying Theory. Use of refrigeration systems to reduce temperature is not generally cost-effective for feed grains but may have application for higher value food grains.

Chemical treatment of grain is becoming more common and is briefly described in the section on Prevention of Deterioration.

When grain is placed in airtight silos, the oxygen level is rapidly reduced, and carbon dioxide increases. Although many fungi will not grow under ideal hermetic conditions, some will grow initially in imperfectly sealed bins, and this growth can reduce the feeding

value of the grain for some animals. Partially emptied bins may support harmful mold, yeast, and bacterial growth, which makes the grain unsuitable for human consumption. Airtight storage is briefly addressed in the section on Oxygen and Carbon Dioxide under Factors Determining Safe Storage.

Deterioration from insects can also be prevented by a combination of reducing moisture and lowering temperature. Lowering of temperatures is best achieved by aeration with cool ambient air during cool nights and periods of cool weather. Both the use of clean storage structures and the segregation of new crop grain from carryover grain or grain contaminated with insects are important. If insect infestation has already occurred, fumigation is often used to kill the insects. Aeration with cold air may retard the development of the insect population. Prevention and control of insect infestations are addressed in the section on Prevention of Deterioration.

For information on rodent problems, see the section on Prevention of Deterioration.

Moisture content is the most important factor determining successful storage. Although some grains are harvested at safe storage moistures, other grains (notably corn, rice, and most oilseeds) must usually be artificially dried prior to storage. During some harvest seasons, wheat and soybeans are harvested at moistures above those safe for storage and, therefore, also require drying.

Sauer (1992), Brooker et al. (1992), Hall (1980), Christensen and Meronuck (1986), and Gunasekaran (1986) summarize the basic aspects of grain storage and grain drying. Chapter 22 of the 1999 *ASHRAE Handbook—Applications* covers crop-drying equipment and aeration systems.

## FACTORS DETERMINING SAFE STORAGE

### Moisture Content

Grain is bought and sold on the basis of characteristics of representative samples. Probes or samplers, such as diverters, are used to obtain representative subsamples. Often representative subsamples must be taken from a large quantity (several tonnes) of grain. Manis (1992) summarizes sampling procedures and equipment. For safe storage, it is necessary to know the range in moisture content within a given bulk and whether any of the grain in the bulk has a moisture content high enough to permit damaging fungal growth. This range can be determined by taking probe samples from different portions of the bulk. Commonly, in large quantities of bulk-stored grain, some portions have moisture contents 2 to 3% higher than the average (Brusewitz 1987). If the moisture content anywhere in the bulk is too high, fungi will grow, regardless of the average. Therefore, the moisture content of a single representative sample is not a reliable measure of storage risk or spoilage hazard. Measurement of moisture content and the precision of various moisture-measuring methods are covered in the section on Moisture Measurement.

Table 1 summarizes recommended safe storage moistures for several common grains. Note that for long-term storage, lower

The preparation of this chapter is assigned to TC 2.2, Plant and Animal Environment.

moistures are recommended. Most storage fungi will not grow in environments where the relative humidity of the air between kernels is lower than 60%. The relationship between grain moisture and the relative humidity of air between kernels is addressed in the section on Equilibrium Moisture. Table 2 summarizes the relative humidities and temperatures that permit the growth of common storage fungi. Table 3 summarizes the relative humidities and temperatures that permit growth of common storage insects.

### Moisture Transfer

If temperatures vary within bulk-stored grain, moisture migrates from warmer to cooler portions. The rate of movement depends on the gradients in moisture content and temperature. Sellam and Christensen (1976) studied moisture transfer in a sample of 28.3 L of shelled corn initially at 15.5% moisture. They used heat lamps to produce a temperature differential of 10 K along the length of a sealed plastic container 370 mm long. After 2 days, this gradient (approximately 27 K/m) caused the moisture content at the cool end

to increase by 1.2% and the moisture content at the warm end to decrease by 1.1%.

Thorpe (1982) developed an equation to describe moisture transfer caused by a temperature gradient. The equation was solved numerically, and laboratory experiments of moisture transfer in wheat were successfully modeled initially at 12% moisture content. In the experiments, a 10 K temperature gradient was developed across a column of wheat 0.2 mm thick (equivalent to a gradient of 50 K/m). After one month, the moisture content of the warmest grain dropped to 10.6%, while the moisture content of the coolest grain increased to 14%.

Smith and Sokhansanj (1990a) provided a method of approximate analysis of the energy and velocity equations of the natural convection in grain bins. They showed that for small cereals such as wheat, the influence of convection on temperature gradients may not be significant, whereas for larger cereals such as corn, the effect of convection is more noticeable. Smith and Sokhansanj (1990b) also showed that convection flows in a grain bin are significant if the radius of the storage bin is approximately equal to the height of the bin.

Christensen and Meronuck (1986) cite an example of heating that developed in wheat initially at 13.2% in a nonaerated bin. Specially prepared samples were placed at various positions in the bin at the time the bin was filled. After 3 months, the grain began to heat from fungal activity. Moisture content in some of the samples had increased to 18%, while in others it had decreased to 10%.

These examples illustrate the importance of aeration in long-term storage. Aeration is generally required for storage structures with capacities exceeding 70 m<sup>3</sup> or 45 t. Moisture migration can initiate fungal and insect growth, and the heat of respiration generated by these organisms accelerates their growth and leads to spoilage. Studies suggest that temperature gradients could promote spoilage of grain loaded into a ship or barge—even if the grain is initially at a uniform moisture. Most shipments do not spoil because they remain in the ship or barge for a short time and because large temperature gradients do not develop. Christensen and Meronuck (1986) report studies of grain quality in barges and ships.

**Table 1 Safe Storage Moisture for Aerated Good-Quality Grain**

Grain	Maximum Safe Moisture Content, % wet basis
Shelled corn and sorghum	
To be sold as #2 grain or equivalent by spring	15
To be stored up to 1 year	14
To be stored more than 1 year	13
Soybeans	
To be sold by spring	14
To be stored up to 1 year	12
Wheat	13
Small grain (oats, barley, etc.)	13
Sunflower	
To be stored up to 6 months	10
To be stored up to 1 year	8

<sup>a</sup> Approximate corn moisture content at 25°C, which gives an interseed relative humidity equal to the minimum at which fungus can germinate. It is probably below the moisture content at which the fungus would be able to compete with other fungi on

grain, except for *Aspergillus glaucus*. The latter has no real competitor at 72% rh, except occasionally *Aspergillus restrictus*.

<sup>b</sup> Approximately 5% or more of the population can germinate at this relative humidity.

<sup>c</sup> Rarely found growing in stored grain, regardless of moisture and temperature.

**Temperature**

Most processes that cause spoilage in stored grains are accompanied by a temperature rise. Therefore, temperatures should be monitored throughout the bulk. Temperature monitoring is commonly done by attaching thermocouples to cables that extend through the bulk from the top to the bottom, with thermocouples about 0.9 to 1.8 m apart on each cable. Single cables are used in the center of circular bins up to 7.6 m in diameter. In large bins or flat storage structures, cables are spaced 6 to 7.6 m apart. Relatively dry grain is a good insulator, so a **hot spot** can develop without being detected immediately (Foster and Mayes 1962). However, when these thermocouple spacings are used, extensive spoilage can usually be detected by a temperature rise at a nearby thermocouple. A temperature rise of even a few degrees is evidence that grain has spoiled or is spoiling. Forced aeration maintains a uniform and preferably low temperature throughout the bulk.

Table 2 summarizes minimum, optimum, and maximum temperatures for the growth of some common storage fungi. Storage molds grow slowly at 0 to 4.5°C. However, at higher moisture contents, some species of *Penicillium* will grow when the temperature is slightly below freezing. Grains with a moisture content high enough for invasion by *Aspergillus glaucus* will deteriorate rapidly at temperatures of 24 to 29°C but can be kept for months without damage at 4.5 to 10°C. Most grain-infesting insects become inactive below about 10°C. Mites remain active but cannot develop rapidly below about 4.5°C. Control of fungi and insects is described further in the section on Prevention of Deterioration.

**Oxygen and Carbon Dioxide**

Only a few fungi that cause stored grain deterioration can grow in an atmosphere containing only 0.1 to 0.2% oxygen or more than 60% carbon dioxide. Some yeasts can grow in grain stored in airtight storage at moisture contents above 18 to 19% and temperatures above 4.5°C, producing flavors that make the grain unsuitable as food. However, the grain remains suitable feed for cattle and swine (Bell and Armitage 1992), and its nutritional value may be enhanced (Beeson and Perry 1958).

Dry grain is stored in airtight underground or earth-sheltered structures in many parts of the world (Dunkel 1985, Bell and Armitage 1992). Janardhana et al. (1998) reported that while storing

shelled corn at 15 to 20% moisture in a warm, high-humidity environment, visible molding and the loss of food reserves can be postponed up to 45 days by using high carbon dioxide in the storage. Alagusundaram et al. (1996) studied the diffusion of carbon dioxide introduced into bulk stored grain. Bell and Armitage (1992) and Shejbal (1980) cover controlled atmosphere storage in more detail.

Insects present when dry grain is put into storage usually die when oxygen has been depleted, and do not usually reproduce if grain is sufficiently dry and in good condition. Insects can also be controlled in conventional storage structures by forcing carbon dioxide or other gases such as nitrogen through the grain (Jay 1980, Ripp 1984, White and Jayas 1991). Generally, carbon dioxide environments are effective for insect control only when concentrations are greater than 40% for long periods. Paster et al. (1990, 1991) investigated biogenerated modified atmospheres for insect control. Athie et al. (1998) reported that using the toxic chemical phosphine with a high carbon dioxide environment increased the effectiveness of the phosphine, particularly in resistant populations. However, the costs of controlled-atmosphere storage may be uneconomic unless the structure can be inexpensively sealed or the gases can be inexpensively generated or purchased.

**Grain Condition**

Grain that has been stored for several months may already be invaded by storage fungi and partly deteriorated, whether or not this is evident to the naked eye. Molding occurs more rapidly in partially deteriorated grain than in sound grain when the grain is exposed to conditions favorable to mold growth. Microscopic examination and plating techniques can often reveal the fungal infection of grain in its early stages (Sauer et al. 1992, Christensen and Meronuck 1986, Stroshine et al. 1984). Accelerated storage tests, in which samples of grain are stored at a moisture content in equilibrium with air at 80% rh and 29°C and examined periodically, are useful in evaluating storability. These tests enable a manager to estimate the risk of spoilage during storage and to take appropriate action.

**Equilibrium Moisture**

If air remains in contact with a product for sufficient time, the partial pressure of the water vapor in the air reaches equilibrium

**Table 3 Estimates of Optimum and Minimum Temperatures and Relative Humidity Conditions for Population Increase of Grain-Infesting Insects**

Insect Type		Species	Temperature, °C		Minimum Relative Humidity, %
In Regard to Temperature	In Regard to Relative Humidity		Minimum	Optimum	
<b>Species Needing High Temperatures</b>					
Cold hardy	Tolerant of low	<i>Trogoderma granarium</i>	24	33 to 37	1
		<i>Cryptolestes ferrugineus</i>	23	32 to 35	10
		<i>Oryzaephilus surinamensis</i>	21	31 to 34	10
	Need moderate	<i>Plodia interpunctella</i>	18	28 to 32	40
	Need high	<i>Cryptolestes turcicus</i>	21	30 to 33	50
Moderately cold hardy	Tolerant of low	<i>Tribolium confusum</i>	21	30 to 33	1
	Need moderate	<i>Rhyzopertha dominica</i>	23	32 to 35	30
		<i>Lasioderma serricorne</i>	22	32 to 35	30
Cold susceptible	Tolerant of low	<i>Tribolium castaneum</i>	22	32 to 35	1
	Need high	<i>Oryzaephilus mercator</i>	20	31 to 34	10
		<i>Cryptolestes pusillus</i>	22	28 to 33	60
<b>Species Thriving at Moderate Temperatures</b>					
Cold hardy	Need moderate	<i>Sitotroga cerealella</i>	16	26 to 30	30
	Need high	<i>Sitophilus granarius</i>	15	26 to 30	50
	Need high	<i>Stegobium paniceum</i>	17	25 to 28	60
		<i>Acarus siro</i>	7	21 to 27	65
		<i>Sitophilus oryzae</i>	17	27 to 31	60

with the partial pressure of the water vapor in the material. The relative humidity of the air at equilibrium with a material of a given moisture is the **equilibrium relative humidity**. The moisture content of a hygroscopic material in equilibrium with air of a given relative humidity is the **equilibrium moisture content**  $M_e$ .

Several theoretical, semitheoretical, and empirical models have been proposed for calculating the  $M_e$  of grains. Morey et al. (1978) report that the modified Henderson equation is among the best equations available:

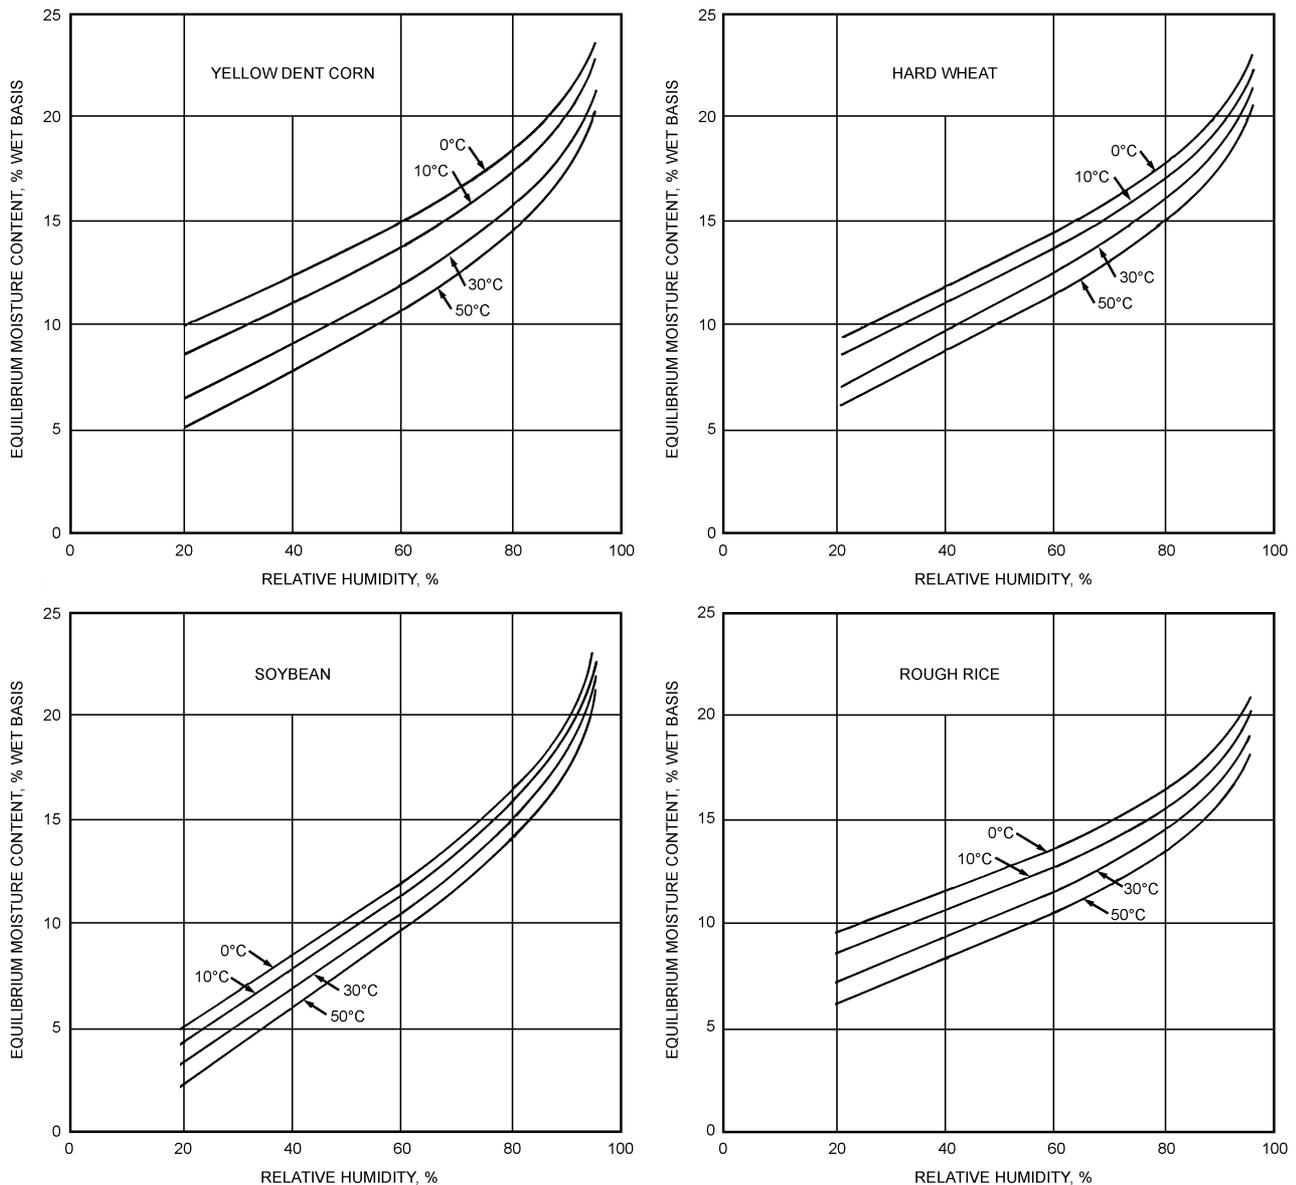

$$M_e = \frac{1}{100} \left[ \frac{\ln(1.0 - \phi)}{-K(t + C)} \right]^{1/N} \quad (1)$$

where

- $M_e$  = equilibrium moisture content, decimal, dry basis
- $t$  = temperature, °C
- $\phi$  = relative humidity, decimal equivalent
- $K, N, C$  = empirical constants

Table 4 lists values for  $K, N,$  and  $C$  for various crops. ASAE *Standard D245.5* also gives the Chung-Pfost equation, another equation used to predict  $M_e$ . Figure 1, based on the Chung-Pfost equation, shows equilibrium moisture content curves for shelled corn, wheat, soybeans, and rice. Note that equilibrium moisture depends strongly on temperature. ASAE *Standard D245.5* gives additional curves drawn from the Chung-Pfost equation and tabulated experimental data. Pfost et al. (1976) summarize variations in reported values of  $M_e$  for several grains. Locklair et al. (1957) give data for tobacco.

The modified Henderson and the Chung-Pfost equations give only approximate values of  $M_e$  and are for desorption. When grain is rewetted after it has been dried to a low moisture, the value of  $M_e$  is generally lower for a given relative humidity. Sun and Woods (1993) reviewed the equilibrium relationship between wheat moisture content and air relative humidity. They reported that the hysteresis effect was greatest at 20 to 40% rh. They also observed that the modified Henderson equation was least effective for wheat.

Variations of as much as 0.5 to 1.0% can result from differences in variety; maturity; and relative starch, protein, and oil content. Shivhare et al. (1992) reported that, under a microwave drying regime,  $M_e$  increased with drying air velocity and decreased with microwave power.

High-temperature drying can decrease the  $M_e$  of shelled corn by 0.5 to 1.0% for a given relative humidity (Tuite and Foster 1963). Sun and Woods (1994) reported that the equilibrium moisture content for wheat dried at low temperatures was generally higher than the data reported in the literature. Chung and Verma (1991) studied the  $M_e$  of rice during drying and storage.

### MOISTURE MEASUREMENT

Rapid and accurate measurement of moisture of grains, seeds, and other farm crops determines whether they can be safely stored. Allowable upper limits for moisture are set by the market, and discounts and/or drying charges are usually imposed for higher moistures. Drying the grain to moistures below the accepted market limit or the limit for safe storage moisture results in additional drying expense and may actually decrease the value of the grain.

If shelled corn is dried to 12% moisture, it becomes brittle and breaks more easily during handling. The moisture removal also reduces the total mass of grain. After drying 1 kg of shelled corn at 18% moisture to 15%, only 0.965 kg remains. However, at high moistures, seed respiration and fungal growth can cause greater loss in value.

Moisture content can be expressed on a wet or dry basis. The wet basis is used by farmers and the grain trade, while dry-basis moistures are often used by engineers and scientists to describe drying rates. Unless otherwise noted, moisture contents in this chapter are on a **wet basis** and are calculated by dividing the mass of water in the material by the total mass. The **dry basis** is calculated by dividing the mass of water by the mass of dry matter.

$$\% \text{ Moisture (wet basis): } M_w = \frac{100W_w}{W_w + W_d} \quad (2)$$

$$\% \text{ Moisture (dry basis): } M_d = \frac{100W_w}{W_d} \quad (3)$$

where

$W_w$  = mass of water  
 $W_d$  = mass of dry matter

Percent moisture on a wet basis  $M_w$  can be converted to percent moisture on a dry basis  $M_d$  and vice versa by the following formulas:

$$M_d = \frac{100M_w}{100 - M_w} \quad (4)$$

$$M_w = \frac{100M_d}{100 + M_d} \quad (5)$$

The mass change resulting from a change in moisture can be determined by assuming that the mass of dry matter is constant. The dry matter is calculated by multiplying the mass of grain by the quantity  $(1 - M_w/100)$ . For example, 1000 kg of wheat at 15% moisture has 1000  $(1 - 15/100) = 850$  kg of dry matter and 150 kg water. As grain dries, the dry matter remains constant and the mass of water is reduced. If the dry matter is constant, the mass or moisture content of the dried grain is

$$W_w \left(1 - \frac{M_w}{100}\right) = W_d \left(1 - \frac{M_d}{100}\right) \quad (6)$$

The mass  $W_d$  of the dried grain after it reaches a moisture content of  $M_d$  is

$$W_d = W_w \left(\frac{100 - M_w}{100 - M_d}\right) \quad (7)$$

For example, if 1000 kg of grain is dried from 15% to 13% moisture, the dried mass is

$$W_d = 1000 \left(\frac{100 - 15}{100 - 13}\right) = 977 \text{ kg}$$

Similarly, to find the moisture content  $M_d$  of grain after it reaches a dried mass of  $W_d$

$$M_d = 100 - \frac{W_w}{W_d} (100 - M_w) \quad (8)$$

For example, 100 kg of grain at 15% is dried to a mass of 950 kg. The dried moisture content is

$$M_d = 100 - \frac{1000}{950} (100 - 15) = 10.5\%$$

If two quantities of grain at differing moistures are mixed, the final moisture of the mixture can be determined by calculating the mass of water in each, adding these together, and dividing by the total mass. The mass of water is the product of the decimal equivalent of  $M_w$  and the total mass. For example, if 500 kg of grain at 16% moisture is mixed with 1000 kg of grain at 14% moisture, the mass of water in each sample is

$$(500 \text{ kg})(0.16) = 80 \text{ kg}$$

$$(1000 \text{ kg})(0.14) = 140 \text{ kg}$$

The moisture content after mixing will be

$$\left[\frac{80 + 140}{500 + 1000}\right] \times 100 = 14.7\%$$

Either a **direct method** or an **indirect method** is used to determine moisture content. Direct methods involving the use of an oven determine moisture content based on the loss in product mass caused by evaporation of the water. The Karl Fischer method, a

basic reference method involving a chemical reaction of water and a reagent, is classified as a direct method.

Indirect methods such as moisture meters measure the properties of the material that are functions of moisture content. Indirect moisture measurement methods are used in commercial practice. Direct methods are used in research and to calibrate indirect methods. Christensen et al. (1992) summarize approved methods used in Europe and the United States.

### Direct Methods

Christensen et al. (1992) describe the fundamental or basic methods of moisture determination as (1) drying in a vacuum with a desiccant and (2) titration with a Karl Fischer reagent. It is assumed that these methods measure the true water content and can be used to verify measurements obtained with routine reference methods, including oven drying and the Brown-Duval distillation method. The Brown-Duval method, not commonly used, involves heating the grain in a special apparatus and condensing and collecting the vaporized water.

Oven techniques use either forced-convection air ovens or vacuum ovens and either ground or whole kernels. Drying times and temperatures vary considerably, and the different techniques can give significantly different results. Oven techniques are used to calibrate moisture meters (see the section on Indirect Methods). As a result, during the export of grain, the meter moisture measurements can vary between arrival and destination if the importing country uses a different standard oven technique than the exporting country.

ASAE *Standard* S352.2 is a widely used standard that recommends heating temperatures and times for various grains. The temperatures may be either 103°C (shelled corn, soybeans, sunflower) or 130°C (wheat, barley, onion). Heating times vary between 50 min (onion seeds) and 72 h (soybeans, shelled corn).

Grinding samples and using a vacuum oven reduce heating time. When initial moistures are high, a two-stage method may be used (USDA 1971). A weighed sample of whole grain is partially dried to a moisture content of 13% or below, weighed, and then ground and completely dried as in the one-stage method. The mass lost in both stages is used to calculate moisture content.

### Indirect Methods

**Electronic moisture meters** are simple to operate and give readings within minutes. Direct methods of moisture measurement are used to calibrate the meters for each type of grain. Meters are sensitive to grain temperature, and calibration must include a temperature correction factor. The newer automatic meters or **moisture computers** sense and correct for sample temperature and print or display the corrected moisture.

**Near infrared reflectance (NIR) instruments** have been developed that measure moisture, protein, starch, and oil content of ground samples (Butler 1983, Cooper 1983, Watson 1977). **Near infrared transmittance (NIT) instruments** measure the properties of whole seeds.

**Conductance meters** measure resistance, which varies with grain moisture. The practical range of moisture content measurable by conductance meters is approximately 7 to 23%. For up to 72 h after moisture addition or removal, the moisture at the surface of the kernels differs from the moisture in the interior. Therefore, recently dried grain reads low and recently wetted grain reads high. Mixing wet and dry grain and mixing good grain with partially deteriorated grain also result in erroneous readings. Martin et al. (1986) measured the signal from the conductance Tag-Heppenstall meter and related this to individual kernel moisture variations in mixtures of wet and dry corn.

The dielectric properties of products depend largely on moisture content. The **capacitance meter** uses this relationship by using grain as the dielectric in a capacitor in a high-frequency electrical

circuit. Although the capacitive reactance is the primary portion of the overall impedance measured, the resistive component is also significant in many capacitance meters. At higher frequencies and in instruments with insulated electrodes, the relative effect of the resistance is reduced, which is important in reducing errors introduced by unusual product surface conditions. Capacitance meters are affected less than conductance meters by uneven moisture distribution within kernels. Sokhansanj and Nelson (1988a) showed that the capacitance meters give low and high readings, respectively, on recently dried or rewetted grain. The range of measurable moisture content is slightly wider than that for conductance meters.

Moisture measurement by capacitance meters is sensitive to temperature, product mass, and product density (Sokhansanj and Nelson 1988b). To reduce these sources of error, a weighed sample is introduced into the measuring cell by reproducible mechanical means. Calibration, including temperature correction, is required. At least one commercially available unit measures bulk density and corrects for this factor as well as temperature. Tests of moisture meter accuracy have been reported by Hurburgh et al. (1985, 1986). Accuracy of moisture readings can be improved by taking multiple samples from a grain lot and averaging the meter measurements. Equipment for continuous measurement of moisture in flowing grain is available commercially but is not widely used in the grain trade.

**Equilibrium relative humidity** (described in the section on Equilibrium Moisture) can be used to indicate moisture content. It also indicates storability independent of the actual moisture content because the equilibrium relative humidity of the air surrounding the grain, to a large extent, determines whether mold growth can occur (see Table 2). Measurement of equilibrium relative humidity at specific points within a grain mass requires specialized sampling equipment and has been used primarily for research.

Hay moisture content does not receive the consideration devoted to grains. Oven methods (ASAE *Standard* S358.2) are used extensively, as well as some commercial hay and forage moisture meters. Several conductance moisture meters are available for both hay and forages, but the extreme variability of the moisture and density of the material tested lead to great variability in the readings obtained. A reasonable indication of the average moisture content of a mass of hay can be obtained if many (25 or more) measurements are taken and averaged.

**Microwave radiation** can be used to sense properties of grains. Kraszewski and Nelson (1992) reviewed the use of resonant microwave cavities to determine simultaneously both mass and moisture content in grain kernels.

## PREVENTION OF DETERIORATION

### Fungal Growth and Mycotoxins

Fungal growth is the most important limitation to successful drying and storage of grain. Sauer et al. (1992) provide a good review of microflora in grains. Early detection of mold growth would provide the storage manager with a management tool. Magan (1993) reviews early detection methods, including enzyme and biochemical tests, fungal volatiles, and respiration activity.

Mycotoxins (fungal metabolites) may affect the marketability and use of moldy grains. Wicklow (1988) reported that climate and other natural processes influenced the distribution of aflatoxigenic strains of microflora. Choudhary and Sinha (1993) reported that aflatoxigenic *Aspergillus* species were positively correlated with grain moisture content in the field and afternoon relative humidity.

In the United States, corn is one of the major crops that must be harvested above safe storage moistures. Shelled corn can be held at these higher moistures for a limited time before it must be dried. Mold growth produces carbon dioxide (CO<sub>2</sub>). Allowable storage time at moistures above those for safe storage can be estimated by measuring CO<sub>2</sub> production of samples. By assuming that a simple

sugar is being oxidized by microbial respiration, CO<sub>2</sub> production can be expressed in terms of dry matter loss in percent by mass.

Saul and Steele (1966) and Steele et al. (1969) studied the production of CO<sub>2</sub> in shelled corn, mostly on samples above 18%. Based on changes in the official grade of shelled corn, Saul and Steele (1966) established a criterion for acceptable deterioration of quality as 0.5% dry matter loss. This is equivalent to the production of 0.00735 kg of CO<sub>2</sub> per kilogram of dry matter. Thompson (1972) expressed Saul's data on dry matter loss per kilogram of dry matter as a function of moisture, time, and temperature using the following mathematical expression:

$$DML = 1.3 \left[ \exp\left(\frac{0.006\theta}{K_m K_t}\right) - 1.0 \right] + \frac{0.015\theta}{K_m K_t} \quad (9)$$

with

$$K_m = 0.103 \left[ \exp\left(\frac{455}{M_d^{1.53}}\right) - 0.00845M_d + 1.558 \right] \quad (10)$$

$$K_t = A \exp[B(0.03t + 0.533)] + C \exp(0.0183t - 0.285) \quad (11)$$

where

- DML = dry matter loss per kilogram of dry matter, kg/kg
- θ = time in storage, h
- t = grain temperature, °C
- M<sub>d</sub> = moisture content, % dry basis

Table 5 lists values for A, B, and C. According to Steele (1967), the damage level effect can be determined for dry matter losses of 0.1, 0.5, and 1.0% by multiplying θ from Equation (9) by K<sub>d</sub>, where K<sub>d</sub> is calculated as follows:

$$0.1\% \text{ DML: } K_d = 1.82 \exp(-0.0143d) \quad (12a)$$

$$0.5\% \text{ DML: } K_d = 2.08 \exp(-0.0239d) \quad (12b)$$

$$1.0\% \text{ DML: } K_d = 2.17 \exp(-0.0254d) \quad (12c)$$

where d = mechanical damage, % by mass.

Seitz et al. (1982a, 1982b) found unacceptable levels of aflatoxin production prior to the time when 0.5% dry matter loss occurred. Nevertheless, Equations (9) through (12) give approximate predictions of mold activity, and they have been used in several computer simulation studies (Thompson 1972, Pierce and Thompson 1979, Brooker and Duggal 1982). Based on a simulation, Thompson (1972) concluded that for airflow rates between 7 and 27 L/(s·m<sup>3</sup>), grain deterioration in the top layer during low-temperature drying is doubled when the airflow rate is halved. Thompson also concluded that weather variations during harvest and storage seasons can cause up to a twofold difference in deterioration. Pierce and Thompson (1979) recommend airflow rates for several common low-temperature drying systems and for various locations in the midwestern United States.

**Table 5 Constants for Dry Matter Loss of Shelled Corn [Equation (11)]**

Temperature Range, °C	Moisture Range, % Wet Bulb.	A	B	C
t < 15	All moistures	128.76	-4.68	0
t ≥ 15	M <sub>w</sub> ≤ 19	32.3	-3.48	0
t ≥ 15	19 < M <sub>w</sub> ≤ 28	32.3	-3.48	(M <sub>w</sub> - 19)/100
t ≥ 15	M <sub>w</sub> > 28	32.3	-3.48	0.09

Acceptable dry matter losses for wheat and barley are much lower than those for shelled corn—0.085% and 0.10%, respectively (Brook 1987). Hamer et al. (1992) reported visible mold growth at 0.15% dry matter loss. Brook reported reasonable agreement with published experimental data for the following equation (Frazer and Muir 1981) for allowable storage time as a function of percent wet basis moisture and temperature based on the development of visible mold:

$$\log \theta_D = A + BM_w + Ct \quad (13)$$

where

- θ<sub>D</sub> = allowable storage time, days
- t = temperature, °C
- A, B, C = empirical constants, defined as follows:

Moisture Range, % w.b.	A	B	C
12.0 < M <sub>w</sub> ≤ 19.0	6.234	-0.2118	-0.0527
19.0 < M <sub>w</sub> < 24.0	4.129	-0.0997	-0.0567

Brook (1987) also reported that an adaptation of Equation (9) by Morey et al. (1981) gave reasonable results for storage time of wheat. Morey's method predicts dry matter loss by adjusting M<sub>d</sub> for differences between corn and wheat equilibrium relative humidities.

Table 2 can be used to gain insight into the deterioration of stored grain. *Aspergillus* and *Penicillium* sp. are primarily responsible for deterioration because some of their species can grow at storage moistures and temperatures frequently encountered in commercial storage. In temperate climates, shelled corn is often harvested at relatively high moistures; during the harvest and storage season, ambient temperatures can be relatively low. Aeration of the grain during cold weather and cool nights can reduce the temperature of the grain to 4 to 16°C. This is below the optimum temperature for growth of *Aspergillus* sp. (Table 2). However, *Penicillium* sp. can still grow if grain moisture is above 16 to 17%; therefore, its growth is a persistent problem in temperate climates. If hot weather prevails prior to harvest, *Aspergillus flavus*, which competes effectively at warmer temperatures and higher moistures, can begin to grow in the field and continue to grow in stored shelled corn. In growing seasons when shelled corn must be harvested at moistures above 22%, *Fusarium*, *Alternaria*, *Epicoccum* and *Mucor* can compete with *Penicillium* sp.

**Chemical Treatment.** Application of chemicals slows deterioration until grain can be either dried or fed to animals. Preservatives include propionic acid, acetic acid, isobutyric acid, butyric acid (Sauer and Burroughs 1974), a combination of sorbic acid and carbon dioxide (Danziger et al. 1973), ammonia (Peplinski et al. 1978), and sulfur dioxide (Eckhoff et al. 1984). Propionic acid (Hall et al. 1974) or propionic-acetic acid mixtures, although not extensively used, are perhaps the most popular in the United States with high-moisture corn. Acetic acid and formic acid are popular in Europe. Grain treated with propionic acid can be used only as animal feed.

Hertung and Drury (1974) summarize fungicidal levels needed to preserve grain at various moistures. Both ammonia (Nofsinger et al. 1979, Nofsinger 1982) and sulfur dioxide (Eckhoff et al. 1984, Tuite et al. 1986) treatments require considerable management. Attention must be given to uniform application of the chemicals to the entire quantity of stored grain.

Antimicrobial properties occurring naturally in plants have been studied (Beuchar and Golden 1989, Shelef 1984). Some of these also inhibit mycotoxin formation (Bullerman et al. 1984, Rusal and Marth 1988). The essential oils of oregano and thyme were tested as fumigants against *Aspergillus* species and natural microflora of wheat (Paster et al. 1995). Oregano oil provided complete control at 2.0 mL/m<sup>3</sup>; thyme oil was not completely effective at 4.0 mL/m<sup>3</sup> and affected seed germination at 5.0 mL/m<sup>3</sup>.

## Insect Infestation

Insects cause major losses of stored grain. Grain containing live insects or insect fragments in sufficient numbers is unsuitable for human food. When grain is stored for long periods (a year or more), insects can infest the grain and cause significant amounts of deterioration. Traps and chemical attractants have been developed that monitor insects in storage facilities (Barak and Harein 1982, Barak and Burkholder 1985, Burkholder and Ma 1985). Detection in samples of grain taken for grading and inspection is often difficult. Many of the insects are relatively small and can be seen easily only with a magnifying lens. Many of the insect larvae develop within the kernels and cannot be detected without staining techniques or grinding of the grain sample. Infested grain mixed with good grain in marketing channels compounds the infestation problem.

Sanitation is one of the most effective methods of insect control. Cleaning of bins after removal of old-crop grain and prior to filling with new-crop grain is essential. In bins containing perforated floors, fine material that collects beneath the floors can harbor insects, which infest new-crop grain when it is added. Control by aeration is feasible in temperate climates because insect activity is reduced greatly at temperatures below 10°C. The effectiveness of temperature control has been documented by Bloome and Cuperus (1984) and Epperly et al. (1987). Chemicals have frequently been used to control live insects in grain, and methods are described by Harein and Davis (1982). Thermal treatments have also been investigated (Lapp et al. 1986). Pederson (1992) summarizes the types of grain insects, the ecology of insect growth, and the methods of detecting insects in samples of grain. Athie et al. (1998) reviewed the status and future of chemical grain protectants. Armitage et al. (1994) proposed an integrated pest management strategy combining surface insecticide treatment and aeration. Control of insects in farm-stored grain is detailed by Storey et al. (1979), Quinlan (1982), and Harein and Davis (1992).

## Rodents

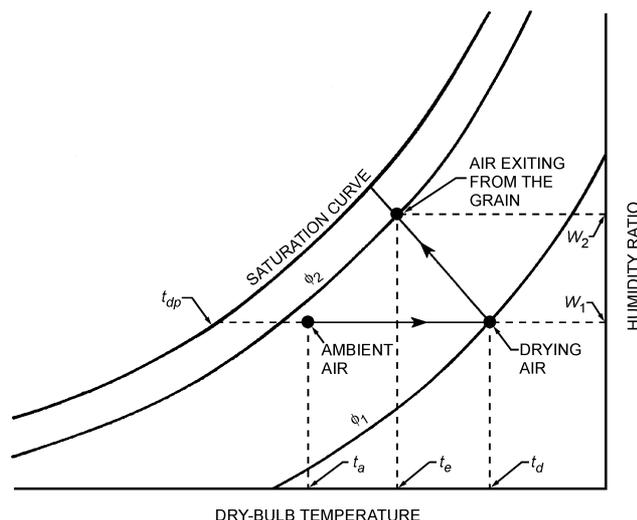

The shift from ear corn harvesting and storage to field shelling and the introduction of metal bins have helped to reduce rodent problems. However, significant problems can arise when rodents consume grain and contaminate it with their hair and droppings. Storage structures should be made rodent-proof whenever possible. Rats can reach 330 mm up a wall, so storage structures should have concrete foundations and metal sides that resist gnawing.

In some countries, smaller on-farm storage structures are often elevated 460 mm to give protection from rodents. Double-wall construction and false ceilings should be avoided, and vents and holes should be covered with wire grates. Proper sanitation can help prevent rodent problems by eliminating areas where rodents can nest and hide. Rodents need water to survive, so elimination of available water is also effective. Techniques for killing rodents include trapping, poisoning with bait, and fumigation. Harris and Bauer (1992) address rodent problems and control in more detail.

## DRYING THEORY

In ordinary applications, drying is a heat and mass transfer process that vaporizes liquid water, mixes the vapor with the drying air, and removes the vapor by carrying away the mixture mechanically. In forced-convection drying, sufficient heat for vaporization of product moisture (about 2560 kJ/kg of water) comes from the sensible heat in the drying air.

The most common mode of drying uses the sensible heat content of the air. The method can be diagrammed on the psychrometric chart by locating the state points for the air as it is heated from ambient temperature to plenum temperature and then exhausted from the grain. The process is assumed to be adiabatic (i.e., all the sensible heat lost by the air is used for moisture vaporization and converted to latent heat of the water vapor in the drying air). Therefore, the

**Fig. 2 Drying Process Diagrammed on Psychrometric Chart Showing Adiabatic Evaporation of Moisture from Grain**

state point of the air can be considered to move along adiabatic saturation lines on the psychrometric chart. In the simplified psychrometric chart in Figure 2, the ambient air at dry-bulb temperature  $t_a$  and dew-point temperature  $t_{dp}$  is heated to drying air temperature  $t_d$ , where it has a relative humidity  $\phi_1$ . As the air passes through the grain, its sensible heat provides the latent heat of vaporization of the water. When the air exits from the grain, its temperature has dropped to  $t_e$ , and its relative humidity has increased to  $\phi_2$ . The moisture gained by each kilogram of drying air is the difference  $W_2 - W_1$  in humidity ratio. If the air has sufficient contact time with the grain, the value for  $\phi_2$  will be the equilibrium relative humidity of the grain at that moisture and temperature  $t_e$ .

**Example 1.** Shelled corn at 20% moisture content is dried with air heated to 70°C. The air has an ambient temperature of 20°C with a dew point of 10°C. The air is observed to exhaust from the shelled corn at 30°C. Find the amount of energy needed to heat the air and the amount of water removed per kilogram of dry air.

**Solution:** Estimate the psychrometric air conditions, using information contained in Chapter 6 and assuming a standard atmospheric pressure of 101.325 kPa.

At 20°C, the enthalpy of the dry air is  $h_a = 20.121$  kJ/kg (Table 2 in Chapter 6) and the saturation vapor pressure  $p_{ws} = 2.3388$  kPa (Table 3 in Chapter 6). At 10°C dew point, the vapor pressure  $p_w = 1.2280$  kPa, and the enthalpy of the water vapor  $h_g = 2519.12$  kJ/kg (Table 3 in Chapter 6). The relative humidity is then  $\phi = 53\%$  [Equation (24) in Chapter 6]; humidity ratio  $W = 0.0076$  kg/kg [Equation (22) in Chapter 6]; and enthalpy  $h = 39.3$  kJ/kg [Equation (29) in Chapter 6]. As the air is heated, the humidity ratio is assumed to remain constant. At 70°C, the enthalpy of the dry air is  $h_a = 70.489$  kJ/kg (Table 2 in Chapter 6) and the saturation vapor pressure  $p_{ws} = 31.198$  kPa (Table 3 in Chapter 6). The relative humidity has been reduced to  $\phi = 4\%$  [Equation (24) in Chapter 6]; enthalpy increased to  $h = 89.6$  kJ/kg [Equation (29) in Chapter 6]; and the wet-bulb temperature of the drying air is  $t^* = 29^\circ\text{C}$  [iterative solution to Equation (35) in Chapter 6]. The amount of energy needed to heat each kilogram of dry air is then  $89.6 - 39.3 = 50.3$  kJ.

As the heated air passes through the grain, it increases in moisture and decreases in temperature until it comes into equilibrium with the corn at the point of air exhaust (initially 20%). The exhaust air relative humidity can be estimated by reading the equilibrium relative humidity from the curve for shelled corn shown in Figure 1. Enter the curve for shelled corn at 20% equilibrium moisture content and a temperature of 30°C. The equilibrium relative humidity is approximately 92%. At 30°C, the saturation vapor pressure of the air  $p_{ws} = 4.2460$  kPa (Table 3 in Chapter 6); the vapor pressure  $p_w = 3.9063$  kPa [Equation (24) in Chapter 6]; and the humidity ratio  $W = 0.0249$  kg/kg [Equation (22) in

Chapter 6]. Each kilogram of dry air carries with it  $0.0249 - 0.0076 = 0.0173$  kg of water from the grain.

After the grain at the air exhaust has dried to 15%, the equilibrium moisture content curve from Figure 1 can be used to estimate the exhaust air relative humidity. If the temperature of the air were  $30^\circ\text{C}$ , then the equilibrium relative humidity would be approximately 76%; if the temperature of the air were  $40^\circ\text{C}$ , then the equilibrium relative humidity would be approximately 81%. From Equation (35) in Chapter 6, the wet-bulb temperatures associated with these two points are  $27^\circ\text{C}$  and  $46^\circ\text{C}$ , respectively. A linear interpolation between these two points results in an air temperature of  $32^\circ\text{C}$  and an equilibrium relative humidity of 77%. At  $32^\circ\text{C}$ , the saturation vapor pressure of the air  $p_{ws} = 4.7585$  kPa (Table 3 in Chapter 6); the vapor pressure  $p_w = 3.664$  kPa [Equation (24) in Chapter 6]; and the humidity ratio  $W = 0.0236$  kg/kg [Equation (22) in Chapter 6]. Each kilogram of dry air carries with it  $0.0236 - 0.0076 = 0.016$  kg of water from the grain.

### Thin Layer Drying

A *thin layer* of grain is a layer of grain no more than several kernels deep. The ratio of grain to air is such that there is only a small change in temperature and relative humidity of the drying air when it exits the grain. The maximum rate ( $dM/d\theta$ ) at which a thin layer of a granular hygroscopic material (such as grain) transfers moisture to or from air can be approximated by the following equation (Hukill 1947):

$$\frac{dM}{d\theta} = -C(p_g - p_a) \quad (14)$$

where

$C$  = constant representing vapor conductivity of kernel and surrounding air film

$p_g$  = partial pressure of water vapor in grain

$p_a$  = partial pressure of water vapor in drying air

If  $p_g > p_a$ , drying takes place. If  $p_g = p_a$ , moisture equilibrium exists and no moisture transfer occurs. If  $p_g < p_a$ , wetting occurs. The assumption of a linear relationship between (1) water vapor pressure and equilibrium relative humidity and (2) equilibrium relative humidity and moisture content over the range in which drying occurs lead to the following equation:

$$\frac{dM}{d\theta} = -k(M - M_e) \quad (15)$$

where

$M$  = moisture content (dry basis) of material at time  $\theta$

$M_e$  = equilibrium moisture content (dry basis) of material in reference to drying air

$k$  = constant dependent on material

The solution to this differential equation is

$$\frac{M - M_e}{M_o - M_e} = \exp(-k\theta) \quad (16)$$

where  $M_o$  = moisture content, dry basis, when  $\theta = 0$ .

In later work (Hukill and Schmidt 1960, Troeger and Hukill 1971), Hukill recognized that Equation (16) did not describe the drying rate of grain adequately. Misra and Brooker (1980) identified the following model as more promising for shelled corn:

$$\frac{M - M_e}{M_o - M_e} = \exp(-K\theta^N) \quad (17)$$

They give an equation for  $K$ , which is a function of drying air temperature and velocity, and another equation for  $N$  as a function of drying air relative humidity and initial grain moisture. Their equations are valid for drying air temperatures of  $2.2$  to  $71^\circ\text{C}$ , drying air

relative humidities of 3 to 83%, drying air velocities of 0.025 to 2.33 m/s, and initial moistures of 18 to 60% (dry basis).

Li and Morey (1984) also fit their data to Equation (17) and found that within the limits of drying airflow rates and air relative humidities used,  $K$  and  $N$  can be expressed as functions of air temperature and initial grain moisture only. Their equations for  $K$  and  $N$  apply to air temperatures ranging from  $27$  to  $115^\circ\text{C}$ , initial grain moistures of 23 to 36% dry basis, airflows of 0.27 to 1.34  $\text{m}^3/(\text{s}\cdot\text{m}^3)$ , and air relative humidities of 5 to 40%.

Other forms of the thin layer drying equation have also been proposed. Thompson et al. (1968) fitted data for shelled corn to the following equation, which is applicable in the range of  $60$  to  $150^\circ\text{C}$ :

$$\theta = A \ln MR + B(\ln MR)^2 \quad (18)$$

where

$$A = -1.70562 + 0.00878t$$

$$B = 427.3740 \exp(-1.0563 - 0.05942t)$$

$$MR = (M - M_e)/(M_o - M_e)$$

$$\theta = \text{time, h}$$

$$t = \text{temperature, } ^\circ\text{C}$$

Martins and Stroschine (1987) describe the effects of hybrid and damage on the thin layer drying rate and give values for constants  $A$  and  $B$  in Equation (18) for several hybrids and damage levels.

Results of thin layer drying tests for other grains have also been reported. Data are available for the following grains:

- Wheat (Watson and Bhargava 1974, Sokhansanj et al. 1984, Bruce and Sykes 1983)
- Soybeans (Hukill and Schmidt 1960, Overhults et al. 1973, Sabbah et al. 1976)
- Barley (O'Callaghan et al. 1971, Sokhansanj et al. 1984, Bruce 1985)
- Sorghum (Hukill and Schmidt 1960, Paulsen and Thompson 1973)
- Rice (Agrawal and Singh 1977, Noomhorm and Verma 1986, Banaszek and Siebenmorgen 1990)
- Sunflower (Syarief et al. 1984, Li et al. 1987)
- Canola (Sokhansanj et al. 1984, Pathak et al. 1991)
- Oats (Hukill and Schmidt 1960)
- Lentil seeds (Tang et al. 1989)

Sokhansanj and Bruce (1987) developed more rigorous thin layer drying equations based on simultaneous heat and mass transfer through a single kernel and demonstrated that such a model accurately predicts the temperature and moisture content of the grain throughout the drying process. Jayas et al. (1991) reviewed thin-layer drying models, and Parti (1993) presented comparisons of models under different conditions.

Equations (16) through (18) do not describe the usual drying process, where grain is in a deep bed and where drying air changes condition but does not necessarily reach moisture equilibrium with the grain. Those models, which are formulated using thin layer drying equations such as these, are summarized in the section on Deep Bed Drying.

### Airflow Resistance

Data on resistance of grain to airflow are used for a variety of design calculations such as selecting fans, determining optimum depths for drying bins, predicting airflow paths in bins with aeration ducts, and determining the practical limitations on airflow caused by fan power requirements. For a given fan and dryer or bin, airflow resistance can change with the type of grain being dried, the depth of grain, and the amount of fine material in the grain. In many grain-drying applications, such as when air is forced through a grain bin that has a uniform grain depth and a full perforated floor, airflow is one-dimensional and the pressure drop per unit depth of grain can be assumed to be constant. Shedd (1953) determined pressure drop per

unit depth versus airflow for a number of grains and seeds and summarized by plotting them on logarithmic axes. These curves (commonly called **Shedd's curves**) are included in ASAE *Standard D272.3*. They can also be calculated from the following equation (ASAE 1996, Sokhansanj and Yand 1996):

$$\frac{\Delta p}{L} = \frac{aQ^2}{\ln(1 + bQ)} \quad (19)$$

where

$\Delta p$  = pressure, Pa

$L$  = bed depth, m

$Q$  = airflow rate,  $\text{m}^3/(\text{s}\cdot\text{m}^2)$

$a, b$  = empirical constants

Table 6 summarizes the constants for Equation (19) for some of the more common grains. Constants for grass seeds and some vegetables are included in ASAE *Standard D272.3*. Jayas and Mann (1994) reviewed the presentation of airflow resistance data for 22 different seeds, including grains. They reported that the mean relative percent error for each grain could be significantly reduced if the airflow range were divided into two subranges: 0.004 to 0.05  $\text{m}^3/(\text{s}\cdot\text{m}^2)$  and 0.05 to 0.35  $\text{m}^3/(\text{s}\cdot\text{m}^2)$ .

Equation (19) gives the airflow resistance for clean, dry grain when the bin is loaded by allowing the grain to flow into the bin through a chute from a relatively low height. Kumar and Muir (1986) reported on the effect of filling method on the airflow resistance of wheat and barley. Jayas et al. (1987) showed that the resistance of canola to airflow in a horizontal direction was 0.5 to 0.7 times the resistance to airflow for the vertical direction.

The presence of fine material in grain can significantly alter the airflow resistance. Fine material is generally defined as broken kernels and other matter that can pass through a round hole sieve with a hole size slightly less than the kernel size. For shelled corn, a 4.76 mm round hole sieve is used to measure fines.

The pressure drop per meter is routinely increased by multiplying the value from Equation (19) by a packing factor. A factor of 1.5 is used for shelled corn; 1.2 for other grains. Haque et al. (1978) developed a correction factor for airflow resistance in shelled corn with fine material fractions from 0 to 20%

**Table 6 Constants for Airflow Resistance [Equation (19)]**

Material	Value of $a$ , $\text{Pa}\cdot\text{s}^2/\text{m}^3$	Value of $b$ , $\text{m}^2\cdot\text{s}/\text{m}^3$	Range of $Q$ , $\text{m}^3/(\text{s}\cdot\text{m}^2)$
Barley	$2.14 \times 10^4$	13.2	0.0056 to 0.203
Canola (rapeseed)	$5.22 \times 10^4$	7.27	0.0243 to 0.2633
Ear corn	$1.04 \times 10^4$	325	0.051 to 0.353
Lentils	$5.43 \times 10^4$	36.79	0.0028 to 0.5926
Oats	$2.41 \times 10^4$	13.9	0.0056 to 0.203
Peanuts	$3.80 \times 10^3$	111	0.030 to 0.304
Popcorn, white	$2.19 \times 10^4$	11.8	0.0056 to 0.203
Popcorn, yellow	$1.78 \times 10^4$	17.6	0.0056 to 0.203
Rice, rough	$2.57 \times 10^4$	13.2	0.0056 to 0.152
Rice, long brown	$2.05 \times 10^4$	7.74	0.0055 to 0.164
Rice, long milled	$2.18 \times 10^4$	8.34	0.0055 to 0.164
Rice, medium brown	$3.49 \times 10^4$	10.9	0.0055 to 0.164
Rice, medium milled	$2.90 \times 10^4$	10.6	0.0055 to 0.164
Shelled corn	$2.07 \times 10^4$	30.4	0.0056 to 0.304
Shelled corn, low airflow	$9.77 \times 10^3$	8.55	0.00025 to 0.0203
Sorghum	$2.12 \times 10^4$	8.06	0.0056 to 0.203
Soybeans	$1.02 \times 10^4$	16.0	0.0056 to 0.304
Sunflower, confectionery	$1.10 \times 10^4$	18.1	0.055 to 0.178
Sunflower, oil	$2.49 \times 10^4$	23.7	0.025 to 0.570
Wheat	$2.70 \times 10^4$	8.77	0.0056 to 0.203
Wheat, low airflow	$8.41 \times 10^3$	2.72	0.00025 to 0.0203

Source: ASAE *Standard D272.3*.

Grama et al. (1984) reported the effect of fine material particle size distribution on resistance in shelled corn. They also reported the effect of the increased resistance from fines on fan power requirements. Kumar and Muir (1986) reported the effects of fines in wheat. Bern and Hurburgh (1992) reviewed the characteristics of fines in shelled corn, including their composition, size distribution, density, airflow resistance, and nutritive and economic value. They concluded that fines can increase airflow resistance up to 200%.

Bulk density can have a significant effect on airflow resistance. For moderate heights of 4 to 7.5 m, drop height does not affect bulk density in bins filled with a spout (Chang et al. 1986). Bern et al. (1982) reported that auger stirring can decrease the bulk density of bins filled with a grain spreader but has no effect on or increases bulk density in bins filled by gravity. Magnitudes of the increase in bulk density caused by grain spreaders have been reported by Stephens and Foster (1976b, 1978) and Chang et al. (1983).

Moisture content also affects airflow resistance. Its effect may, in part, be caused by its influence on bulk density. Shedd's curves include a footnote recommending that for loose fill of clean grain, airflow resistance should be multiplied by 0.80 if the grain is in equilibrium with air at relative humidities greater than 85% (ASAE *Standard D272.2*). At 21°C, this corresponds to a moisture of 18% or more for shelled corn (Figure 1). Haque et al. (1982) give equations that correct for the effects of moisture content of shelled corn, sorghum, and wheat.

Li and Sokhansanj (1994) argued that a generalized equation for airflow resistance, a modification of Leva's equation (Leva 1959), could account for airflow resistance differences due to variations in grain density, moisture content, and fines. Supporting constants for nine seeds are presented. Giner and Denisienia (1996) proposed a modified Ergun equation for the quadratic moisture effects and linear fines effects in wheat.

When the flow lines are parallel and airflow is linear (as is the case in a drying bin with a full perforated floor), calculation of the airflow is a straightforward application of Equation (16). For a given fan attached to a particular bin filled to a uniform depth with grain, the operating point of the fan can be determined as follows. A curve is plotted showing the total static pressure in the bin plenum versus airflow to the bin. Airflow rate is calculated by dividing the total air volume supplied to the plenum by the cross-sectional area of the bin. Using Equation (16), the pressure drop per unit depth can be calculated and multiplied by the total depth of grain in the bin to give total static pressure in the plenum. The fan curve showing air delivery volume versus static pressure can be plotted on the same axes. The intersection of the curves is the operating point for the fan. These calculations can also be done on a computer, and the point of intersection of the curves can be determined using appropriate numerical methods. McKenzie et al. (1980) and Hellevang (1983) summarize airflow resistances for various bin and fan combinations in tabular and graphical form. Sokhansanj and Woodward (1991) developed a design procedure for use on personal computers to select fans for near-ambient drying of grain.

In cases where airflow is nonlinear, as in conical piles or systems with air ducts, computation is complex (Miketinac and Sokhansanj 1985). Numerical methods for predicting airflow patterns have been developed and applied to bins aerated with ducts (Brooker 1969, Segerlind 1982, Khompos et al. 1984), conical-shaped piles (Jindal and Thompson 1972), and bins in which porosity varies within the bed (Lai 1980). Lai's study applies to bins in which filling methods have created differences in bulk density within the bin or where fine material is unevenly distributed. Alagusundaram et al. (1994) studied airflow patterns through wheat, barley, and canola in bins with different patterns of partially perforated floors.

### Analysis of Deep Bed Drying

The ability to predict the rate at which grain dries in a given type of dryer operating in specific weather conditions with a specified

airflow and air temperature can assist designers in developing dryers for maximum efficiency. It can also guide operators in finding the optimum way to operate their particular dryers for given weather conditions. Computer simulations have helped researchers understand the mechanisms and processes involved in drying.

Two relatively simple prediction equations can be solved on a hand calculator. Hukill (1947) developed a widely known and used method that predicts the moisture distribution in a bed of grain during drying. A graphical presentation of one of the equations, which further simplifies calculations, is available. Hukill's method is summarized by Brooker et al. (1992), who give an example calculation for shelled corn drying. Barre et al. (1971) made further adaptations of Hukill's method, and Foster (1986) gives a historical perspective on the development and utility of the method. Brooker et al. (1992) also present a technique called the *heat balance equation*, which equates the heat available in the air for drying with the amount of heat needed to evaporate the desired amount of water from the grain. Both of the above methods take into account airflow, drying air temperature and relative humidity, exit air conditions, grain moisture, and the amount of grain to be dried.

Thompson et al. (1968) considered a deep bed of grain as a series of thin layers of grain stacked one on top of another. Algebraic heat and mass balances were applied to each layer, with the exit air conditions of one layer becoming the input conditions of the next layer. Thompson et al. (1969) used the model to predict concurrent-flow, crossflow, and counterflow drying of shelled corn. Paulsen and Thompson (1973) used it to evaluate crossflow drying of sorghum. Stephens and Thompson (1976) and Pierce and Thompson (1981) used the model to make recommendations about optimum design of high-temperature grain dryers.

Bakker-Arkema et al. (1978) used simultaneous heat and mass transfer equations in a series of coupled partial differential equations to describe deep bed drying. The equations, solved using a finite difference technique, predict grain temperature, grain moisture content, and air temperature and humidity ratio. Bakker-Arkema et al. (1979, 1984) give solutions for in-bin, batch, continuous crossflow, and continuous concurrent-flow dryers. Morey et al. (1976) used the model to evaluate energy requirements for drying. Morey and Li (1984) and Bakker-Arkema et al. (1983) demonstrated the effect of thin layer drying rate on the model predictions. Bridges et al. (1980) used the Thompson model for simulation of batch-in-bin drying. Morey et al. (1978) and Parry (1985) review many of the mathematical models used for high-temperature grain drying.

Computer simulations have also been developed for low-temperature and solar drying. Some of these models have been referenced in the section on Fungal Growth and Mycotoxins under Prevention of Deterioration. Thompson (1972) developed a model that was later used by Pierce and Thompson (1979) to make recommendations on airflow in solar grain drying and by Pierce (1986) to evaluate natural air drying. Sabbah et al. (1979) used the logarithmic model of Barre et al. (1971) for simulation of solar grain drying. Bridges et al. (1984) used a model to evaluate the economics of stirring devices in in-bin drying systems. Morey et al. (1979), Frazer and Muir (1981), Bowden et al. (1983), and Smith and Bailey (1983) have also modeled low-temperature drying. Sharp (1982) reviewed low-temperature drying simulation models.

### Aeration of Grain

Aeration involves forcing small amounts of air through the stored grain to maintain a uniform temperature. Prior to the development of this concept, grain was turned by moving it from one storage bin to another. Foster (1986) credits Hukill (1953) with developing the concept of aeration. As mentioned in the sections on Fungal Growth and Mycotoxins and Insect Infestation, lowering of the grain temperature during winter in temperate climates can reduce the rate of deterioration from molds and insects. Aeration can also prevent temperature gradients from developing within the

grain mass. Such gradients can cause moisture migration, which results in unacceptably high moistures in certain portions of the bin.

Aeration is used to cool stored grain in the fall. A typical practice is to aerate the grain when the difference between grain temperature and the average daily outside temperature exceeds 5.5 K. In the United States, grain is usually not warmed in the spring unless it is to be stored past early June. Foster and McKenzie (1979) and McKenzie (1980) give practical recommendations for aeration of grain. Airflow rates of 0.3 to 6.7 L/(s·m<sup>3</sup>) are normally used. Air is usually distributed through the bottom of the bin using ducts. Duct spacing and fan selection are related to bin size and shape and to the airflow rate. Foster and Tuite (1992) give an overview of the topic and include information and charts used for design of such systems. Peterson (1982) gives recommendations for duct spacing in flat storages.

Several computer simulations have been developed to study the effects of heat buildup from microbial activity with and without aeration (Thompson 1972, Brooker and Duggal 1982, Metzger and Muir 1983, Lissik 1986). Aldis and Foster (1977) and Schultz et al. (1984) studied the effect of aeration on grain moisture changes.

## DRYING SPECIFIC CROPS

### Hay

Forage crops can be either harvested, dried, and stored as hay or harvested and stored under anaerobic conditions as silage. Hay quality can be judged by its color, leafiness, and appearance. Laboratory tests and feeding trials give a more detailed picture of hay quality. The traditional method of making hay is to mow the forage and allow it to field cure or dry in the swath and windrow. Harvesting at higher moistures with subsequent artificial drying may be economically feasible, depending on the local weather conditions.

Basic principles of hay drying and storage are covered by Hall (1980), FEC (1985), and Schuler et al. (1986). Forage must be harvested in the proper stage of maturity to attain maximum feeding value. Leaf loss from alfalfa is high when it is handled at moistures below 39%. Therefore, if it is baled at 40% moisture and dried artificially to the recommended storage moisture of 20% (Schuler et al. (1986), a significantly higher feeding value can be achieved. Both Schuler et al. (1986) and Hall (1980) give sketches for batch and in-storage hay dryers. They recommend airflows of 75 to 100 L/s per square metre of mow floor area.

Dehydrated alfalfa meal supplies provitamin A (carotene), vitamin E, xanthophylls (poultry pigmenting factors), vitamin K, vitamin C, and B vitamins. Figure 3 shows losses from field drying of hay found in tests conducted by Shepherd (1954). The rapid loss of carotene immediately after the forage is cut indicates the need for

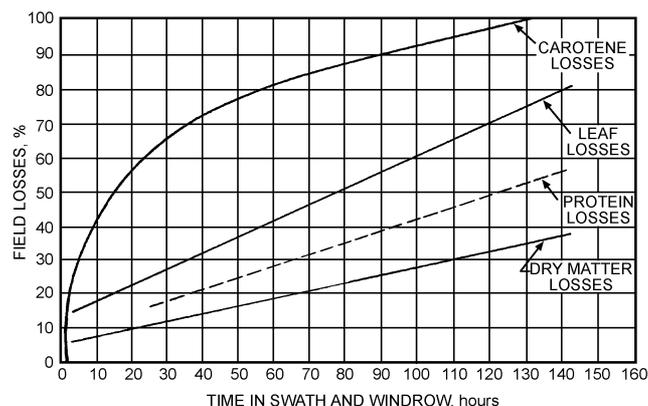

Fig. 3 Time in Swath and Windrow Versus Field Losses of Leaves, Dry Matter, Protein, and Carotene for Hay Drying

**Table 7 Effect of Heating Chopped Alfalfa on Carotene Loss During Subsequent Storage of Meal**

Hours in Oven at 100°C	Initial Carotene, ppm	Carotene Retained 7 Days at 65°C, %

Note: Alfalfa is fresh frozen from Ryer Island, CA.

rapid transport to the dehydrator when alfalfa meal with high vitamin content is desired.

Several factors influence retention of vitamins during storage, including the starting plant material, dehydration conditions, addition of stabilizers, and storage conditions. Lowering the temperature reduces the loss rate. Inert gas atmosphere in storage also reduces losses (Hoffman et al. 1945). According to Shepherd (1954), blanching of fresh alfalfa before drying does not alter the storage stability of carotene. Table 7 shows Shepherd's results on the effect of prolonged heating at 100°C. The alfalfa was dried after 45 min; heating beyond this time represented excessive exposure to this temperature. Carotene retention in the intact meal at 65°C storage temperature was considered a measure of storage stability. Normal storage moisture is 8 to 9%. Thompson et al. (1960) summarize the effects of over- and underdrying on carotene stability.

Drying and handling of large round bales has been researched. These bales may have a mass of 385 to 680 kg and are handled individually with forklifts. Verma and Nelson (1983) studied storage of large round bales and found that dry matter loss was the primary component of the total storage losses. Bales stored so that they were protected from the weather had lower losses of dry matter than bales exposed to the weather. They were also higher in total protein. Jones et al. (1985) found significant dry matter loss in large round bales of mature fescue hay. Harrison (1985) found that addition of sulfur dioxide at the rate of 1% of dry matter had little effect on dry matter loss and nutrient contents for a mixture of alfalfa and brome grass. However, bales protected with plastic bags did have significantly lower dry matter loss. Jones et al. (1985) found that bales of mature fescue hay stored inside and bales treated with ammonia had less dry matter loss and higher *in vitro* dry matter digestibility. Henry et al. (1977) and Frisby et al. (1985) developed and tested solar dryers for large round bales.

## Grain

The physiological factors involved in drying and storing grain are different from those of forages. Grain is the end product of plant growth, and most physiological activity within the grain or seed is approaching a low level when harvested. With forage, the biological activity within the plant is at or near its peak at the time of harvest.

Both the deterioration of grain harvested at moistures above those safe for storage and the chemical preservation of grain are addressed in the section on Fungal Growth and Mycotoxins. Preservation by ensiling or airtight storage is addressed in the section on Oxygen and Carbon Dioxide.

For more information on grain drying, see Chapter 22 of the 1999 ASHRAE Handbook—Applications and Brook (1992).

## Corn

Shelled field corn is used primarily as livestock feed, but some is used by milling or processing industries for manufacturing starch, corn oil, and other products. Little information is available on the relationship between the drying method and the feed value of corn.

Market grade, as established by the Agricultural Marketing Service of the United States Department of Agriculture (USDA), is the primary criterion for determining corn value. Tests by Cabell et al. (1958) indicated that shelled corn with a moisture content of 29 to 32% can be dried without loss of protein nutritive value by air with temperatures as high as 115°C, provided the airflow rate is approximately 1.5 m<sup>3</sup>/(s·m<sup>3</sup>).

**Breakage Susceptibility.** The market grade of dry corn is affected more by the amount of fine material than by other grading factors. Fine material is defined as the broken grain and other material that passes through a 4.76 mm round-hole sieve. The physical damage done to wet corn or the brittleness imparted to the corn during drying causes it to break each time it is handled. The propensity of corn to break during subsequent handling, called **breakage susceptibility**, can be measured with a multiple-impact device called the *Stein breakage tester*. Stephens and Foster (1976a) demonstrated that corn breakage in the tester was correlated with damage during handling. Watson et al. (1986) give a standardized procedure for using the Stein breakage tester, and Watson and Herum (1986) describe and compare other devices developed for measurement of breakage susceptibility. They concluded that a device developed by Singh and Finner (1983) offers great potential for testing of grain for breakage susceptibility in commercial situations.

Paulsen et al. (1983) found significant variations in breakage susceptibility among hybrids. Corn dried with air at high temperatures (60°C) was two to six times more susceptible to breakage than corn dried at near-ambient temperatures. Gustafson and Morey (1979) found that delayed cooling (maintaining the corn at or near its temperature at the end of drying for 6 to 12 h) reduced breakage susceptibility and improved the test mass.

In a study of combination drying, Gustafson et al. (1978) found that combination drying (high-temperature drying to 18% followed by low-temperature drying to 16.6% moisture or below) significantly reduced the increase in breakage susceptibility normally caused by high-temperature drying.

**Quality.** Both drying temperature and corn hybrid can affect the quality of shelled corn for specific end uses. Brekke et al. (1973) found that drying at temperatures above 60°C reduced the quality of the corn for dry milling. Peplinski et al. (1982) found that optimum dry milling quality could be achieved by harvesting corn at moistures below 25%, minimizing machinery-induced damage to the kernels, and drying at air temperatures below 82°C. Paulsen and Hill (1985) found that the yield of flaking grits from dry milling of corn was significantly greater for corn that had a high test mass and relatively low breakage susceptibility. Weller et al. (1987) found that corn variety affected wet milling quality. At drying temperatures between 49 and 71°C, protein conformational changes occurred and decreased the ethanol soluble protein. Hybrids differ in resistance to storage mold (Tuite and Foster 1979), thin layer drying rate, and dry milling quality (Stroshine et al. 1986). Watson (1987) gives an extensive summary of measurement and maintenance of quality of corn, and Foster (1975) summarizes approaches to reducing damage during harvesting, handling, and drying.

## Cotton

The lint moisture content for best results in ginning cotton appears to be 5 to 7%, with an optimum moisture content of 6% (Franks and Shaw 1962). Cotton, like grain, is hygroscopic and should be dried just prior to ginning. The wide variation in incoming moisture content usually requires different amounts of drying for each load. Rapid changes in the amount of drying required can best be handled by using a multipath drying tower in which the cotton is exposed for various lengths of time (2 to 10 s) at temperatures not exceeding 175°C. The air-to-cotton ratio can range from 40 to 100 m<sup>3</sup>/(s·t) of cotton (Franks and Shaw 1962). Laird and Baker (1983) found that substantial amounts of heat could be reclaimed and used for drying in commercial cotton gin plants. Equilibrium moisture

content data for newly harvested cotton fibers are given by Griffin (1974). Anthony (1982) studied moisture gain of cotton bales during storage.

Cottonseed removed from the fibers is also dried. The germination of cottonseed is unimpaired by drying if the internal cottonseed temperatures do not exceed 60°C (Shaw and Franks 1962). This temperature is not exceeded in the tower dryer described previously. However, the moisture content of the seed can be above the recommended level of 12% following the multipath tower drying. Drying seed in a triple-pass drum at 120 to 150°C with an exposure time of 4 min, followed by cooling, reduces moisture content, inhibits the formation of free fatty acids, and improves germination compared to undried seed. Anthony (1983) dried cottonseed in a vacuum microwave dryer. The cottonseed would not germinate, but its oil properties were not harmed as long as lower temperatures were used. The drying rate was increased by reducing pressure below atmospheric. Rayburn et al. (1978) studied preservation of high-moisture cottonseed with propionic acid.

### Peanuts

Peanuts in the shell normally have a moisture content of about 50% at the time of digging. Allowing peanuts to dry on the vines in the windrows for a few days removes much of this water. However, peanuts normally contain 20 to 30% moisture when removed from the vines, and some artificial drying in the shell is necessary. Drying should begin within 6 h after harvesting in order to prevent peanuts from self-heating. The maximum temperature and rate of drying must be controlled to maintain quality. High temperatures result in off-flavor or bitterness. Overly rapid drying without high temperatures results in blandness or inability to develop flavor when roasted (Bailey et al. 1954). High temperatures and rapid or excessive drying also cause the skin to slip easily and the kernels to become brittle. These conditions result in damage in the shelling operation and can be avoided if the moisture removal rate does not exceed 0.5% per hour. Because of these limitations, continuous-flow drying is not usually recommended.

Young (1984) found energy savings up to 26% when comparing recirculating dryers with conventional peanut dryers. Smith and Davidson (1982) and Smith et al. (1985) address the aeration of peanuts during warehouse storage.

### Rice

Of all grains, rice is possibly the most difficult to process without quality loss. Rice containing more than 12.5% moisture cannot be stored safely for long periods, yet the recommended harvest moisture content for best milling and germination ranges from 20 to 26% (Kramer 1951). If the rice is harvested at this moisture content, drying must begin promptly to prevent heat-related damage, which can result in "stack-burn," a yellowing of the kernel. To prevent excessive internal fissuring, which results in broken kernels during milling, multiple-pass drying is usually necessary (Calderwood and Webb 1971). Kunze and Calderwood (1980) summarize rice-drying techniques.

Because the market demands polished whole kernels of rice, it is necessary to prevent damage in the form of fissures. Rapid moisture removal or addition can create moisture gradients within kernels. According to Kunze (1984), gradients can develop in the field on a humid night before harvest, in a hopper containing a mixture of rice kernels at varying moistures, and in certain types of dryers. Banaszek and Siebenmorgen (1990) quantified the rate at which moisture absorption reduces head rice yields. Velupillai and Verma (1986) report that drying at 93°C followed by tempering in a sealed container for 24 h gave good kernel strength and head rice yields. They also found that storing the rice after drying for 3 weeks gave optimum grain quality. Bakker-Arkema et al. (1984) achieved good rice quality with concurrent-flow drying of rice.

### Soybean, Sunflower, and Edible Beans

Prolonged periods of extremely wet weather during the harvest season can make artificial drying of soybeans necessary. Like peanuts and other oilseeds, soybeans cannot be dried satisfactorily with the high-temperature, high-speed methods used for cereal grains. Because of the different seed structure, rapid drying splits the seed coat and reduces quality and storage life. Overhults et al. (1975) reported a significant decrease in the quality of oil extracted from soybeans dried at temperatures above 71°C. Soybeans have one of the slowest thin layer drying rates of commonly grown cereals and oilseeds (Bakker-Arkema et al. 1983). Therefore, they dry more slowly and require more energy when dried in continuous-flow dryers.

Sunflower is a major crop in some areas of the United States. Hellevang (1987) recommends maximum drying temperatures of 93°C for continuous-flow drying of oil sunflower and 82°C for non-oil sunflower to prevent scorching of the seed meat. Schuler (1974) gives data on equilibrium moisture, airflow resistance, and specific heat of sunflower seeds. Because sunflower is about half the density of shelled corn, moisture can be removed more rapidly, and there is a tendency to overdry. This factor, along with accumulation of foreign material when drying, causes an increased fire hazard (Hellevang 1982). Schmidt and Backer (1980) attribute most of the problems encountered with storage of sunflower seed to improper drying and/or aeration.

Edible beans, a major crop in several states, should be dried with air at relative humidities above 40% to prevent stress cracking. Natural air or low-temperature drying is best (Hellevang 1987). If dried at high rates, seed coats may crack, and beans may split during subsequent handling (Otten et al. 1984, Radajewski et al. 1992). Broken beans can develop a bitter or undesirable flavor and spoil more easily during storage (Uebersax and Bedford 1980).

### Wheat and Barley

In northern regions of the United States, wheat and barley may be harvested above safe storage moistures to prevent excessive field losses. Bruce (1992) modeled the effect of heated-air drying on the bread baking quality of wheat. The quality indicator was loaf volume. Moilanen et al. (1973) recommended that hard red spring wheat be dried at temperatures below 70, 60, and 50°C, respectively, for harvest moistures of 16, 20, and 24% wet basis. These data assumed airflow of 0.5 to 0.75 m<sup>3</sup>/(s·m<sup>2</sup>). For airflow of 0.25 m<sup>3</sup>/(s·m<sup>2</sup>), the authors recommended that the drying air temperature be reduced by 5 to 8 K. In the case of barley used for malting, the seed must be able to germinate. Therefore, the maximum recommended drying air temperature is 43 to 50°C (Hellevang 1987, Jilak 1993). Watson et al. (1962) studied the effects of harvest moisture and drying temperature on barley malting quality and recommended harvesting below 20% moisture. If wheat or barley is used for seed, the maximum recommended drying air temperature is 43°C.

In regions where soft wheat is grown, it may be economical to harvest at 20 to 24% moisture to allow double cropping with soybeans; this allows wheat harvest to begin 5 to 7 days earlier than normal and increases the yield of the soybeans (Swearingen 1979). In areas where double cropping is feasible, soft wheat can be dried using low-temperature solar drying or ambient drying with intermittent fan operation (Barrett et al. 1981). High-speed and continuous-flow systems with reduced drying air temperatures can also be used (Parsons et al. 1979). Kirleis et al. (1982) harvested soft red winter wheat at moistures of 25% or below and dried with air temperatures of 65°C or below without adverse effects on milling or cookie baking quality.

In high-temperature continuous-flow dryers, wheat and barley reduce airflow because they have a high airflow resistance. Bakker-Arkema et al. (1983) report that thin layer drying rates for barley and wheat are much faster than for corn. Barley dries more slowly

than wheat, presumably because the kernels are larger. In their computer simulations of a concurrent-flow dryer, wet bushel capacity for wheat was about 80% of the capacity for shelled corn when moisture content was reduced by 4.7%. The drying capacity difference was probably caused by a decrease in airflow.

### Tobacco (Curing)

Tobacco leaves normally have a moisture content of about 85% at harvest. The major methods of tobacco drying are air curing and flue curing (Johnson et al. 1960).

For **air curing**, whole plants are cut and allowed to wilt in the field until the leaves reach about 70% moisture (Walton et al. 1994). The plants are then hung in open barns, where temperatures range from 15 to 32°C and humidities from 65 to 70%. The curing period is 28 to 56 days (Jefries 1940). The desired end product for air curing is a tan leaf. Overdrying at low temperatures results in green color and low sugar content; overdrying at high temperatures results in yellow color (Walton and Henson 1971). Both conditions are undesirable because the normal chemical changes are arrested prematurely. Subsequent drying at optimum rates can reverse some damage. Underdrying at all temperatures results in undesirable dark color and damage from mold and bacterial growth (Walton et al. 1973).

**Flue curing** uses artificial heat. The leaves are harvested and hung in closed barns where temperatures are increased gradually during the curing period. Normally, 3 days of drying at temperatures of 32 to 50°C brings about yellowing. For the next 2 days, temperatures of 50 to 60°C are used for leaf drying; then, stems are dried at 77°C for 1 to 2 days. A bright yellow to orange color is desirable in flue-cured or bright-leaf tobacco.

<i>Inorganic Gases</i> .....	12.11	<i>Soil Gases</i> .....	12.17
<b>SPECIAL TYPES OF AIR CONTAMINANTS</b> .....	12.12		

**A**IR IS COMPOSED mainly of gases. The major gaseous components of clean, dry air near sea level are approximately 21% oxygen, 78% nitrogen, 1% argon, and 0.04% carbon dioxide.

Normal outdoor air contains varying amounts of foreign materials (permanent atmospheric impurities). These materials can arise from natural processes such as wind erosion, sea spray evaporation, volcanic eruption, and metabolism or decay of organic matter. The natural contaminant concentrations in the air that we breathe vary but are usually lower than those caused by human activity.

Man-made outdoor contaminants are many and varied, originating from numerous types of human activity. Electric power-generating plants, various modes of transportation, industrial processes, mining and smelting, construction, and agriculture generate large amounts of contaminants.

Contaminants that present particular problems in the indoor environment include, among others, tobacco smoke, radon, and formaldehyde.

Air composition may be changed accidentally or deliberately. In sewers, sewage treatment plants, tunnels, and mines, the oxygen content of air can become so low that people cannot remain conscious or survive. Concentrations of people in confined spaces (theaters, survival shelters, submarines) require that carbon dioxide given off by normal respiratory functions be removed and replaced with oxygen. Pilots of high-altitude aircraft, breathing at greatly reduced pressure, require systems that increase oxygen concentration. Conversely, for divers working at extreme depths, it is common to increase the percentage of helium in the atmosphere and reduce nitrogen and sometimes oxygen concentrations.

At atmospheric pressure, oxygen concentrations less than 12% or carbon dioxide concentrations greater than 5% are dangerous, even for short periods. Lesser deviations from normal composition can be hazardous under prolonged exposures. Chapter 9 further details environmental health issues.

### CLASSES OF AIR CONTAMINANTS

The major classes of air contaminants are particulate and gaseous. The **particulate** class covers a vast range of particle sizes from dust large enough to be visible to the eye to submicroscopic particles that elude most filters. Particulates may be solid or liquid. The following traditional contaminant classifications are subclasses of particulates:

---

The preparation of this chapter is assigned to TC 2.3, Gaseous Air Contaminants and Gas Contaminant Removal Equipment, in conjunction with TC 2.4, Particulate Air Contaminants and Particulate Contaminant Removal Equipment.

- **Dusts, fumes, and smokes**, which are mostly solid particulate matter, although smoke often contains liquid particles
- **Mists, fogs, and smogs**, which are mostly suspended liquid particles smaller than those in dusts, fumes, and smokes
- **Bioaerosols**, including viruses, bacteria, fungal spores, and pollen, whose primary impact is related to their biological origin
- Particle size definitions such as **coarse** or **fine**, **visible** or **invisible**, and **macroscopic**, **microscopic**, or **submicroscopic**
- Definitions that relate to particle interaction with the human respiratory system, such as **inhalable** and **respirable**

These classes, their characteristics, units of measurement, and measurement methods are discussed in more detail in this chapter.

The **gaseous** class covers chemical contaminants that can exist as free molecules or atoms in air. Molecules and atoms are smaller than particles and may behave differently as a result. This class covers two important subclasses:

- **Gases**, which are naturally gaseous under ambient indoor or outdoor conditions
- **Vapors**, which are normally solid or liquid under ambient indoor or outdoor conditions, but which evaporate readily

Through evaporation, liquids change into vapors and mix with the surrounding atmosphere. Like gases, they are formless fluids that expand to occupy the space or enclosure in which they are confined. Typical gaseous contaminants, their characteristics, units of measurement, and measurement methods are discussed in detail later in this chapter.

Air contaminants can also be classified according to their sources; their properties; or the health, safety, and engineering issues faced by people exposed to them. Any of these can form a convenient classification system because they allow grouping of applicable standards, guidelines, and control strategies. Most of the following classes include both particulate and gaseous contaminants. This chapter covers the background information for these classes, while Chapter 9 deals with the applicable indoor health and comfort regulations. The classes are

- Industrial air contaminants
- Nonindustrial indoor air contaminants (including indoor air quality)
- Flammable gases and vapors
- Combustible dusts
- Radioactive contaminants
- Soil gases

## PARTICULATE CONTAMINANTS

### PARTICULATE MATTER

Airborne particulate matter is not a single substance but a complex mixture of many different components, usually from several different sources. Particles can be anthropogenic or natural in origin. **Anthropogenic** particles are those produced by human activities, including fossil fuel combustion, industrial processes, and road dust. Particles from **natural** sources do not involve human activity. They include wind-blown dust and smoke from forest fires.

Particles can be generated by primary or secondary processes. Particles from **primary processes** are those emitted directly into the air. Particles from **secondary processes** are those formed from condensable vapors and chemical reactions.

Details on the different particle types are given below.

#### Types of Solid Particles

**Dusts** are solid particles projected into the air by natural forces such as wind, volcanic eruption, or earthquakes, or by mechanical processes including crushing, grinding, demolition, blasting, drilling, shoveling, screening, and sweeping. Some of these forces produce dusts by reducing larger masses, while others disperse materials that have already been reduced. Particles are not considered to be dust unless they are smaller than about 100  $\mu\text{m}$ . Dusts can be mineral, such as rock, metal, or clay; vegetable, such as grain, flour, wood, cotton, or pollen; or animal, including wool, hair, silk, feathers, and leather.

**Fumes** are solid particles formed by condensation of vapors of solid materials. Metallic fumes are generated from molten metals and usually occur as oxides because of the highly reactive nature of finely divided matter. Fumes can also be formed by sublimation, distillation, or chemical reaction. Such processes create airborne particles smaller than 1  $\mu\text{m}$ . Fumes permitted to age may agglomerate into larger clusters.

**Bioaerosols** include airborne viruses, bacteria, pollen, and fungus spores. **Viruses** range in size from 0.003 to 0.06  $\mu\text{m}$ , although they usually occur in colonies or attached to other particles. Most **bacteria** range between 0.4 and 5  $\mu\text{m}$  and are usually associated with large particles. **Fungus** spores are usually 2 to 10  $\mu\text{m}$ , while **pollen** grains are 10 to 100  $\mu\text{m}$ , with many common varieties in the 20 to 40  $\mu\text{m}$  range.

#### Types of Liquid Particles

**Mists** are small airborne droplets of materials that are ordinarily liquid at normal temperatures and pressure. They can be formed by atomizing, spraying, mixing, violent chemical reactions, evolution of gas from liquid, or escape as a dissolved gas when pressure is released. Small droplets expelled or atomized by sneezing constitute mists.

**Fogs** are fine airborne droplets, usually formed by condensation of vapor, which remain airborne longer than mists. Fog nozzles are named for their ability to produce extra fine droplets, as compared with mists from ordinary spray devices. Many droplets in fogs or clouds are microscopic and submicroscopic and serve as a transition stage between larger mists and vapors.

The volatile nature of most liquids reduces the size of their airborne droplets from the mist to the fog range and eventually to the vapor phase, until the air becomes saturated with that liquid. If solid material is suspended or dissolved in the liquid droplet, it remains in the air as particulate contamination. For example, sea spray evaporates fairly rapidly, generating a large number of fine salt particles that remain suspended in the atmosphere.

### Complex Particles

**Smokes** are small solid and/or liquid particles produced by incomplete combustion of organic substances such as tobacco, wood, coal, oil, and other carbonaceous materials. The term smoke is applied to a mixture of solid, liquid, and gaseous products, although technical literature distinguishes between such components as soot or carbon particles, fly ash, cinders, tarry matter, unburned gases, and gaseous combustion products. Smoke particles vary in size, the smallest being much less than 1  $\mu\text{m}$  in diameter. The average is often in the range of 0.1 to 0.3  $\mu\text{m}$ .

**Environmental tobacco smoke** consists of a suspension of 0.01 to 1.0  $\mu\text{m}$  (mass median diameter of 0.3  $\mu\text{m}$ ) liquid particles that form as the superheated vapors leaving the burning tobacco condense. Also produced are numerous gaseous contaminants including carbon monoxide.

**Smog** commonly refers to air pollution; it implies an air mixture of smoke particles, mists, and fog droplets of such concentration and composition as to impair visibility, in addition to being irritating or harmful. The composition varies among different locations and at different times. The term is often applied to haze caused by a sunlight-induced photochemical reaction involving the materials in automobile exhausts. Smog is often associated with temperature inversions in the atmosphere that prevent normal dispersion of contaminants.

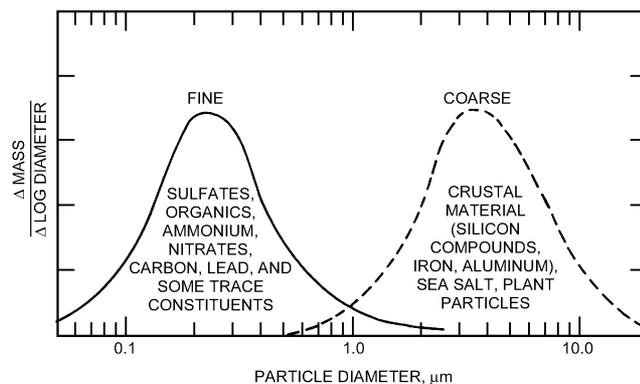

### Sizes of Airborne Particles

Particle size can be defined in several different ways. These depend, for example, on the source or method of generation, the visibility, or the effects.

Particles can be classified as coarse or fine. Coarse particles are larger, and are generally formed by mechanical breaking up of solids. They generally have a minimum size of 1 to 3  $\mu\text{m}$  (EPA 1996). Fine particles are generally formed from chemical reactions or condensing gases. These particles have a maximum size of about 1 to 3  $\mu\text{m}$ . Fine particles are usually more chemically complex, anthropogenic, and secondary in origin, while the coarse particles are predominantly primary, natural, and chemically inert. Coarse particles also include bioaerosols such as mold spores, pollen, animal dander, and dust mite particles that can affect the immune system.

The differences between fine and coarse particles lead to a bimodal distribution of particles in most environments with concentration peaks at about 0.25  $\mu\text{m}$  and 5  $\mu\text{m}$ . Figure 1 shows a typical urban distribution including the chemical species present in each mode.

The size of a particle determines where in the human respiratory system the particle is deposited. The **inhalable mass** is made up of

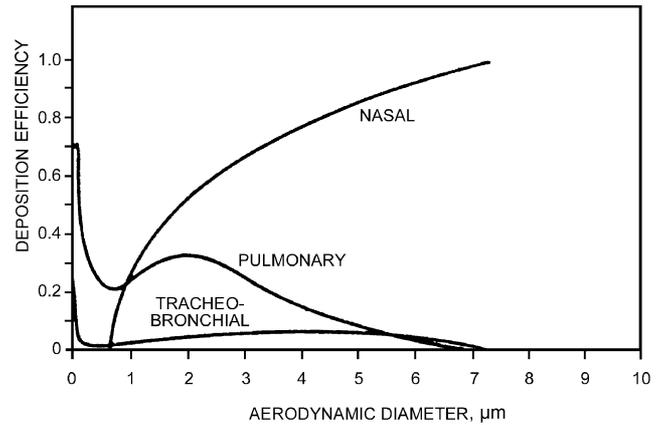

**Fig. 1 Typical Urban Aerosol Composition by Particle Size Fraction**  
(EPA 1982, Willeke and Baron 1993)

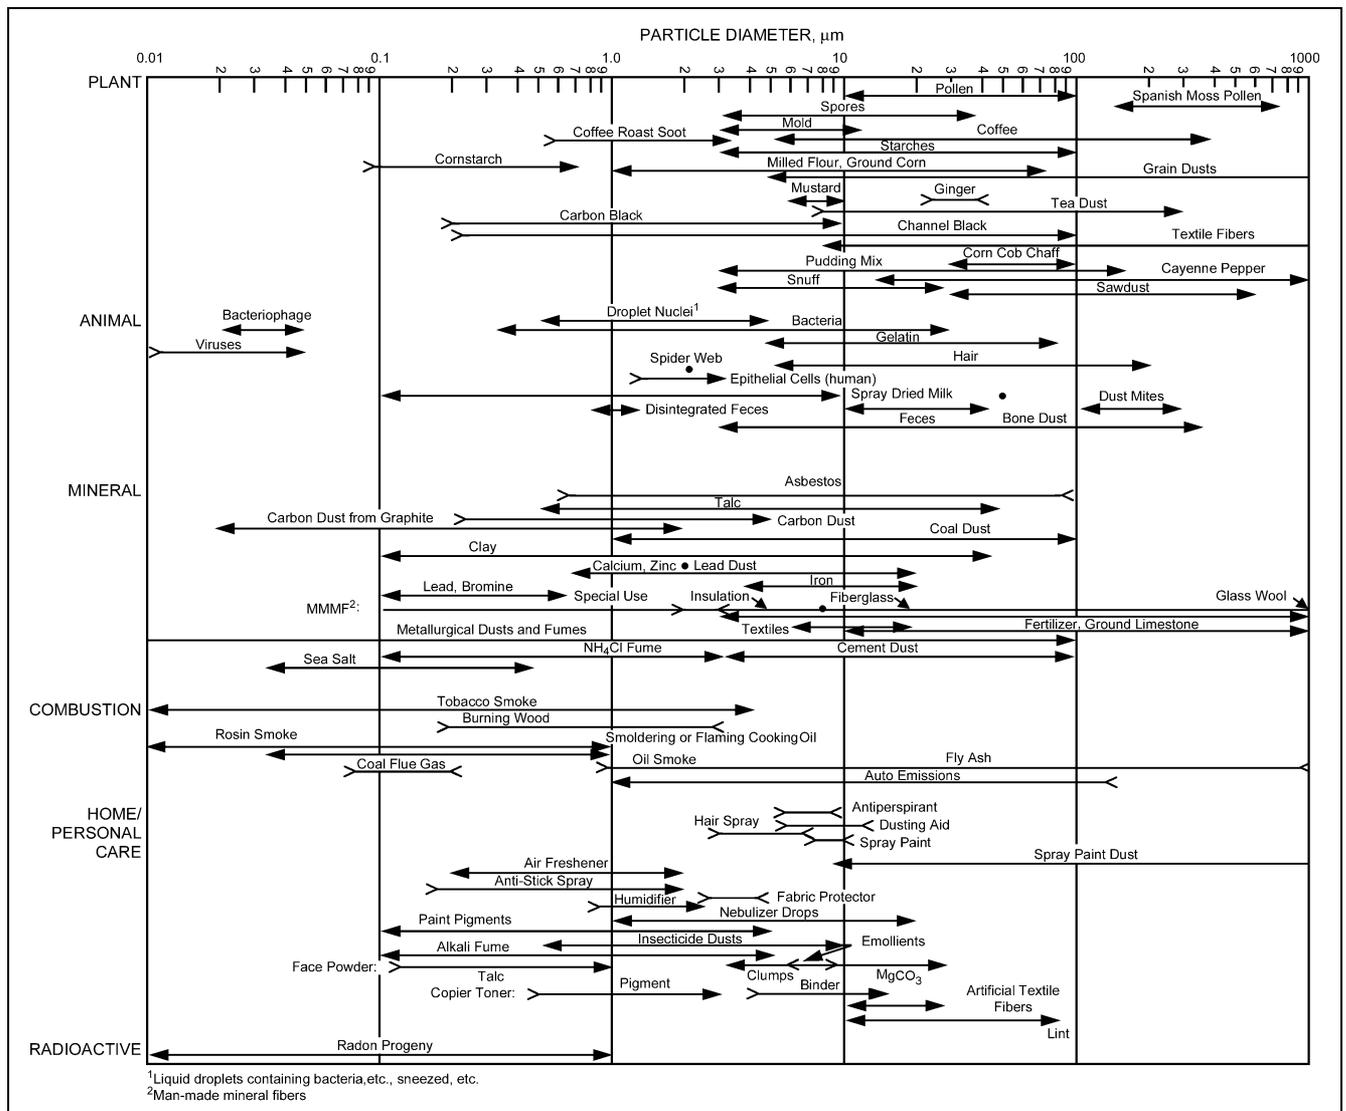

particles that may deposit anywhere in the respiratory system and is represented by a sample with a median cut point of 100  $\mu\text{m}$ . The **thoracic particle mass** is that fraction which can penetrate to the lung airways and is represented by a sample with a median cut point of 10  $\mu\text{m}$ . The **respirable particulate mass** is that fraction that can penetrate to the gas-exchange region of the lungs and is represented by a sample with a median cut point of 4  $\mu\text{m}$  (ACGIH 1998). Figure 2 illustrates the relative deposition efficiencies of various sizes of particles. The characteristics described above were used by the EPA in development of their outdoor  $\text{PM}_{10}$  and  $\text{PM}_{2.5}$  standards.

Most particles are irregular in shape, and it is useful to characterize their size in terms of some standard particle. For example, the **aerodynamic (equivalent) diameter** of a particle is defined as the diameter of a unit-density sphere having the same gravitational settling velocity as the particle in question (Willeke and Baron 1993).

The tendency of particles to settle on surfaces is a property of interest. Figure 3 shows the sizes of typical indoor airborne solid and liquid particles. Particles smaller than 0.1  $\mu\text{m}$  behave like gas molecules exhibiting Brownian motion due to collisions with air

**Fig. 2 Relative Deposition Efficiencies of Different Sized Particles in the Three Main Regions of the Human Respiratory System, Calculated for Moderate Activity Level (Task Group on Lung Dynamics 1966)**

**Fig. 3 Sizes of Indoor Particles (Owen et al. 1992)**

**Table 1 Approximate Particle Sizes and Their Times to Settle One Metre**

Type of Particle	Diameter, $\mu\text{m}$	Settling Time
Human hair	100 to 150	5 s
Skin flakes	20 to 40	
Observable dust in air	>10	
Common pollens	15 to 25	
Mite allergens	10 to 20	5 min
Common spores	2 to 10	
Bacteria	1 to 5	
Cat dander	1±0.5	10 h
Tobacco smoke	0.1 to 1	
Metal and organic fumes	<0.1 to 1	
Cell debris	0.01 to 1	
Viruses	<0.1	10 days

Source: J.D. Spengler, Harvard School of Public Health.

**Table 2 Relation of Screen Mesh to Particle Size**

U.S. Standard sieve mesh	400	325	200	140	100	60	35	18
Nominal sieve opening, $\mu\text{m}$	37	44	74	105	149	250	500	1000

molecules and having no measurable settling velocity. Particles in the range from 0.1 to 1  $\mu\text{m}$  have settling velocities that can be calculated but are so low that settling is usually negligible, since normal air currents counteract any settling. By number, over 99.9% of the particles in a typical atmosphere are below 1  $\mu\text{m}$  (this means fewer than 1 particle in every 1000 is larger than 1  $\mu\text{m}$ ).

Particles in the 1 to 10  $\mu\text{m}$  range settle in still air at constant and appreciable velocity. However, normal air currents keep them in suspension for appreciable periods.

Particles larger than 10  $\mu\text{m}$  settle fairly rapidly and can be found suspended in air only near their source or under strong wind conditions. Exceptions are lint and other light fibrous materials, such as portions of certain weed seeds, which remain suspended longer. Table 1 shows settling times for various types of particles.

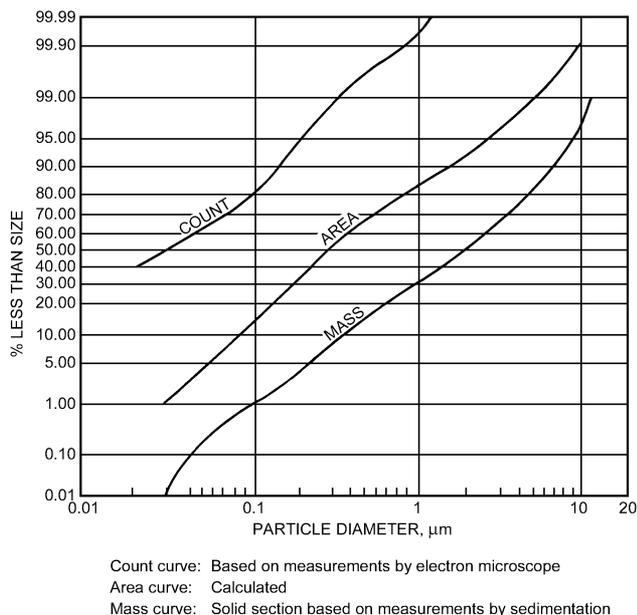

Most individual particles 10  $\mu\text{m}$  or larger are visible to the naked eye under favorable conditions of lighting and contrast. Smaller particles are visible only in high concentrations. Cigarette smoke (with an average particle size less than 0.5  $\mu\text{m}$ ) and clouds are common examples.

Direct fallout in the vicinity of the dispersing stack or flue and other nuisance problems of air pollution involve larger particles. Smaller particles, as well as mists, fogs, and fumes, remain in suspension longer. In this size range, meteorology and topography are more important than physical characteristics of the particles. Since settling velocities are small, the ability of the atmosphere to disperse these small particles depends largely on local weather conditions.

Comparison is often made to screen sizes used for grading useful industrial dusts and granular materials. Table 2 illustrates the relationship of U.S. standard sieve mesh to particle size in micrometres. Particles above 40  $\mu\text{m}$  are the screen sizes, and those below are the subscreen or microscopic sizes.

### Particle Size Distribution

The particle size distribution in any sample can be expressed as the percentage of the number of particles smaller than a specified size, area, or mass. The upper curve of Figure 4 shows these data plotted for typical atmospheric contamination. The middle curve shows the percentage of the total projected area of the particles contributed by particles less than a specified size. The lower curve shows the percentage of the total particle mass contributed by those particles less than a given size. Thus, for particles 10  $\mu\text{m}$  and larger, 4% by mass, a 90% arrestance filter essentially removes 90% of 4% for an efficiency by mass of 3.6%.

**Fig. 4 Particle Size Distribution of Atmospheric Dust**  
(Whitby et al. 1955, 1957)

The differences among values presented by the three curves should be noted. For example, particles 0.1  $\mu\text{m}$  or less in diameter (but still above electron microscope minimum detection size of about 0.005  $\mu\text{m}$ ) make up 80% of the number of particles in the atmosphere but contribute only 1% of the mass. Also, the 0.1% of particles by number larger than 1  $\mu\text{m}$  carry 70% of the total mass, which is the direct result of the mass of a spherical particle increasing as the cube of its diameter. Although most of the mass is contributed by intermediate and larger particles, over 80% of the area (staining) contamination is supplied by particles less than 1  $\mu\text{m}$  in diameter, which is in the center of the respirable particle size range and is the size most likely to remain in the lungs. (See Chapter 9.) Of possible concern to the HVAC industry is the fact that most of the staining effect on ceilings, walls, windows, and light fixtures, as well as fouling of heat transfer devices and rotating equipment, results from particles less than 1  $\mu\text{m}$  in diameter. Suspended particles in urban air are predominantly smaller than 1  $\mu\text{m}$  (aerodynamic diameter) and have a distribution that is approximately log-normal.

### Units of Measurement

The quantity of particulate matter in the air can be determined as mass or particle count in a given volume of air. Mass units are milligrams per cubic metre of air sampled ( $\text{mg}/\text{m}^3$ ) or micrograms per cubic metre of air sampled ( $\mu\text{g}/\text{m}^3$ ).  $1 \text{ mg}/\text{m}^3 = 1000 \mu\text{g}/\text{m}^3$ . Particle counts are usually quoted for volumes of 0.1  $\text{ft}^3$ , 1  $\text{ft}^3$ , or 1 litre and are specified for a given range of particle diameter.

### Measurement of Airborne Particles

Suitable methods for determining the quantity of particulate matter in the air vary depending on the amount present and on the size of particles involved.

The particle mass (total or respirable) is easily determined by measuring the mass of a filter before and after drawing a known volume of dusty air through it. This method is widely used in industrial workplaces, where there may be significant numbers of large particles, but is not sensitive enough for evaluating office environments.

**Optical particle counters** are widely used and likely to become more so since ASHRAE adopted *Standard 52.2*. This standard defines a laboratory method for assessing the performance of media

filters using an optical particle counter to measure particle counts upstream and downstream of the filter in 12 size ranges between 0.3 and 10  $\mu\text{m}$ . Filters are then given a **minimum efficiency reporting value** (MERV) rating based on the count data.

Counters are also used to test cleanrooms for compliance with Federal *Standard 209E* and ISO *Standard 14644-1*. Cleanrooms are defined in terms of the number of particles in certain size ranges that they contain. Chapter 15 of the 1999 *ASHRAE Handbook—Applications* has further information on cleanrooms.

Optical particle counters use laser light-scattering to continuously count and size airborne particles and can detect particles down to 0.1  $\mu\text{m}$  (ASTM *Standard F 50*). A **condensation nucleus counter** can count particles to below 0.01  $\mu\text{m}$ . These particles, present in great numbers in the atmosphere, serve as nuclei for condensation of water vapor (Scala 1963).

Another indirect method measures the **optical density** of the collected dust based on the projected area of the particles. Dust particles can be sized with graduated scales or optical comparisons using a standard **microscope**. The lower limit for sizing with the light field microscope is approximately 0.9  $\mu\text{m}$ , depending on the vision of the observer, the dust color, and the contrast available. This size can be reduced to about 0.4  $\mu\text{m}$  by using oil immersion objective techniques. Dark field microscopic techniques reveal particles smaller than these, to a limit of approximately 0.1  $\mu\text{m}$ . Smaller submicroscopic dusts can be sized and compared with the aid of an electron microscope. Other sizing techniques may take into account velocity of samplings in calibrated devices and actual settlement measurements in laboratory equipment. The electron microscope and various sampling instruments such as the **cascade impactor** have been successful in sizing particulates, including fogs and mists.

Each of the various methods of measuring particle size distribution gives a different value for the same size particle, since different properties are actually measured. For example, a microscopic technique may measure longest dimension, while impactor results are based on aerodynamic behavior (ACGIH 2001).

### Typical Particle Levels

Particle counters, which detect particles larger than about 0.1  $\mu\text{m}$ , have indicated that the number of suspended particles is enormous. A room with heavy cigarette smoke has a particle concentration of  $10^9$  particles per cubic metre. Even clean air typically contains over  $35 \times 10^6$  particles/ $\text{m}^3$ . If smaller particles detectable by other means, such as an electron microscope or condensation nucleus counter, are also included, the total particle concentration would be greater than the above concentrations by a factor of 10 to 100.

Extensive measurements have been made of outdoor pollution, but limited data have been gathered on indoor pollution not associated with specific industrial processes. Indoor levels are influenced by the number of people and their activities, building materials and construction, outside conditions, ventilation rate, and the air-conditioning and filtration system. For further information, see the section on Nonindustrial Indoor Air Contaminants, Spengler et al. (1982), and NRC (1981).

## BIOAEROSOLS

Bioaerosols are airborne microbiological particulate matter derived from fungi, bacteria, viruses, protozoa, algae, pollen, mites, and their cellular or cell mass components. Bioaerosols are universally present in both indoor and outdoor environments. Problems of concern to engineers occur when microorganisms grow and reproduce indoors.

Microorganisms break down complex molecules found in dead organic materials to simple substances such as carbon dioxide, water, and nitrates. These components are then used by photosyn-

thetic organisms such as plants and algae. Thus, the presence of bacteria and fungi in soil, water, and atmospheric habitats is normal. Spores of *Cladosporium*, a fungus commonly found on leaves and dead vegetation, are almost always found in outdoor air samples. They are found in variable numbers in indoor air, depending on the amount of outdoor air that infiltrates into interior spaces or is brought in by the HVAC system. Outdoor microorganisms can also enter on shoes and clothing and be transferred to other surfaces in buildings.

Public interest has focused on airborne microorganisms responsible for diseases and infections, primarily bacteria and viruses. This is discussed in more detail in Chapter 9. A variety of airborne microorganisms are of economic significance and can cause product contamination or loss. In the food processing industry, yeast and mold can reduce the shelf life of some products. Refined syrups can be damaged by mold scums. Wild yeast can destroy a batch of beer. Antibiotic yields can be reduced by foreign organisms in the culture mix.

### Fungi

Much attention has been given to fungi, which include yeasts, molds, and mildews, as well as large mushrooms, puffballs, and bracket fungi. All fungi depend on external sources of organic material for both energy requirements and carbon skeletons. Thus, they cannot increase in number unless supplied with a suitable food source such as small quantities of dust, paper, or wood. Reproduction also requires appropriate temperatures (20 to 40°C) and the presence of water, high air humidity (typically greater than 60%), and/or high moisture content in the food source.

### Bacteria

Cooling towers, evaporative condensers, and domestic water service systems all provide water and nutrients for amplification of microorganisms such as *Legionella pneumophila*. Growth of microbial populations to excessive concentrations is generally associated with inadequate preventive maintenance of these systems, at least in cooling towers. A body of literature has identified characteristics of indoor plumbing and heating systems associated with frequent isolation of *Legionella* species, including blind ends, scale, upright electric water heaters, and lower water temperatures. The survival of *Legionella* is enhanced by a variety of parameters including but not limited to warm temperatures, particular algal and protozoan associations, and symbiotic relationships with certain aquatic plants (Fliermans 1985). Evidence has indicated that amoebae and other protozoa act as natural hosts and amplifiers for *Legionella* in the environment (Barbaree et al. 1986). ASHRAE (1989) has further information on the topic.

Bacteria from the soil are likely to be spore-formers and are capable of surviving in hostile environments. Other airborne bacteria, especially within closed occupied spaces, may originate from droplet nuclei caused by actions such as sneezing or be carried on human or animal skin scales.

### Pollen

Pollen grains discharged by weeds, grasses, and trees (Hewson et al. 1967, Jacobson and Morris 1977, Solomon and Mathews 1978) and capable of causing hay fever have properties of special interest to air-cleaning equipment designers (see Chapter 24 of the 2000 *ASHRAE Handbook—Systems and Equipment*). Whole grains and fragments transported by air range between 10 and 50  $\mu\text{m}$ ; however, some measure as small as 5  $\mu\text{m}$ , and others measure over 100  $\mu\text{m}$  in diameter. Ragweed pollen grains are fairly uniform in size, ranging from 15 to 25  $\mu\text{m}$ .

Most pollen grains are hygroscopic and, therefore, vary in mass with the humidity. Illustrations and data on pollen grains are avail-

able in botanical literature. Geographical distribution of plants that produce hay fever is also recorded.

The quantity of pollen in the air is generally estimated by exposing an adhesive-coated glass plate outdoors for 24 h, then counting calibrated areas under the microscope. Methods are available for determining the number of pollen grains in a measured volume of air. However, despite their greater accuracy, these methods have not replaced the simpler gravity slide method used for most pollen counts. Counting techniques vary, but daily pollen counts reported in local newspapers during hay fever season usually represent the number of grains found on 180 mm<sup>2</sup> of a 24 h gravity slide.

Hay fever sufferers may experience the first symptoms when the pollen count is 10 to 25; in some localities, maximum figures for the seasonal peak may approach 1000 or more for a 24 h period, depending on the sampling and reporting methods used by the laboratory. Translation of gravity counts by special formulas to a volumetric basis (i.e., number of grains per unit volume of air) is unreliable, due to the complexity of the modifying factors. When such information is important, it should be obtained directly by a volumetric instrument. The number of pollen grains per cubic yard of air varies from 2 to 20 times the number found on 1 cm<sup>2</sup> of a 24 h gravity slide, depending on grain diameter, shape, specific gravity, wind velocity, humidity, and physical placement of the collecting plate.

Pollen grains can be removed from the air more readily than the dust particles prevalent in outdoor air or those produced by dusty processes, since a larger fraction of them are in the size range easily removed by building HVAC filters.

Whole-grain pollens are easily removed from the outside air entering a ventilation system with medium-efficiency [35 to 45% (MERV 9 to 11)] filters selected to remove 99% of particles 10 µm and greater. Once they have entered a building, whole-grain pollens settle rapidly, reducing concentrations without the need for air cleaning. On resuspension from occupant activities, the whole-grain pollens may disintegrate into fragments, which may possibly be controlled effectively with a high-efficiency [70 to 95% (MERV 12 to 14)] filter capable of removing a high percentage of particles in the 0.3 to 3.0 µm range.

### Sampling for Bioaerosols

Sampling for biological agents such as fungi and bacteria can include visual observation of colonies, collection of bulk or surface samples, or air sampling. The principles of sampling and analysis for microorganisms are reviewed by Chatigny (1983). ACGIH (1989) and AIHA (1996) have developed assessment guidelines for the collection of microbiological particulates. An introduction is given below.

**Preassessment.** Sampling for microorganisms should be undertaken when medical evidence indicates the occurrence of diseases such as humidifier fever, hypersensitivity pneumonitis, allergic asthma, and allergic rhinitis. A walk-through examination of the indoor environment for visual detection of possible microbial reservoirs and amplification sites should be performed before sampling. Note that a visual examination will miss reservoirs that are behind walls. If a reservoir or amplifier is visually identified, it is useful to obtain bulk or source samples from it. Also, removal of clearly identified reservoirs and amplifiers is preferable to complicated and costly air-sampling procedures.

**Air Sampling.** The same principles that affect the collection of an inert particulate aerosol also govern air sampling for microorganisms. Air sampling is not likely to yield useful data and information unless the sample collected is representative of exposure. The most representative samples are those that are collected in breathing zones over the range of aerosol concentrations. Presently, no personal sampling method has been proposed that is sensitive enough for any bioaerosol (Burge 1995). Thus, ambient sampling designs that obtain reasonable estimates of exposures of

given populations over representative periods are necessary. Because *Legionella* requires special nutrients for growth and does not produce resistant spores, this bacterium is difficult to recover from air.

Concentrations of microorganisms in the atmosphere vary from a few to several hundred per cubic metre, depending on many factors. The sampling method for microorganisms has an effect on the measured count. Collection on **dry filter paper** can cause count degradation because of the dehydration loss of some organisms. **Glass impingers** may give high counts because agitation can cause clusters to break up into smaller individual organisms. **Slit samples** may give a more accurate colony count.

The viability and/or antigenicity of the microbial particulates must be protected during sampling. In general, **culture plate impactors**, including multiple- and single-stage devices as well as **slit-to-agar samplers**, are most useful in office environments where low concentrations of bacteria and fungi are expected. Because not all microorganisms will grow on the same media, liquid impingement subculturing may be more suitable. **Filter cassette samplers** are useful for microorganisms or components of microorganisms (i.e., endotoxins), although binding to glass and plastic has been reported (Milton et al. 1990). Filter cassettes can also be used for spore counts. Area sampling is often used. Some investigators attempt to replicate exposure conditions through disturbance of the environment (semiaggressive sampling) such as occurs through walking on carpets, slamming doors, and opening books or file cabinets.

Viruses, many bacteria, algae, and protozoa are more difficult to culture than fungi, and air-sampling methodology for these agents is less well known and defined (ASTM 1990).

**Data Interpretation.** Rank order assessment is a method used to interpret air-sampling data for microorganisms (ACGIH 1989). Individual organisms are listed in descending order of abundance for a complainant indoor site and for one or more control locations. The predominance of one or more microbes in the complainant site, but not in the control sites or outdoors, suggests the presence of an amplifier for that organism. In the example in Table 3, *Tritirachium* and *Aspergillus* were the predominant fungi represented in complainant locations in an office building, where *Cladosporium* and *Fusarium* dominated outdoor collections. In this case, *Tritirachium* and *Aspergillus* were being amplified in the building. In addition to comparing individual organisms, indoor-outdoor ratios of overall quantities of culturable microorganisms are useful.

### Control of Bioaerosols

When maximum removal of airborne microorganisms is either necessary or desirable, high-efficiency particulate air (HEPA) or ultralow penetration air (ULPA) filters are used. These filters create essentially sterile atmospheres and are more frequently employed than chemical scrubbers and ultraviolet radiation for control of airborne microorganisms. They have been used to prevent cross-infection in hospitals, to protect clean rooms from contamination, and to assemble and launch space probes under sterile conditions.

**Table 3 Example Case of Airborne Fungi in Building and in Outdoor Air**

Location	cfu/m <sup>3</sup>	Rank Order Taxa
Outdoors	210	<i>Cladosporium</i> > <i>Fusarium</i> > <i>Epicoccum</i> > <i>Aspergillus</i>
Complainant Office #1	2500	<i>Tritirachium</i> > <i>Aspergillus</i> > <i>Cladosporium</i>
Complainant Office #2	3000	<i>Tritirachium</i> > <i>Aspergillus</i> > <i>Cladosporium</i>

Notes:

cfu/m<sup>3</sup> = Colony-forming units per cubic metre of air.

Culture media was malt extract agar (ACGIH 1989).

In many situations, total control of airborne microorganisms is not required. For these applications, there are various other types of high-efficiency dry media extended-surface filters that will provide the necessary efficiency. These filters have lower pressure differentials than HEPA filters operating at the same face velocity and, when properly selected, will remove the contaminants of concern.

## GASEOUS CONTAMINANTS

The terms gas and vapor are both used to describe the gaseous state of a substance. **Gas** is the correct term for describing any pure substance or mixture that naturally exists in the gaseous state at normal atmospheric conditions. Examples are oxygen, helium, ammonia, and nitrogen. **Vapor** is used to describe a substance in the gaseous state whose natural state is a liquid or solid at normal atmospheric conditions. Examples include benzene, carbon tetrachloride, and water. There are differences between the two classes that reflect their preferred states:

- The concentration of gases in air is limited only by the strength of the source, so that gases can completely fill a space, driving out the oxygen necessary for survival.

- Vapors can never exceed their saturated vapor pressure in air. The most familiar example of a vapor is water, with relative humidity expressing the air concentration as a percentage of the saturated vapor pressure.
- Vapors, because their natural state is liquid or solid, have a tendency to condense on surfaces and be adsorbed.

Gaseous contaminants can also be divided into organic and inorganic types. **Organic** compounds include all chemicals based on a skeleton of carbon atoms. Since carbon atoms easily combine to form chain, branched, and ring structures, there is a bewildering variety of organic compounds. They include gases such as methane, but the majority are vapors. All other gaseous contaminants are classified as **inorganic**. Most of the inorganic air contaminants of interest to engineers are gases.

Major chemical families of gaseous pollutants and examples of specific compounds are shown in Table 4. The *Merck Index* (Budavi 1996), the *Toxic Substances Control Act Chemical Substance Inventory* (EPA 1979), and *Dangerous Properties of Industrial Materials* (Sax and Lewis 1988) are all useful in identifying contaminants,

**Table 4 Major Chemical Families of Gaseous Air Pollutants (with Examples)**

Inorganic Pollutants		
1. Single-element atoms and molecules	11. Chlorinated hydrocarbons	19. Aromatic hydrocarbons
chlorine	carbon tetrachloride	benzene
radon	chloroform	toluene
mercury	1,1,1-trichloroethane	<i>p</i> -xylene
2. Oxidants	tetrachloroethylene	naphthalene
ozone	dichlorobenzene	benz- $\alpha$ -pyrene
nitrogen dioxide	12. Halide compounds	20. Terpenes
3. Reducing agents	methyl bromide	2-pinene
carbon monoxide	methyl iodide	limonene
4. Acid gases	13. Alcohols	21. Heterocyclics
carbon dioxide	methanol	ethylene oxide
sulfur dioxide	ethanol	tetrahydrofuran
sulfuric acid	2-propanol (isopropanol)	1, 4-dioxane
hydrochloric acid	phenol	pyrrole
hydrogen sulfide	ethylene glycol	pyridine
nitric acid	14. Ethers	nicotine
5. Nitrogen compounds	ethyl ether	caffeine
ammonia	methoxyvinyl ether	22. Organophosphates
hydrazine	<i>n</i> -butoxyethanol	malathion
nitrous oxide	15. Aldehydes	tabun
6. Miscellaneous	formaldehyde	sarin
arsine	acetaldehyde	soman
	acrolein	23. Amines
	benzaldehyde	trimethylamine
	16. Ketones	ethanolamine
	2-propanone (acetone)	cyclohexylamine
	2-butanone (MEK)	morpholine
	methyl isobutyl ketone (MIBK)	24. Monomers
	chloroacetophenone	vinyl chloride
	17. Esters	methyl formate
	ethyl acetate	ethylene
	vinyl acetate	methyl methacrylate
	methyl formate	25. Mercaptans and other sulfur compounds
	dioctyl phthalate (DOP)	bis-2-chloroethyl sulfide (mustard gas)
	18. Nitrogen compounds other than amines	ethyl mercaptan
	nitromethane	carbon disulfide
	acetonitrile	carbonyl sulfide
	acrylonitrile	26. Organic acids
	urea	formic acid
	uric acid	acetic acid
	skatole	butyric acid
	putrescine	27. Miscellaneous
	hydrogen cyanide	phosgene
	peroxyacetal nitrite (PAN)	
<b>Organic Pollutants</b>		
7. <i>n</i> -Alkanes		
methane		
<i>n</i> -butane		
<i>n</i> -hexane		
<i>n</i> -octane		
<i>n</i> -hexadecane		
8. Branched alkanes		
2-methyl pentane		
2-methyl hexane		
9. Alkenes and cyclic hydrocarbons		
butadiene		
1-octene		
cyclohexane		
4-phenyl cyclohexene (4-PC)		
10. Chlorofluorocarbons		
R-11 (trichlorofluoromethane)		
R-114 (dichlorotetrafluoroethane)		

including some known by trade names only. Chemical and physical properties can be found in reference books such as the *Handbook of Chemistry and Physics* (Lide 1996). Note that a single chemical compound, especially if it is an organic compound, may have several scientific names. To reduce confusion, the Chemical Abstracts Service (CAS) has assigned each chemical a unique identifier number containing five to nine digits.

### Harmful Effects of Gaseous Contaminants

Harmful effects may be divided into four categories: toxicity, odor, irritation, and material damage.

**Toxicity.** The harmful effects of gaseous pollutants on a person depend on both short-term peak concentrations and the time-integrated exposure received by the person. Toxic effects are generally considered to be proportional to the exposure dose, although individual response variation can obscure the relationship. The allowable concentration for short exposures is higher than that for long exposures. Safe exposure limits have been set for a number of common gaseous contaminants in industrial settings. This topic is covered in more detail in the section on Industrial Air Contaminants and in Chapter 9.

**Irritation.** Although gaseous pollutants may have no discernible continuing health effects, exposure may cause physical irritation to building occupants. This phenomenon has been studied principally in laboratories and nonindustrial work environments and is discussed in more detail in the section on Nonindustrial Indoor Air Contaminants and in Chapter 9.

**Odors.** Gaseous contaminant problems often appear as complaints about odors, and these usually are the result of concentrations considerably below industrial exposure limits. Odors are discussed in more detail in Chapter 13.

**Damage to Materials.** Material damage from gaseous pollutants may take such forms as corrosion, embrittlement, or discoloration. Because such effects usually involve chemical reactions that need water, material damage from air pollutants is less severe in the relatively dry indoor environment than outdoors, even at similar gaseous contaminant concentrations. To maintain this advantage, indoor condensation should be avoided. However, some dry materials can be significantly damaged. These effects are most serious in museums, as any loss of color or texture changes the essence of the object. Libraries and archives are also vulnerable, as are pipe organs and textiles. Ventilation is often a poor method of protecting collections of rare objects because these facilities are usually located in the centers of cities that have relatively polluted ambient outdoor air. Gaseous compounds known to be harmful include ozone, nitrous oxides, sulfur dioxide, hydrochloric acid, many volatile organic compounds, and hydrogen sulfide. Various concerns about material damage by indoor air pollutants are discussed by Lull (1995), Walsh et al. (1977), Chiarenzelli and Joba (1966), NTIS (1982, 1984), Braun and Wilson (1970), Jaffe (1967), Grosjean et al. (1987), American Guild of Organists (1966), Mathey et al. (1983), Haynie (1978), Graminski et al. (1978), and Thomson (1986).

Unlike the human body, conservation items have no repair mechanism, yet they are expected to have a longer life than people. This is one reason the acceptable levels of contaminants in museums, archives, and other conservation applications are very low—1 to 2 orders of magnitude below U.S. EPA standards (Mathey et al. 1983, Thomson 1986). Achieving these levels and measuring performance is difficult. Lull (1995) discusses ventilation and air cleaning specifically for conservation environments.

### Units of Measurement

Concentrations of gaseous contaminants are usually expressed in the following units:

ppm = parts of contaminant by volume per million parts of air by volume

ppb = parts of contaminant by volume per billion parts of air by volume

1000 ppb = 1 ppm

mg/m<sup>3</sup> = milligrams of contaminant per cubic metre of air

µg/m<sup>3</sup> = micrograms of contaminant per cubic metre of air

The conversions between ppm and mg/m<sup>3</sup> are

$$\text{ppm} = [8.309(273.15 + t)/Mp] \text{ mg/m}^3 \quad (1)$$

$$\text{mg/m}^3 = [0.1204Mp/(273.15 + t)] (\text{ppm}) \quad (2)$$

where

$M$  = relative molecular mass of contaminant

$p$  = mixture pressure, kPa

$t$  = mixture temperature, °C

Concentration data is often reduced to standard temperature and pressure (i.e., 25°C and 101.325 kPa), in which case

$$\text{ppm} = (24.45/M)(\text{mg/m}^3) \quad (3)$$

### Measurement of Gaseous Contaminants

The concentration of contaminants in the air needs to be measured to determine whether the indoor air quality conforms to occupational health standards (in industrial environments) and is acceptable (in nonindustrial environments).

Measurement methods for airborne chemicals that are important industrially have been published by several organizations including OSHA (1995) and NIOSH (1994). Methods typically involve sampling air with pumps for several hours to capture the contaminant on a filter or in an adsorbent tube, followed by laboratory analysis for detection and determination of contaminant concentration. Concentrations measured in this way can usefully be compared to 8 h industrial exposure limits.

The measurement of gaseous contaminants at the lower levels acceptable for indoor air is not always as straightforward. Relatively costly analytical equipment may be needed, and it must be calibrated and operated by experienced personnel.

Currently available sampling techniques are listed in Table 5 with details of their advantages and disadvantages. Analytical techniques are shown in Table 6 with information on the types of contaminants to which they apply.

The first two techniques in Table 5 combine sampling and analysis in one piece of equipment and give immediate results on-site. The other sampling methods require laboratory analysis following the field work. Equipment employing the first technique in Table 5 can be coupled with a data logger to perform continuous monitoring and to obtain average concentrations over a time period. Most of the sampling techniques can capture several contaminants. Several allow pollutants to be accumulated or concentrated over time so that very low concentrations can be measured.

Some analytical techniques are specific for a single pollutant, while others are capable of providing concentrations for many contaminants simultaneously. Note that formaldehyde requires different measurement methods from other volatile organic compounds.

Measurement instruments used in industrial situations should be able to detect contaminants of interest at about one-tenth of threshold limit value (TLV) levels. If odors are of concern, detection sensitivity must be at odor threshold levels. Procedures for evaluating odor levels are given in Chapter 13.

When sampling and analytical procedures appropriate to the application have been selected, a pattern of sampling locations and times must be carefully planned. The building and air-handling system layout and the space occupancy and use patterns must be con-

Table 5 Gaseous Contaminant Sampling Techniques

Technique <sup>a</sup>	Advantages	Disadvantages
1. Direct flow to detectors	Real-time readout, continuous monitoring possible Several pollutants possible with one sample (when coupled with chromatograph, spectroscope, or multiple detectors)	Average concentration must be determined by integration No preconcentration possible before detector; sensitivity may be inadequate On-site equipment complicated, expensive, intrusive
2. Colorimetric detector tubes	Very simple, relatively inexpensive equipment and materials Immediate readout Integration over time	Rather long sampling period normally required One pollutant per sample Relatively high detection limit Poor precision
3. Capture by pumped flow through solid absorbent; subsequent desorption for concentration measurement	On-site sampling equipment relatively simple and inexpensive Preconcentration and integration over time inherent in method Several pollutants possible with one sample	Sampling media and desorption techniques are compound-specific Interaction between captured compounds and between compounds and sampling media; bias may result Gives only average over sampling period, no peaks
4. Collection in evacuated containers	Very simple on-site equipment No pump (silent) Several pollutants possible with one sample	Gives only average over sampling period, no peaks
5. Collection in nonrigid containers (plastic bags) held in an evacuated box	Simple, inexpensive on-site equipment (pumps required) Several pollutants possible with one sample	Cannot hold same pollutants
6. Cryogenic condensation	Wide variety of organic pollutants can be captured Minimal problems with interferences and media interaction Several pollutants possible with one sample	Water vapor interference
7. Passive diffusional samplers	Simple, unobtrusive, inexpensive No pumps; mobile; may be worn by occupants to determine average exposure	Gives only average over sampling period, no peaks
8. Liquid impingers (bubblers)	Integration over time Several pollutants possible with one sample	May be noisy

Sources: NIOSH (1977, 1994), Lodge (1988), Taylor et al. (1977), and ATC (1990).

<sup>a</sup>All techniques except 1 and 2 require laboratory work after completion of field sampling. Only technique 1 is adaptable to continuous monitoring and able to detect short-term excursions.

sidered so that representative concentrations will be measured. Traynor (1987) and Nagda and Rector (1983) offer guidance in planning such surveys.

### VOLATILE ORGANIC COMPOUNDS

The entire range of organic indoor pollutants has been categorized as indicated in Table 7 (WHO 1989). No sharp limits exist between the categories, which are defined by boiling-point ranges. **Volatil organic compounds** (VOCs) have attracted considerable attention in nonindustrial environments. They have boiling points in the range approximately 50 to 250°C, and vapor pressures greater than about 10<sup>-3</sup> to 10<sup>-4</sup> mm Hg.

Sources of VOCs include solvents, reagents, and degreasers in industrial environments; and furniture, furnishings, wall and floor finishes, cleaning and maintenance products, and office and hobby activities in nonindustrial environments.

Berglund et al. (1988) found that the sources of VOCs in nonindustrial indoor environments are confounded by the variable nature of emissions from potential sources. Emissions of VOCs from indoor sources can be classified by their presence and rate patterns. For example, emissions are continuous and regular from building materials and furnishings (e.g., carpet and composite-wood furniture); whereas emissions from other sources can be continuous but irregular (e.g., paints used in renovation work), intermittent and regular (e.g., VOCs in combustion products from gas stoves or cleaning products), or intermittent and irregular (e.g., VOCs from carpet shampoos) (Morey and Singh 1991).

Many "wet" emission sources (paints and adhesives) have very high emission rates immediately after application, and rates drop quite steeply with time until the product has cured or dried. New "dry" materials (carpets, wall coverings, and furnishings) also emit chemicals at higher rates until aged. Decay of these elevated VOC

concentrations to what can be considered normal constant-source levels can take weeks to months, depending on emission rates, surface areas of materials, and ventilation protocols. Renovation activities can cause similar increases of somewhat lower magnitude. The total VOC concentration in new office buildings at the time of initial occupancy can be 50 to 100 times that present in outdoor air (Sheldon et al. 1988a, 1988b). In new office buildings with adequate outdoor air ventilation, these ratios often fall to less than 5:1 after 4 or 5 months of aging. In older buildings with continuous, regular, and irregular emission sources, indoor/outdoor ratios of total VOCs may vary from nearly 1:1 when maximum amounts of outdoor air are being used in HVAC systems to greater than 10:1 during winter and summer months when minimum amounts of outdoor air are being used (Morey and Jenkins 1989, Morey and Singh 1991).

While direct VOC emissions are usually the primary source of VOCs in a space, some materials act as sinks for emissions and then become secondary sources as they reemit adsorbed chemicals (Berglund et al. 1988). Adsorption may lower the peak concentrations achieved, but the subsequent desorption prolongs the presence of indoor air pollutants. Sink materials include carpet, fabric partitions, and other fleecy materials, as well as ceiling tiles and wallboard. The type of material and compound affects the rate of adsorption and desorption (Colombo et al. 1991). Indoor air quality models using empirically derived adsorption and desorption rates have been developed to predict the behavior of sinks. Experiments conducted in an IAQ test house confirmed the importance of sinks when trying to control the level of indoor VOCs (Tichenor et al. 1991). Longer periods of increased ventilation lessen sink and reemission effects.

Because of the large number of VOCs usually found indoors and the impossibility of identifying all of them in samples, the concept of total VOC or TVOC was developed. Some researchers have used it to represent the sum of all detected VOCs. TVOC concentrations

Table 6 Gaseous Contaminant Concentration Measurement Methods

Method	Description	Typical Application
1. Gas chromatography (Using the following detectors)	Separation of gas mixtures by time of passage down an absorption column	
Flame ionization	Change in flame electrical resistance due to ions of pollutant	Volatile, nonpolar organics
Flame photometry	Measures light produced when pollutant is ionized by a flame	Sulfur, phosphorous compounds
Photoionization	Measures ion current for ions created by ultraviolet light	Most organics (except methane)
Electronic capture	Radioactively generated electrons attach to pollutant atoms; current measured	Halogenated organics Nitrogenated organics
Mass spectroscopy	Pollutant molecules are charged, passed through electrostatic magnetic fields in a vacuum; path curvature depends on mass of molecule, allowing separation and counting of each type	Volatile organics
2. Infrared spectroscopy and Fourier transform infrared (FTIR) spectroscopy	Absorption of infrared light by pollutant gas in a transmission cell; a range of wavelengths is used, allowing identification and measurement of individual pollutants	Acid gases Many organics
3. High-performance liquid chromatography (HPLC)	Pollutant is captured in a liquid, which is then passed through a liquid chromatograph (analogous to a gas chromatograph)	Aldehydes, ketones Phosgene Nitrosamines Cresol, phenol
4. Colorimetry	Chemical reaction with pollutant in solution yields a colored product whose light absorption is measured	Ozone Oxides of nitrogen Formaldehyde
5. Fluorescence and pulsed fluorescence	Pollutant atoms are stimulated by a monochromatic light beam, often ultraviolet; they emit light at characteristic fluorescent wavelengths, whose intensity is measured	Sulfur dioxide Carbon monoxide
6. Chemiluminescence	Reaction (usually with a specific injected gas) results in photon emission proportional to concentration	Ozone Nitrogen compounds Several organics
7. Electrochemical	Pollutant is bubbled through reagent/water solution, changing its conductivity or generating a voltage	Ozone Hydrogen sulfide Acid gases
8. Titration	Pollutant is absorbed into water	Acid gases
9. Ultraviolet absorption	Absorption of UV light by a cell through which the polluted air passes	Ozone Aromatics Sulfur dioxide Oxides of nitrogen Carbon monoxide
10. Atomic absorption	Contaminant is burned in a hydrogen flame; a light beam with a spectral line specific to the pollutant is passed through the flame; optical absorption of the beam is measured	Mercury vapor

Sources: NIOSH (1977,1994), Lodge (1988), Taylor et al (1977), and ATC (1990).

can also be determined by using methods such as photoionization and flame ionization that do not separate chemicals. All methods for TVOC determination are intrinsically of low to moderate accuracy due to variations in detector response to different classes of VOCs. Both theoretical and practical limitations of the TVOC approach have been discussed (Hodgson 1995, Otson and Fellin 1993).

Wallace et al. (1991) showed that individual VOC concentrations in homes and buildings are 2 to 5 times those of outdoors, and personal TVOC exposures were estimated to be 2 to 3 times greater than general indoor air concentrations. Normal daily activities carried out by individuals are the cause of these higher personal exposures. Personal activities frequently bring individuals close to air contaminant sources. The degree of exposure also depends on how air flows around the body due to convective forces, air turbulence, and obstructions nearby (Rodes et al. 1991).

Individual organic compounds seldom exceed  $0.05 \text{ mg/m}^3$  ( $50 \text{ }\mu\text{g/m}^3$ ) in air. An upper extreme average concentration of TVOCs in normally occupied houses is approximately  $20 \text{ mg/m}^3$ . The Large Buildings Study by the U.S. EPA (Brightman et al. 1996) developed the VOC sample target list shown in Table 8 to identify

common VOCs that should be measured. Lists of common indoor VOCs prepared by other organizations are similar.

A VOC enrichment factor (VEF) has been described to quantify VOC concentrations due to building sources beyond those expected as bioeffluents (Batterman and Peng 1995). A VEF > 1 describes the overabundance, while a VEF < 1 denotes the depletion of VOCs compared to VOCs expected as bioeffluents. Bioeffluents alone should produce a VEF of 1. The VEF ranged from 0.6 to 17.1 for the 20 office building studies reviewed.

Because chlorofluorocarbons (CFCs) are hydrocarbons with some hydrogen atoms replaced by chlorine, bromine, and fluorine atoms, they are classed as organic chemicals. They have been widely used as heat transfer gases in refrigeration applications, blowing agents, and propellants in aerosol products (including medications and consumer products) and as expanders in plastic foams. CFCs are discussed in Chapter 19 and in ASHRAE *Standards* 15 and 34. During the 1970s and 1980s, strong evidence was found linking use of CFCs to depletion of the earth's stratospheric ozone layer. CFCs add chlorine and bromine atoms to the atmosphere, which accelerate the natural ozone destruction rate. Ozone deple-

Table 7 Classification of Indoor Organic Pollutants

Description	Abbreviation	Boiling Point Range, °C
Very volatile (gaseous) organic compounds	VVOC	<0 to 50–100
Volatile organic compounds	VOC	50–100 to 240–260
Semivolatile organics (pesticides, polynuclear aromatic compounds, plasticizers)	SVOC	240–260 to 380–400

Source: WHO (1989).

Note: Polar compounds and VOCs with higher relative molecular masses appear at the higher end of each boiling-point range.

tion is linked to increases in the amount of ultraviolet radiation (UV-B) reaching the earth's surface. Increasing UV-B can adversely affect human health, most notably by causing malignant melanoma and cataracts, harm the environment, and decrease crop production. As a result, CFCs are now being phased out. New refrigerants with lower ozone reduction potential are being used, including hydrochlorofluorocarbons (HCFCs). In addition, there has been a return to refrigerants such as ammonia and propellants such as butane and hexane.

Exposure to CFCs and HCFCs occurs mainly through inhalation and can occur from leaks in refrigeration equipment or during servicing of HVAC systems.

### Controlling Exposures to Volatile Organic Compounds

Much can be done to reduce building occupants' exposures to emissions of VOCs from building materials and products and to prevent outdoor VOCs from being brought into buildings. The control principles of substitution, isolation, and ventilation apply. Control measures include careful planning; specifications; and selection, modification, and treatment of products, as well as special installation procedures and proper ventilation system operation. Chapter 44 of the 1999 *ASHRAE Handbook—Applications* provides full details.

Levin (1989, 1991) has written extensively about designing new buildings for good indoor air quality. Reducing VOC emissions by careful selection and installation of building materials and furnishings is a most effective strategy for controlling IAQ. Advances in product formulation and emission testing are leading to products claimed to be low-polluting, nontoxic, and environmentally safe. Requiring the submission of emission testing data by manufacturers for building products, whether for a new building, for a building renovation or remodeling, or for substitution of a consumable product (housekeeping supplies), is becoming accepted practice. Eliminating the sources of VOCs prevents them from becoming a problem in the first place.

Gas-phase air filtration has been applied to control industrial gaseous contaminants for many years. The application of this technology to nonindustrial building HVAC is of interest for improving IAQ, whether it is to provide ventilation without the need to use more outdoor air or to help clean poor-quality outdoor air. Activated carbon and potassium permanganate-impregnated alumina are effective adsorbents that can be used, based on the contaminant mixture present (Liu and Huza 1995, Muller and England 1995, VanOsdell and Sparks 1995). Portable air cleaners with sorbent sections are only marginally effective (Shaughnessy et al. 1994). Photocatalytic reactors capable of destroying VOCs are being studied (Peral et al. 1997). These reactors use ultraviolet light and a catalytic surface, such as titanium dioxide, to convert organic pollutants to CO<sub>2</sub> and water.

Ventilation has traditionally been considered the primary means for controlling indoor VOC contaminants. Dilution ventilation is an effective way to control normal constant-emission sources present in buildings, assuming no unusually strong sources. Compliance

Table 8 Example Sample Contaminant Target List

benzene	styrene
<i>m</i> -, <i>p</i> -xylene	<i>p</i> -dichlorobenzene
1,2,4-trimethylbenzene	<i>n</i> -undecane
<i>n</i> -octane	<i>n</i> -nonane
<i>n</i> -decane	ethylacetate
<i>n</i> -dodecane	dichloromethane
butylacetate	1,1,1-trichloroethane
chloroform	tetrachloroethylene
trichloroethylene	carbon disulfide
trichlorofluoromethane	acetone
dimethyl disulfide	2-butanone
4-methyl-2-pentanone	methyl tertiary butyl ether
limonene	naphthalene
α,β-pinene	4-phenylcyclohexene
propane	butane
butyl cellosolve	ethanol
isopropanol	phenol
formaldehyde	siloxanes
toluene	

with ASHRAE *Standard 62* should satisfy indoor dilution ventilation requirements. Local exhaust ventilation is effective for controlling known, unavoidable point emissions sources. It is prudent to isolate office machines, such as photocopiers and laser printers, food service equipment, such as microwave ovens and coffee makers, and work areas, such as graphics and photographic labs, using dedicated local exhaust systems that vent to the outside and away from outdoor air intakes.

A good ventilation protocol during renovation or remodeling includes using a single-pass (100% outdoor air) system during and at the finish of these activities, continuing until enough time has passed to lower emitted concentrations to near background. This practice minimizes sink effects and secondary emissions.

Prudent practice and administrative control should be used to minimize the generation of VOCs in indoor air during occupied hours whenever possible. Scheduling the use of volatile organic products, housekeeping activities, and pesticide application when occupant density is lowest should be considered. VOC-containing supplies should be stored in well-ventilated areas other than HVAC mechanical rooms or plenums.

### INORGANIC GASES

Several inorganic gases are of concern because of their effects on human health and comfort and on materials. These include carbon dioxide, carbon monoxide, oxides of nitrogen, sulfur dioxide, ozone, and ammonia. Most have both outdoor and indoor sources.

**Carbon dioxide** (CO<sub>2</sub>) or carbonic acid gas is produced by human respiration. It is not normally considered to be a toxic air contaminant, but it can be a simple asphyxiant (by oxygen displacement) in confined spaces such as submarines. CO<sub>2</sub> is found in the ambient environment at 330 to 370 ppm. Levels in the urban environment may be higher due to emissions from gasoline and, more often, diesel engines. Measurement of CO<sub>2</sub> in occupied spaces has been widely used to evaluate the amount of outdoor air supplied to indoor spaces. In ASHRAE *Standard 62*, a level of 1000 ppm (or 650 ppm above outdoor air) has been suggested as being representative of delivery rates of 7 L/s per person of outside air when CO<sub>2</sub> is measured at equilibrium concentrations and at occupant densities of 10 people per 100 m<sup>2</sup> of floor space. Measuring CO<sub>2</sub> level before it has reached steady-state conditions can lead to inaccurate conclusions regarding the amount of outside air used in the building.

**Carbon monoxide** (CO) is an odorless, colorless, and tasteless gas produced by the incomplete combustion of hydrocarbons. It is a common ambient air pollutant and is very toxic. Common indoor sources of CO include gas stoves, kerosene lanterns and heaters, mainstream and sidestream tobacco smoke, woodstoves, and unvented or improperly vented combustion sources. Building makeup air intakes located at street level or near parking garages can entrain CO from automobiles and carry it to the indoor environment.

The major predictors of indoor CO concentrations are indoor fossil fuel sources, such as gas furnaces, hot water heaters, and other combustion appliances; attached garages; and weather inversions. Levels in homes only rarely exceed 5 ppm. In one sample of randomly selected homes, 10% failed a backdrafting test (Conibear et al. 1996). Under backdrafting conditions, indoor CO sources may contribute to much higher, dangerous levels of CO.

**Oxides of nitrogen** (NO<sub>x</sub>) indoors result mainly from cooking appliances, pilot lights, and unvented heaters. Sources generating carbon monoxide (CO) often produce nitric oxide (NO) as well. Underground or attached parking garages can also contribute to indoor concentrations of NO<sub>x</sub>. An unvented gas cookstove contributes approximately 0.025 ppm of nitrogen dioxide (NO<sub>2</sub>) to a home. During cooking, 0.2 ppm to 0.4 ppm peak levels may be reached (Samet et al. 1987). Ambient air pollution from vehicle exhausts in urban locations can contribute NO<sub>x</sub> to the indoor environment in makeup air. Oxides of nitrogen also are present in mainstream and sidestream tobacco smoke. Nitric oxide and nitrogen dioxide are of most concern.

**Sulfur dioxide** (SO<sub>2</sub>) can result from the emissions of kerosene space heaters; the combustion of fossil fuels such as coal, heating oil, and gasoline; or burning any material containing sulfur. As a result, sulfur dioxide is a common ambient air pollutant in many urban areas.

**Ozone** (O<sub>3</sub>) is a photochemical oxidant that forms at ground level when hydrocarbons and oxides of nitrogen react with ultraviolet radiation in sunlight to produce photochemical smog. Ozone can be emitted by the electrical or coronal discharges from office equipment including laser printers and photocopiers. It can also be generated when ozone-generating devices—often marketed as portable air cleaners and ionizers—are used in the indoor environment (Esswein and Boeniger 1994).

### Controlling Exposures to Inorganic Gases

Three methods of control for inorganic gaseous contaminants should be considered: source control, ventilation control, and removal by filters. **Source control** involves limiting (or removing) the source of the problem; for example, gas cookstoves should not be used for space heating (often a problem in low-income urban residences). Another example is limiting automobile parking around building makeup air intakes. Source control should always be the primary consideration. But source control is not always feasible when there are many diverse contaminant sources as in new buildings where the building itself or building furnishings may be the prime contributors to the problem.

**Ventilation control** involves bringing clean dilution air into the occupied space or directly exhausting air contaminants at the point of generation. ASHRAE *Standard* 62 provides guidance in applying the Ventilation Rate Procedure and the Indoor Air Quality Procedure for ventilation control.

Where neither source control nor ventilation control appear likely to control gaseous air contaminants, **air filtration** should be investigated. Gas-phase air filtration involves dry scrubbing to remove contaminants by adsorption onto several sorbents, including granular activated carbon (GAC), potassium permanganate-impregnated alumina (PIA), and alkaline-impregnated carbon filters. Muller and England (1995), Liu and Huza (1995), VanOsdell

(1995), and Coutant et al. (1994) review various filtration procedures.

No one media is effective for the broad range of gaseous contaminants found indoors. Granular activated charcoal is generally an agent of choice for nonpolar compounds and is a suitable choice for O<sub>3</sub> and NO<sub>2</sub> but not for SO<sub>x</sub> and NO. Permanganate-impregnated alumina is more appropriate for SO<sub>x</sub> and NO.

Ozone can be best controlled by local exhaust ventilation for demonstrated sources of ozone, such as photocopiers and equipment creating coronal discharges. Routine cleaning of attractor plates in an electrostatic precipitator and ensuring adequate pre-filters can reduce ozone generation and limit arcing in this type of particle removal equipment. The use of ozone-generating devices as a means of air cleaning or purification has not been documented as a prudent means of air contaminant control considering the potential health effects of the use of ozone indoors (Esswein and Boeniger 1994). The Food and Drug Administration (FDA 1990) specifically limits the use of ozone in concentrations greater than 50 ppb in areas intended for continuous occupancy, such as residences, offices, schools, and hospitals.

Carbon monoxide exposure control strategies primarily involve identification and control of CO emissions directly at their source. Local exhaust ventilation is an appropriate and effective control in most cases. For example, automobile repair garages commonly use a tailpipe exhaust extension to control the CO exposure of the mechanics working in the repair bays. Relocating building makeup air intakes or limiting vehicle access are reasonable means to prevent entrainment of automobile exhausts into building HVAC systems.

Carbon monoxide, however, is a common pollutant of ambient air. As a result, direct control by dilution may not be feasible if ambient air is heavily contaminated with CO. Diesel or natural gas may be substituted for gasoline engines to reduce CO where specific sources from engine exhaust are identified or are a concern. Adequate venting of any combustion sources is critical to prevent the buildup of CO indoors. CO may be monitored by a properly calibrated, direct-reading CO monitor, colorimetric indicator tubes, or passive diffusion sampling badges.

Exposure controls for carbon dioxide are generally limited to situations where exposure concentrations are expected to exceed 3 to 5%. CO<sub>2</sub> is not encountered at levels harmful to humans in the ambient environment. It is normally present at 350 to 375 ppm, and slightly higher in congested cities. With the exception of an intentional or accidental CO<sub>2</sub> “dump” from a fire suppression system or in a dry ice manufacturing facility, CO<sub>2</sub> is not encountered in significant concentrations that require specific engineering controls. However, CO<sub>2</sub> is denser than air and can persist for some time in low areas such as trenches, depressions, and pits. This characteristic creates a simple asphyxiation hazard because CO<sub>2</sub> displaces oxygen.

## SPECIAL TYPES OF AIR CONTAMINANTS

### OUTDOOR AIR CONTAMINANTS

The total amount of suspended particulate matter in the atmosphere can influence the loading rate of air filters and their selection. The amount of soot that falls in U.S. cities ranges from 7 to 70 Mg/km<sup>2</sup> per month. Soot fall data indicate effectiveness of smoke abatement and proper combustion methods and serve as comparative indices of such control programs. However, the data are of limited value to the ventilating and air-conditioning engineer, since they do not accurately represent airborne soot concentrations.

Concentrations of outdoor pollutants are important, as they may determine indoor concentrations in the absence of indoor sources. Table 9 presents typical urban outdoor concentrations of some com-

**Table 9 Typical Outdoor Concentrations of Selected Gaseous Air Pollutants**

Pollutant	Typical Concentration, $\mu\text{g}/\text{m}^3$		Typical Concentration, $\mu\text{g}/\text{m}^3$
		Pollutant	
Acetaldehyde	20	Methylene chloride	2.4
Acetone	3	Nitric acid	6
Ammonia	1.2	Nitric oxide	10

Lead particulate	1.5	3 months		

<sup>a</sup>Standard is met when the number of days per year with maximum hour-period concentration above 235  $\mu\text{g}/\text{m}^3$  is less than one.

<sup>b</sup>PM<sub>10</sub> = particulates below 10  $\mu\text{m}$  diameter

mon gaseous pollutants. Higher levels might be found if the building under consideration were located near a major source of contamination such as a power plant, a refinery, or a sewage treatment plant. Note that levels of sulfur dioxide and nitrogen dioxide, which are often attached to particles, may be reduced by about half by building filtration systems. Also, ozone is a reactive gas that can be significantly reduced by contact with ventilation system components (Weschler et al. 1989).

The U.S. Environmental Protection Agency has identified several important outdoor contaminants as **criteria pollutants**. The list includes suspended particulate matter, lead particulate matter, ozone, nitrogen dioxide, sulfur dioxide, carbon monoxide, and total hydrocarbons. Standards have been set for these contaminants, as shown in Table 10, and levels measured at a large number of locations in the United States are published by the EPA each year (40 CFR 50).

Daily concentrations of VOCs in outdoor air can vary drastically (Ekberg 1994). These variations are due to vehicle traffic density, wind direction, industrial emissions, and photochemical reactions.

**Table 11 Characteristics of Selected Gaseous Air Pollutants**

Pollutant	Chemical and Physical Properties		
	Family <sup>a</sup>	BP <sup>b</sup> , °C	M <sup>c</sup>

## INDUSTRIAL AIR CONTAMINANTS

Many industrial processes produce significant quantities of air contaminants in the form of dusts, fumes, smokes, mists, vapors, and gases. Table 11 lists chemical and physical properties of some common gaseous industrial contaminants.

Particulate and gaseous contaminants are best controlled at the source so that they are neither dispersed through the factory nor allowed to increase to toxic concentration levels. Dilution ventilation is much less effective than local exhaust for reducing contamination from point source emissions and is used for control only when sources are distributed and not amenable to capture by an exhaust hood. For sources generating high levels of contaminants, it may also be necessary to provide equipment that reduces the amount of material discharged to the atmosphere (e.g., a dust collector for particulate contaminants and/or a high dwell time gas-phase media bed for solvent vapors). Control methods are covered in Chapters 24 and 25 of the 2000 *ASHRAE Handbook—Systems and Equipment* and Chapters 29 and 44 of the 1999 *ASHRAE Handbook—Applications*.

Zero concentration of all contaminants is not economically feasible. Absolute control of all contaminants cannot be maintained, and workers can assimilate small quantities of various toxic materials without injury. Industrial hygiene science is based on the fact that most air contaminants become toxic only if their concentration exceeds a maximum allowable limit for a specified period. Allowable limits in industrial environments are covered in Chapter 9.

Although the immediately dangerous to life and health (IDLH) toxicity limit is rarely a factor in HVAC design, HVAC engineers should consider it when deciding how much recirculation is safe in a given system. Ventilation airflow must never be so low that the concentration of any gaseous contaminant could rise to the IDLH level. Another toxic effect that may influence design is the loss of sensory acuity due to gaseous contaminant exposure. For example, high concentrations of hydrogen sulfide, which has a very unpleasant odor, effectively eliminate a person's ability to smell the gas.

Carbon monoxide, which has no odor to alert people to its presence, affects psychomotor responses and could be a problem in areas such as air traffic control towers. Clearly, waste anesthetic gases should not be allowed to reach levels in operating suites such that the alertness of any of the personnel is affected. NIOSH recommendations are frequently based on such subtle effects.

## NONINDUSTRIAL INDOOR AIR CONTAMINANTS

Indoor air quality in residences, offices, and other indoor, non-industrial environments has become a widespread concern (Spengler et al. 1982, NRC 1981). Exposure to indoor pollutants can be as important as exposure to outdoor pollutants because a large portion of the population spends up to 90% of their time indoors and because indoor pollutant concentrations are frequently higher than corresponding outdoor contaminant levels.

Symptoms of exposure include coughing; sneezing; eye, throat, and skin irritation; nausea; breathlessness; drowsiness; headaches; and depression. Rask (1988) suggests that when 20% of a single building's occupants suffer such irritations, the structure is suffering from **sick building syndrome** (SBS). Case studies of such occurrences have consisted of analyses of questionnaires submitted to building occupants, measurements of contaminant levels, or both of these. Some attempts to relate irritations to gaseous contaminant concentrations are reported (Lamm 1986, Cain et al. 1986, Berglund et al. 1986, Molhave et al. 1982). The correlation of reported complaints with gaseous pollutant concentrations is not strong; many factors affect these less serious responses to pollution. In general, physical irritation does not occur at odor threshold concentrations.

Characterization of indoor air quality has been the subject of numerous recent studies. ASHRAE *Indoor Air Quality (IAQ) Conference Proceedings* discuss indoor air quality problems and some practical controls. ASHRAE *Standard 62* addresses many indoor air quality concerns. Table 12 illustrates the sources, levels, and indoor-to-outdoor concentration ratios of several contaminants found in indoor environments. Chapter 9 has further information on indoor health issues.

**Table 12 Sources, Possible Concentrations, and Indoor-to-Outdoor Concentration Ratios of Some Indoor Pollutants**

Pollutant	Sources of Indoor Pollution	Possible Indoor Concentration	I/O Concentration Ratio	Location
Carbon monoxide	Combustion equipment, engines, faulty heating systems	100 mg/kg	>>1	Skating rinks, offices, homes, cars, shops
Respirable particles	Stoves, fireplaces, cigarettes, condensation of volatiles, aerosol sprays, resuspension, cooking	100 to 500 $\mu\text{g}/\text{m}^3$	>>1	Homes, offices, cars, public facilities, bars, restaurants
Organic vapors	Combustion, solvents, resin products, pesticides, aerosol sprays	NA	>1	Homes, restaurants, public facilities, offices, hospitals
Nitrogen dioxide	Combustion, gas stoves, water heaters, driers, cigarettes, engines	200 to 1000 $\mu\text{g}/\text{m}^3$	>>1	Homes, skating rinks
Sulfur dioxide	Heating system	20 $\mu\text{g}/\text{m}^3$	<1	Removal inside
Total suspended particles without smoking	Combustion, resuspension, heating system	100 $\mu\text{g}/\text{m}^3$	1	Homes, offices, transportation, restaurants
Sulfate	Matches, gas stoves	5 $\mu\text{g}/\text{m}^3$	<1	Removal inside
Formaldehyde	Insulation, product binders, particleboard	0.05 to 1.0 mg/kg	>>1	Homes, offices
Radon and progeny	Building materials, groundwater, soil	0.1 to 100 nCi/m <sup>3</sup>	>>1	Homes, buildings
Asbestos	Fireproofing	<10 <sup>6</sup> fiber/m <sup>3</sup>	1	Homes, schools, offices
Mineral and synthetic fibers	Products, cloth, rugs, wallboard	NA	—	Homes, schools, offices
Carbon dioxide	Combustion, humans, pets	3000 mg/kg	>>1	Homes, schools, offices
Viable organisms	Humans, pets, rodents, insects, plants, fungi, humidifiers, air conditioners	NA	>1	Homes, hospitals, schools, offices, public facilities
Ozone	Electric arcing	20 $\mu\text{g}/\text{kg}$	<1	Airplanes
	Ultraviolet light sources	200 $\mu\text{g}/\text{kg}$	>1	Offices

Source: NRC (1981).

<sup>a</sup>Concentrations listed are only those reported indoors. Both higher and lower concentrations have been measured. No averaging times are given. NA indicates that it is not appropriate to list a concentration.

A knowledge of sources frequently present in different types of buildings can be useful during investigations of the causes of SBS. Common nonindustrial indoor sources are discussed in some detail below. Technical advances have allowed generation rates to be measured for a number of these sources. These rates are necessary inputs for design of control equipment, and full details are given in Chapter 44 of the 1999 *ASHRAE Handbook—Applications*.

**Building materials and furnishing** sources have been well studied. Particleboard, which is usually made from wood chips bonded with a phenol-formaldehyde or other resin, is widely used in current construction, especially for mobile homes, carpet underlay, and case goods. These materials, along with ceiling tiles, carpeting, wall coverings, office partitions, adhesives, and paint finishes emit formaldehyde and other VOCs. Latex paints containing mercury have been shown to emit mercury vapor. While the emission rates for these materials decline steadily with age, the half-life of emissions is surprisingly long. Black and Bayer (1986), Nelms et al. (1986), and Molhave et al. (1982) report on these sources.

**Ventilation systems** may be a source of VOCs (Molhave and Thorsen 1990). The interior of the HVAC system can have large areas of porous material used as acoustical liner that can adsorb odorous compounds. This material can also hold nutrients and, with moisture, can become a reservoir for microorganisms. Microbial contaminants produce characteristic VOCs, called microbial VOCs (MVOCs), associated with their metabolism. Other HVAC components, such as condensate drain pans, fouled cooling coils, and some filter media, may support microbiological life. Deodorants, sealants, and encapsulants are also sources of VOCs in HVAC systems.

**Equipment** sources in commercial and residential spaces have generation rates that are usually substantially lower than in the industrial environment. As these sources are rarely hooded, emissions go directly to the occupants. In commercial spaces, the chief sources of gaseous contaminants are office equipment, including dry-process copiers (ozone), liquid-process copiers (VOCs), diazo printers (ammonia and related compounds), carbonless copy paper (formaldehyde), correction fluids, inks, and adhesives (various VOCs), spray cans, cosmetics, and so forth (Miksch et al. 1982). Medical and dental activities generate pollutants from the escape of anesthetic gases (nitrous oxide and isoflurane) and from sterilizers (ethylene oxide). The potential for asphyxiation is always a concern when compressed gases are present, even if that gas is nitrogen.

In residences, the main sources of equipment-derived pollutants are gas ranges, wood stoves, and kerosene heaters. Venting is helpful, but some pollutants escape into the occupied area. The pollutant contribution by gas ranges is somewhat mitigated by the fact that they operate for shorter periods than heaters. The same is true of showers, which can contribute to radon and halocarbon concentrations indoors.

**Cleaning agents and other consumer products** can act as contaminant sources. Commonly used liquid detergents, waxes, polishes, spot removers, and cosmetics contain organic solvents that volatilize slowly or quickly. Mothballs and other pest control agents emit organic vapors. Knoepfel and Schauenburg (1989), Black and Bayer (1986), and Tichenor (1989) report data on the release of these volatile organic compounds (VOCs). Field studies have shown that such products contribute significantly to indoor pollution; however, a large variety of compounds is in use, and few studies have been made that allow calculation of typical emission rates. Pesticides, both those applied indoors and those applied outdoors to control termites, also pollute building interiors.

**Tobacco smoke** is a prevalent and potent source of indoor air pollutants. Almost all tobacco smoke arises from cigarette smoking. Environmental tobacco smoke (ETS), sometimes called second-hand smoke, is the aged and diluted combination of sidestream smoke (the smoke from the lit end of a cigarette and the smoke that escapes from the filter between puffs) and mainstream smoke (the smoke exhaled by a smoker). Emission factors for ETS compo-

nents, the ratio of ETS components to marker compounds, and apportionment of ETS components in indoor air are reported in the literature by Heavner et al. (1996), Hodgson et al. (1996), Martin et al. (1996), and Nelson et al. (1994).

**Occupants**, both humans and animals, emit a wide array of pollutants by breath, sweat, and flatus. Some of these emissions are conversions from solids or liquids within the body. Many volatile organics emitted are, however, reemissions of pollutants inhaled earlier, with the tracheobronchial system acting like a physical adsorber.

**Floor dust**, which is different from the dust in the air, has been found to be a sink (adsorption medium) and secondary emission source for VOCs. Floor dust is a mixture of organic and inorganic particles, hair and skin scales, and textile fibers. The fiber portion of floor dust has been shown to contain 169 mg/kg TVOC, and the particle portion 148 mg/kg (Gyntelberg et al. 1994). These VOCs were correlated to the prevalence of irritative (sore throat) and cognitive (concentration problems) symptoms among building occupants. One hundred eighty-eight compounds were identified from thermal desorption of office dust at 121°C (Wilkins et al. 1993). Household dust was found to be similar in composition (Wolkoff and Wilkins 1994).

Contaminants from other sources include chloroform from water; tetrachloroethylene and 1,1,1-trichloroethane from cleaning solvents; methylene chloride from paint strippers, fresheners, cleaners, and polishers; *a*-pinene and limonene from floor waxes; and 1-methoxy-2-propanol from spray carpet cleaners. Formaldehyde, a major VOC, has many sources, but pressed wood products appear to be the most significant.

## FLAMMABLE GASES AND VAPORS

The use of flammable materials is widespread. Flammable gases and vapors (NFPA *Standard* 325M) can be found in sewage treatment plants, sewage and utility tunnels, dry-cleaning plants, automobile garages, and industrial finishing process plants.

A flammable liquid's vapor pressure and volatility or rate of evaporation determine its ability to form an explosive mixture. These properties can be expressed by the **flash point**, which is the temperature to which a combustible liquid must be heated to produce a flash when a small flame is passed across the surface of the liquid. Depending on the test methods, either the open cup or closed cup flash point may be listed. The higher the flash point, the more safely the liquid can be handled. Liquids with flash points under 21°C should be regarded as highly flammable.

In addition to having a low flash point, the air-vapor or air-gas mixture must have a concentration in the explosive range before it can be ignited. The **explosive range** is the range between the upper and lower explosive limits, expressed as percent by volume in air. Concentrations of material above the higher range or below the lower range will not explode. The range for many chemicals is found in *National Fire Code* bulletins published by the National Fire Protection Association (NFPA). Some representative limits of flammability are listed in Table 13.

In designing ventilation systems to control flammable gases and vapors, the engineer must consider the following:

Most safety authorities and fire underwriters prefer to limit concentrations to 20 to 25% of the lower explosive limit of a material. The resulting safety factor of 4 or 5 allows latitude for imperfections in air distribution and variations of temperature or mixture and guards against unpredictable or unrecognized sources of ignition. Operation at concentrations above the upper explosive limit should be resorted to only in rare instances. To reach the upper explosive limit, the flammable gas or vapor must pass through the active explosive range, in which any source of ignition can cause an explosion. In addition, a drop in gas concentration due to unfore-

**Table 13 Flammable Limits of Some Gases and Vapors**

Gas or Vapor	Flash Point, °C	Flammable Limits, % by Volume	
		Lower	Upper
Acetone	-18	2.6	12.8
Ammonia	Gas	16	25
Benzene (benzol)	-11	1.3	7.5
<i>n</i> -Butane	Gas	1.9	8.5
Carbon disulfide	-30	1.3	44
Carbon monoxide	Gas	12.5	74
1,2-Dichloroethylene	6	9.7	12
Diethylether	-45	1.9	48
Ethyl alcohol	13	4.3	19
Ethylene	Gas	3.1	32
Gasoline	-43	1.4	7.6
Hydrogen	Gas	4.0	75
Hydrogen sulfide	Gas	4.3	45
Isopropyl alcohol	11.7	2.0	12
Methyl alcohol	11	7.3	36
Methyl ethyl ketone	-6	1.8	10
Natural gas (variable)	Gas	3.8	17
Naphtha (benzine)	10	0.9	6.7
Propane	Gas	2.2	9.5
Toluene (toluol)	4	1.2	7.1
<i>o</i> -Xylene	32	1.0	6.0

seen dilution or reduced evaporation rate may place a system in the dangerous explosive range.

In occupied places where ventilation is applied for proper health control, the danger of an explosion is minimized. In most instances, flammable gases and vapors are also toxic, and the maximum allowable concentrations are far below the lower explosive limit of the material. For example, proper ventilation for acetone vapors keeps the concentration below 1000 mg/m<sup>3</sup>. This is equivalent to 0.1% by mass. The lower explosive limit for acetone is 2.5% by volume.

Proper location of exhaust and supply ventilation equipment depends primarily on how a contaminant is given off and on other problems of the process, and secondarily on the relative density of flammable vapor.

If the specific density of the explosive mixture is the same as that of air, cross drafts, equipment movement, and temperature differentials may cause sufficient mixing to produce explosive concentrations and disperse these throughout the atmosphere. In reasonably still air, heavier-than-air vapors may pool at floor level. Therefore, the engineer must either provide proper exhaust and supply air patterns to control the hazardous material, preferably at its source, or offset the effects of drafts, equipment movement, and convective forces by providing good distribution of exhaust and supply air for general dilution and exhaust. The intake duct should be positioned so that it does not bring in exhaust gases or emissions from ambient sources.

Adequate ventilation minimizes the risk of or prevents fires and explosions and is necessary, regardless of other precautions, such as elimination of the ignition sources, safe building construction, and the use of automatic alarm and extinguisher systems.

Chapter 29 of the 1999 *ASHRAE Handbook—Applications* gives more details about equipment for control of combustible materials.

### COMBUSTIBLE DUSTS

Many organic and some mineral dusts can produce dust explosions (Hartmann 1958). Often, a primary explosion results from a small amount of dust in suspension that has been exposed to a source of ignition; the pressure and vibration created can dislodge large accumulations of dust on horizontal surfaces, creating a larger secondary explosion.

For ignition, dust clouds require high temperatures and sufficient dust concentration. These temperatures and concentrations and the minimum spark energy can be found in Avallone and Baumeister (1987).

Explosive dusts are potential hazards whenever uncontrolled dust escapes, disperses in the atmosphere or settles on horizontal surfaces such as beams and ledges. Proper exhaust ventilation design involves the principles covered in Chapter 29 of the 1999 *ASHRAE Handbook—Applications*. The ventilation systems and equipment chosen must prevent the pocketing of dust inside the equipment. When local exhaust ventilation is used, separation equipment should be installed as close to the dust source as possible to prevent transport of dust in the exhaust system.

### RADIOACTIVE AIR CONTAMINANTS

Radioactive contaminants (Jacobson and Morris 1977) can be particulate or gaseous and are similar to ordinary industrial contaminants. Many radioactive materials would be chemically toxic if present in high concentrations; however, in most cases, the radioactivity necessitates limiting their concentration in air.

Most radioactive air contaminants affect the body when they are absorbed and retained. This is known as the **internal radiation hazard**. Radioactive particulates may settle to the ground, where they contaminate plants and eventually enter the food chain and the human body. Deposited material on the ground increases **external radiation exposure**. However, except for fallout from nuclear weapons or a serious reactor accident, such exposure is insignificant.

Radioactive air contaminants can emit alpha, beta, or gamma rays. The alpha rays penetrate poorly and present no hazard, except when the material is deposited inside or on the body. Beta rays are somewhat more penetrating and can be both an internal and an external hazard. The penetration of gamma rays depends on their energy, which varies from one type of radioactive element or isotope to another. A distinction should be made between the radioactive material itself and the radiation it gives off. Radioactive particles can be removed from air by devices such as HEPA and ULPA filters, and radioactive gases by impregnated carbon or alumina (radioactive iodine) and absorption traps, but the gamma radiation from such material is capable of penetrating solid materials. This distinction is frequently overlooked. The amount of radioactive material in air is measured in becquerels per cubic metre (1 becquerel equals  $2.702702 \times 10^{-11}$  curies), while the dose of radiation from deposited material is measured in rads.

Radioactive materials present problems that make them distinctive. High concentrations of radioactivity can generate enough heat to damage filtration equipment or ignite the material spontaneously. The concentrations at which most radioactive materials are hazardous are much lower than those of ordinary materials; as a result, special electronic instruments that respond to radioactivity must be used to detect these hazardous levels.

The ventilation engineer faces difficulty in dealing with radioactive air contamination because of the extremely low permissible concentrations for radioactive materials. For certain sensitive industrial plants, such as those in the photographic industry, contaminants must be kept from entering the plant. If radioactive materials are handled inside the plant, the problem is to collect the contaminated air as close to the source as possible, and then remove the contaminant from the air with a high degree of efficiency, before releasing it to the outdoors. Filters are generally used for particulate materials, but venturi scrubbers, wet washers, and other devices can be used as prefilters to meet special needs.

The design of equipment and systems for control of radioactive particulates and gases in nuclear laboratories, power plants, and fuel-processing facilities is a highly specialized technology. Careful attention must be given to the reliability, as well as the contaminant-removal ability, of the equipment under the special environmental

stresses involved. Various publications of the U.S. Department of Energy can provide guidance in this field.

### Radon

A major source of airborne radioactive exposure to the population comes from radon. Radon (Rn) is a naturally occurring, chemically inert, colorless, odorless, tasteless radioactive gas. It is produced from the radioactive decay of radium, which is formed through several intermediate steps of the decay of uranium and thorium. Radon is widely found in the natural environment, as uranium salt precursors are widespread. Radon-222 is the most common isotope of radon. Before it decays, radon can move limited distances through very small spaces, such as those between particles of soil and rock, and enter indoor environments (Nazaroff et al. 1988, Tanner 1980). Additional but secondary sources of indoor radon include groundwater (radon is quite soluble in water) and radium-containing building materials.

Radon gas enters a house or building primarily through leakage paths in the foundation and is transported by pressure-driven flow. Entry occurs through cracks, joints, and other holes in concrete foundations; directly through porous concrete blocks; through the joints and openings in crawl space ceilings; and through leakage points in HVAC ductwork that is embedded in slab floors or located in crawl spaces. Pressure-driven flow is the dominant radon entry mechanism in houses with elevated radon concentrations (Nazaroff et al. 1987). Pressure differences are caused by several factors, including the thermal stack effect, wind, and operation of HVAC equipment. In addition to pressure-driven radon entry, Rn can also diffuse directly through substructural materials (e.g., concrete). The diffusive Rn entry rate is often a significant portion of the total entry rate in houses with low Rn concentrations.

**Measurement.** Indoor concentrations of radon can vary hourly, daily, and seasonally, in some cases by as much as a factor of 10 to 20 on a daily basis (Turk et al. 1990). Thus, long-term measurements (3 months to 1 year) made during normal home activities generally provide more reliable estimates of the average indoor concentration than do short-term measurements. Two techniques widely used for homeowner measurements are the short-term charcoal canister (up to 7 days), and the long-term alpha-track methods (90 days to 1 year). Generally, short-term measurements should only be used as a screening technique to determine whether a long-term measurement is necessary. The great uncertainties in measurement accuracy with these devices, up to 50% at the radon levels typically found in homes, as well as the natural variability of radon concentrations should be considered in interpreting the results.

Ideally, long-term measurements should be the basis for decisions on installation of radon mitigation systems, and short-term measurements should only be used as a screening method to identify buildings with Rn concentrations that are very high, justifying immediate remedial action. In practice, short-term measurements at the time a building is sold are the basis for most decisions about remedial action.

**Typical Levels.** The outdoor radon concentration is about  $15 \text{ Bq/m}^3$  ( $0.4 \text{ pCi/L}$ ). The annual average concentration of radon in homes in the United States is about  $46 \text{ Bq/m}^3$  ( $1.25 \text{ pCi/L}$ ) (EPA 1989). While several sources of radon may contribute to the annual indoor average, pressure-driven flow of soil gas constitutes the principal source for elevated concentrations; nonmunicipal water supplies can be a source of elevated indoor radon, but only in isolated instances.

**Control.** Exposure to indoor Rn may be reduced by (1) inhibiting Rn entry into the building or (2) removing or diluting Rn decay products in indoor air. The most effective and energy-efficient control measures are generally those that reduce Rn entry rates (Henschel 1993). One of the most common effective techniques is active subslab depressurization, in which a fan and piping system draw soil gas from beneath the slab and exhaust the gas outside. This

technique reduces or reverses the pressure gradient that normally draws soil gas and Rn into the building and often reduces indoor Rn concentrations by a large factor (e.g., 5 to 10). Passive control methods such as Rn-resistant construction techniques and/or passive stack subslab depressurization systems are also used; however, the performance of these control methods is not well characterized, and average reductions in Rn concentrations may be 50% or less. Sealing cracks and joints in slab floors improve the performance of subslab depressurization systems. Sealing by itself is often not very effective in reducing indoor Rn.

In houses with crawl spaces, active (fan-forced) or passive crawl space ventilation is often effective in maintaining low indoor Rn concentrations, although other techniques are also used (Henschel 1988, 1993).

### SOIL GASES

The radioactive gas radon (Rn) is the best-known soil gas. However, gaseous contaminants other than radon may enter buildings from surrounding soil. Methane from landfills has reached explosive levels in some buildings. Potentially toxic or carcinogenic VOCs in the soil as a consequence of spills, improper disposal, leaks from storage tanks, and disposal in landfills can also be transported into buildings (Wood and Porter 1987, Hodgson et al. 1992, Garbesi and Sextro 1989, Kullman and Hill 1990). Pesticides applied to the soil beneath or adjacent to houses have also been detected in indoor air (Livingston and Jones 1981, Wright and Leidy 1982), and pressure-driven flow is a suspected entry mechanism. The broad significance of the health effects due to exposure to these soil contaminants is not well understood. Techniques that reduce Rn entry from the soil should also be effective in reducing the entry of these contaminants into buildings. Another approach may be to increase ventilation in the building, such as by slightly opening a window. That change in home-use behavior can also help reduce the negative pressure in the house, with respect to the soil gas pressure, created by the stack effect.

## CHAPTER 13

# ODORS

<i>Odor Sources</i> .....	13.1
<i>Sense of Smell</i> .....	13.1
<i>Factors Affecting Odor Perception</i> .....	13.2
<i>Odor Sensation Attributes</i> .....	13.3
<i>Dilution of Odors by Ventilation</i> .....	13.5
<i>Odor Concentration</i> .....	13.5
<i>Olf Units</i> .....	13.6

**V**ARIOUS factors make odor control a primary consideration in ventilation engineering: (1) contemporary construction methods result in buildings that permit less air infiltration through the building envelope; (2) indoor sources of odors associated with modern building materials, furnishings, and office equipment have increased; (3) outdoor air is often polluted; and (4) energy costs have encouraged ventilation rate reductions at a time when requirements for a relatively odor-free environment are greater than ever.

Since Yaglou's classic studies (1936), the philosophy behind the ventilation of nonindustrial buildings has mainly been to provide indoor air that is acceptable to occupants. Air is evaluated by the olfactory sense, although the general chemical sense, which is sensitive to irritants in the air, also plays a role.

This chapter reviews how odoriferous substances are perceived. Chapter 44 of the 1999 *ASHRAE Handbook—Applications* covers control methods. Chapter 9 of this volume has more information on indoor environmental health.

### ODOR SOURCES

Outdoor sources of odors include automotive and diesel exhausts, hazardous waste sites, sewage treatment plants, compost piles, refuse facilities, printing plants, refineries, chemical plants, and many other stationary and mobile sources. These sources produce both inorganic compounds (e.g., ammonia and hydrogen sulfide) and volatile organic compounds (VOCs), including some which evaporate from solid or liquid particulate matter. Odors emitted by outdoor sources eventually enter the indoor environment.

Indoor sources also emit odors. Sources include tobacco products; bathrooms and toilets; building materials (adhesives, paints, caulks, processed wood, carpets, plastic sheeting, and insulation board); consumer products (e.g., food, toiletries, cleaning materials, and polishes); hobby materials; fabrics; and foam cushions. In offices, offset printing processes, copiers, and computer printers may produce odors. If electrostatic processes are involved, ozone may be emitted. Humans emit a wide range of odorants, including acetaldehyde, ammonia, ethanol, hydrogen sulfide, and mercaptans.

Mildew and other processes of decay often produce odors in occupied spaces (home and office), damp basements, and ventilation systems (e.g., from wetted air-conditioning coils and spray dehumidifiers).

Chapter 44 of the 1999 *ASHRAE Handbook—Applications* gives further information on contaminant sources and generation rates.

The preparation of this chapter is assigned to TC 2.3, Gaseous Air Contaminants and Gas Contaminant Removal Equipment.

### SENSE OF SMELL

#### Olfactory Stimuli

Among organic substances, those with relative molecular masses greater than 300 are generally odorless. Some substances with relative molecular masses less than 300 are such potent olfactory stimuli that they can be perceived at concentrations too low to be detected with direct-reading instruments. Trimethylamine, for example, can be recognized as a fishy odor by a human observer at a concentration of about  $10^{-4}$  ppm.

Table 1 shows **threshold concentrations** for selected compounds. These threshold values are not precise numbers and may vary by several orders of magnitude. The **threshold limit value (TLV)** is the concentration of a compound that should have no adverse health consequences if a worker is regularly exposed for 8 h periods (ACGIH, revised annually). Table 1 also includes the ratio

**Table 1 Odor Thresholds, ACGIH TLVs, and TLV:Threshold Ratios of Selected Gaseous Air Pollutants**

Compound	Odor Threshold, <sup>a</sup> ppmv	TLV, ppmv	Ratio
Acetaldehyde	0.067	40	597
Acetone	62	500	8.1
Acetonitrile	1600	40	0.025
Acrolein	1.8	0.1	0.06
Ammonia	17	25	1.5
Benzene	61	0.5	0.01
Benzyl chloride	0.041	1	24
Carbon tetrachloride	250	5	0.02
Chlorine	0.08	0.5	6
Chloroform	192	10	0.05
Dioxane	12	25	2
Ethylene dichloride	26	10	0.4
Hydrogen sulfide	0.0094	10	1064
Methanol	160	200	1.25
Methylene chloride	160	50	0.3
Methyl ethyl ketone	16	200	12.5
Phenol	0.06	5	83
Sulfur dioxide	2.7	2	0.74
Tetrachloroethane	7.3	1	0.14
Tetrachloroethylene	47	25	0.5
Toluene	1.6	50	31
1,1,1-Trichloroethane	390	350	0.9
Trichloroethylene	82	50	0.6
Xylene (isomers)	20	100	5

Sources: AIHA (1989), ACGIH (1998).

<sup>a</sup>All thresholds are detection thresholds (ED<sub>50</sub>).

of the TLV to the odor threshold for each compound. For ratios greater than 1, most occupants can detect the odor and leave the area long before the compound becomes a health risk. As the ratio increases, the safety factor provided by the odor also increases. Table 1 is not a comprehensive list of the chemicals found in indoor air. AIHA (1989) and EPA (1992) have published lists of odor thresholds for selected chemicals.

Olfactory sensitivity often makes it possible to detect potentially harmful substances at concentrations below dangerous levels so that they can be eliminated. Foul-smelling air is often assumed to be unhealthy. In reality, however, there is little correlation between odor perception and toxicity, and there is considerable individual variation in the perception of pleasantness/unpleasantness of odors. When symptoms such as nausea, headache, and loss of appetite are caused by an unpleasant odor, it may not matter whether the air is toxic but whether the odor is perceived to be unpleasant, associated with an unpleasant experience, or simply felt to be out of appropriate context. The magnitude of the symptoms is related to the magnitude of the odor. Even a room with a low but recognizable odor can arouse uneasiness among occupants. Several papers review sensory irritation and its relation to indoor air pollution (Cain and Cometto-Muñiz 1995; Cometto-Muñiz and Cain 1992; Cometto-Muñiz et al. 1997; Shams Esfandabad 1993).

### Anatomy and Physiology

The **olfactory receptors** lie in the **olfactory cleft**, which is high in the nasal cavity. About five million olfactory **neurons** (a small cluster of nerve cells inside the nasal cavity above the bridge of the nose) each send an **axon** (an extension of the neuron) into the olfactory bulb of the brain. Information received from the receptors is passed to various central structures of the brain (e.g., the olfactory cortex, the hippocampus, and the amygdala). One sniff of an odorant can often evoke a complex, emotion-laden memory, such as a scene from childhood.

The surrounding nasal tissue contains other diffusely distributed nerve endings of the trigeminal nerve that also respond to airborne vapors. These receptors mediate the chemosensory responses such as tickling, burning, cooling, and, occasionally, painful sensations that accompany olfactory sensations. Most odorous substances at sufficient concentration will also stimulate these nerve endings.

### Olfactory Acuity

The olfactory acuity of the population is normally distributed. Most people have an average ability to smell substances or to respond to odoriferous stimuli, a few people are very sensitive or hypersensitive, and a few others are insensitive, including some who are totally unable to smell (**anosmic**). The olfactory acuity of an individual varies with the odorant.

Hormonal factors, which often influence emotional states, can modulate olfactory sensitivity. Although the evidence is not uniformly compelling, research has found that (1) the sensitivity of females varies during the menstrual cycle, reaching a peak just before and during ovulation (Schneider 1974); (2) females are generally more sensitive than males, but this difference only emerges around the time of sexual maturity (Koelega and Koster 1974); (3) sensitivity is altered by certain diseases (Schneider 1974); and (4) various hormones and drugs (e.g., estrogen and alcohol) alter sensitivity (Schneider 1974; Engen et al. 1975).

Other factors that may affect olfactory perception include the olfactory acuity of an individual, the magnitude of the flow rate toward the olfactory receptors, the temperature, and the relative humidity. Olfactory acuity can also vary with age (Stevens et al. 1989; Wysocki and Gilbert 1989), genetics (Wysocki and Beauchamp 1984), exposure history (Dalton and Wysocki 1996; Wysocki et al. 1997), and disease or injury (Coward et al. 1993,

1997). Humans are able to perceive a large number of odors, yet untrained individuals are able to name only a few (Ruth 1986).

Individuals exhibiting a total inability to detect odors are relatively rare (Coward et al. 1997). A more common occurrence is an inability to detect one or a very limited number of odors, a condition known as **specific anosmia**. Although the huge number of possible chemicals makes for an untestable hypothesis, it has been posited that most, if not all, individuals have a specific anosmia to one or more compounds (Wysocki and Beauchamp 1984). The fact that individuals with specific anosmias have normal olfactory acuity for all other odors suggests that such anosmias may be due to genetic differences.

Olfactory science uses the term **adaptation** to refer to decreased sensitivity or responsiveness to an odor as a function of prolonged exposures. Such exposure can selectively impair the perception of the exposure odorant, but there are also examples of cross-adaptation, where exposure to one odorant can result in adaptation to other odors as well. Adaptation can occur in the short term, where the perception of a room's odor begins to fade within seconds of entering the room (Cometto-Muñiz and Cain 1995; Pierce et al. 1996). With long-term adaptation, an individual who habitually returns to the same environment does not smell odors that are quite discernible to a naive observer. This effect appears to shift both the threshold and the **suprathreshold** (stimuli above the threshold level) response to the odor (Dalton and Wysocki 1996). This is an important phenomenon for indoor air quality (IAQ) personnel to be aware of because it is often one of the biggest reasons for the variation in detectability or response in real-world environments and makes the choice of test population or panelists for air quality evaluations a critical one.

## FACTORS AFFECTING ODOR PERCEPTION

### Humidity and Temperature

Temperature and humidity can both affect the perception of odors. Cain et al. (1983) reported that a combination of high temperature (25.5°C) and high humidity exacerbates odor problems. Berglund and Cain (1989) found that air was generally perceived to be fresher and less stuffy with decreasing temperature and humidity. Fang et al. (1998a,b) and Toftum (1998) found little or no increase in odor intensity with increasing enthalpy (temperature and humidity) but reported a very significant decrease in odor acceptability with increasing enthalpy.

Not all researchers have supported these findings. Kerka and Humphreys (1956) reported a decrease in odor intensity with increasing humidity. Berg-Munch and Fanger (1982) found no increase in odor intensity with increasing temperature (23 to 32°C). Clausen et al. (1985) found no significant change in odor intensity with increasing relative humidity (30% to 80%).

While the findings are not homogeneous, they do show that temperature and humidity can act together to affect one's perception of odors. Air that is cooler and drier is generally perceived to be fresher and more acceptable even if the odor intensity is not affected.

### Sorption and Release of Odors

Due to sorption of odors by furnishings and interior surfaces during occupancy, with later desorption, spaces frequently retain normal occupancy odor levels long after occupancy has ceased. This phenomenon is observed when furnaces or radiators, after a long shutdown, are heated at winter start-up and when evaporator coils warm up. The rate of desorption can be decreased by decreasing temperature and relative humidity, and increased (as for cleaning) by the reverse.

Environmental tobacco smoke may desorb from surfaces long after smoking has taken place. This phenomenon has caused many hotels to establish nonsmoking rooms.

Where the odor source is intrinsic to the materials (as in linoleum, paint, rubber, and upholstery), reducing the relative humidity decreases the rate of odor release. Quantitative values should not be used without considering the sorption-desorption phenomenon.

### Emotional Responses to Odors

There can be considerable variation between individuals regarding the perceived pleasantness or unpleasantness of a given odor. Responses to odors may be determined by prior experiences and can include strong emotional reactions. This is because one of the brain structures involved in the sense of smell is the **amygdala**, a regulator of emotional behaviors (Frey 1995). Some IAQ complaints can involve emotional responses completely out of proportion to the concentration of the odorant or the intensity of the odor it produces.

Two theories describe physiological reasons for these strong responses. One of these is **kindling**, in which repeated, intermittent stimuli produce an amplification of nerve responses. The other is **response facilitation**, in which an initial stimulus perceived as strong is facilitated (becomes greater) rather than adapted to (Frey 1995).

Because of this emotional aspect, IAQ complaints involving odors can be very difficult to solve, especially if they are coming from a few sensitized individuals. It is important to respond quickly to complaints in order to minimize the risk of kindling or response facilitation.

### ODOR SENSATION ATTRIBUTES

Odor sensation has four components or attributes: detectability, intensity, character, and hedonic tone.

**Detectability** (or **threshold**) is the minimum concentration of an odorant that provokes detection by some predetermined segment of the population. Two types of thresholds exist: the detection threshold and the recognition threshold.

The **detection threshold** is the lowest level that elicits response by a segment of the population. If that segment is 50%, the detection threshold is denoted by ED<sub>50</sub>. **Recognition threshold** is the lowest level at which a segment of the population can recognize a given odor. Thresholds can be attributed to 100%, which includes all olfactory sensitivities, or to 10%, which includes only the most sensitive segment of the population. Threshold values are not physical constants; rather they are statistical measurements of best estimates.

**Intensity** is a quantitative aspect of a descriptive analysis, stating the degree or magnitude of the perception elicited. Intensity of the perceived odor is, therefore, the strength of the odoriferous sensation. Detection threshold values and, most often, odor intensity determine the need for indoor odor controls.

**Character** defines the odor as similar to some familiar smell (e.g., fishy, sour, flowery, and the like). **Hedonics**, or the hedonic tone of an odor, is the degree to which an odor is perceived as pleasant or unpleasant. Hedonic judgments include both a *category* judgment (pleasant, neutral, unpleasant) and a *magnitude* judgment (very unpleasant, slightly pleasant).

Important questions are

1. What is the minimum concentration of odorant that can be detected?
2. How does perceived odor magnitude grow with concentration above the threshold?

No universal method has been accepted to measure either the threshold or the perceived magnitude of the odor above threshold. However, certain guidelines and conventions simplify the choice of methods.

### Detectability

The perception of weak odoriferous signals is probabilistic: at one moment odor may be perceptible, and at the next moment it may not.

Factors affecting this phenomenon include the moment-to-moment variability in the number of molecules striking the olfactory receptors, the variability in which of the receptors are stimulated, the concentration of the odor, the individual's style of breathing, and the individual's previous experience with the odor. The combined effect of these factors may prevent an individual from perceiving an odor during the entire time of the stimulus. During odor evaluation, dilution to detection or recognition threshold values allows determination of the largest number of dilutions that still permits half of the panelists to detect or recognize the odor.

**Determination of Odor Thresholds.** Odor threshold testing is over a century old. The process is complex, and several different methods are used. Partly due to variations in measurement techniques, reported threshold values can vary by several orders of magnitude for a given substance. In order to minimize variation due to experimental techniques, a standard set of criteria has been developed. These criteria include the panel, the presentation apparatus, and the presentation method (AIHA 1989; EPA 1992).

The **panel** should

- Include at least six members per group.
- Be selected based on odor sensitivity. Factors to be considered include anosmia, pregnancy, drug use, and smoking.
- The panel should be calibrated to document individual and group variability.

Considerations concerning the **presentation apparatus** include

- Vapor modality—choice of a gas-air mixture, water vapor, or other substance.
- Diluent—choice of diluent (e.g., air, nitrogen), how it is treated, and what its source is.
- Presentation mode—delivery systems can be nose ports, vents into which the head is inserted, flasks, whole rooms.
- Analytic measurement of odorant concentration.
- System calibration—flow rate and face velocity. Flow rate should be approximately 0.05 L/s. Face velocity should be low enough to be barely perceptible to the panelists.

Criteria for the **presentation method** include

- Threshold type—detection or recognition.
- Concentration presentation—this must take adaptation into account. Presenting ascending concentrations or allowing longer periods between concentrations helps avoid adaptation.
- Number of trials—test-retest reliability for thresholds is low. Increasing the number of trials helps correct for this.
- Forced-choice procedure—panelists must choose between the stimuli and one or two blanks. This helps eliminate false positive responses.
- Concentration steps—odorant should be presented successively at concentrations no more than three times the preceding one.

For more details regarding psychophysical procedures, ways to sample odoriferous air, handling samples, means of stimulus presentation, and statistical procedures, consult ASTM STP 434.

### Intensity

**Psychophysical Power Law.** The relation between **perceived odor magnitude**  $S$  and **concentration**  $C$  conforms to a power function:

$$S = kC^n \quad (1)$$

where

$S$  = perceived intensity (magnitude) of sensation

$k$  = characteristic constant

$C$  = odorant concentration

$n$  = exponent of psychophysical function (slope on a log-log scale)

This exemplifies the psychophysical power law, also called **Stevens' law** (Stevens 1957). In the olfactory realm,  $n < 1.0$ . Accordingly, a given percentage change in odorant concentration causes a smaller percentage change in perceived odor magnitude.

**Scaling Methods.** Of the various ways to scale perceived magnitude, a **category scale**, which can be either number- or word-categorized, is commonly used. Numerical values on this scale do not reflect ratio relations among odor magnitudes (e.g., a value of 2 does not represent a perceived magnitude twice as great as a value of 1). Table 2 gives four examples of category scales.

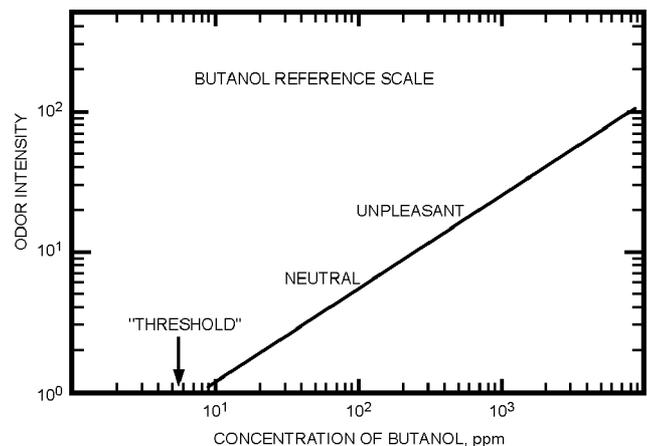

Although category scaling procedures can be advantageous in field situations, **ratio scaling** techniques are used frequently in the laboratory (Cain and Moskowitz 1974). Ratio scaling procedures require observers to assign numbers proportional to perceived magnitude. For example, if the observer is instructed to assign the number 10 to one concentration and a subsequently presented concentration seems three times as strong, the observer calls it 30; if another seems one-half as strong, the observer assigns it 5. This ratio scaling procedure, called **magnitude estimation**, was used to derive the power function for butanol (Figure 1). Ratio scaling techniques allow for such relationships because they require subjects to produce numbers to match perceived sensations in which the numbers emitted reflect the ratio relations among the sensations.

More recently, a hybrid of category and ratio scales known as the **labeled magnitude scale** has been developed (Green et al. 1996). This scale is intended to yield ratio-level data with a true zero and an orderly relationship among the scale values, such that any stimulus can be expressed as being proportionately more or less intense than another. Because it allows subjects to use natural language descriptors to scale perceived experience, it often requires less training than ratio scales and produces absolute intensity estimates of perceived sensation (Figure 2).

**Table 2 Examples of Category Scales**

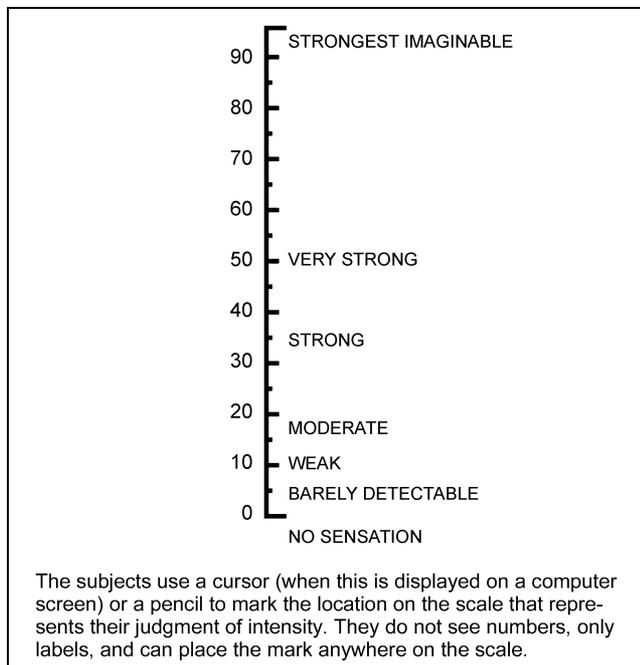

Number Category		Word Category	
Scale I	Scale II	Scale I	Scale II
0	0	None	None at all
1	1	Threshold	Just detectable
2	2.5	Very slight	Very mild
3	5	Slight	Mild
4	7.5	Slight-moderate	Mild-distinct
5	10	Moderate	Distinct
6	12.5	Moderate-strong	Distinct-strong
7	15	Strong	Strong

Source: Meilgaard et al. (1987).

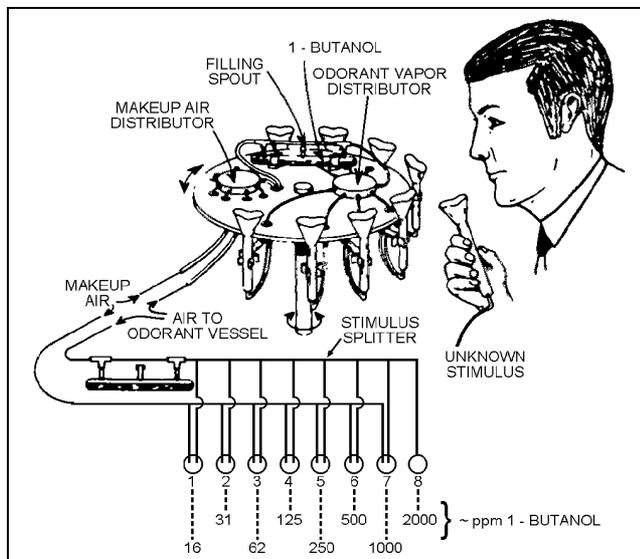

**Fig. 1 Standardized Function Relating Perceived Magnitude to Concentration of 1-Butanol**  
(Moskowitz et al. 1974)

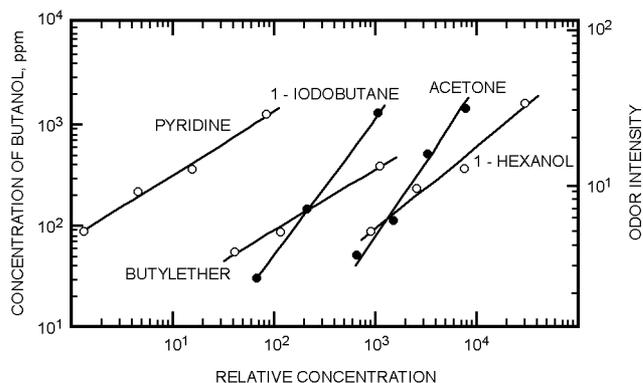

A fourth way to measure suprathreshold odor intensity is to **match the intensity of odorants**. An observer can be given a concentration series of a matching odorant (e.g., 1-butanol) to choose the member that matches most closely the intensity of an *unknown* odorant. The matching odorant can be generated by a relatively inexpensive olfactometer such as that shown in Figure 3. Figure 4 shows, in logarithmic coordinates, functions for various odorants obtained by the matching method (Dravnieks and Laffort 1972). The left-hand ordinate expresses intensity in terms of concentration of butanol, and the right-hand ordinate expresses intensity in terms of perceived magnitude. The two ordinates are related by the function in Figure 1, the standardized function for butanol. The matching method illustrated here has been incorporated into ASTM

**Fig. 2 Labeled Magnitude Scale**

Standard E 544, Standard Practices for Referencing Suprathreshold Odor Intensity.

### Character

The quality or character of an odor is difficult to assess quantitatively. A primary difficulty is that odors can vary along many dimensions. One way to assess quality is to ask panelists to judge the similarity between a test sample and various reference samples, using a five-point category scale. For certain applications, reference odorants can be chosen to represent only that portion of the qualitative range relevant to the odor problem under investigation (e.g., animal odors). Another procedure is to ask panelists to assess the degree of association between a test sample's quality and certain verbal descriptors (e.g., sweaty, woody, chalky, sour).

The number of odorant descriptors and the descriptors to be used have been subjects of disagreement (Harper et al. 1968). The number of descriptors varies from a minimum of seven (Amoore 1962) to as many as 830 used by an ASTM subcommittee. An atlas of odor characters, containing 146 descriptors, was compiled for 180 chemicals by ASTM (1985).

An odor can be characterized either by an open-ended word description or by multidimensional scaling. **Multidimensional scaling** is based on similarity and dissimilarity judgments in comparison to a set of standard odors or to various descriptors.

In some instances, the interest may be merely whether an odor's quality has changed as a result of some treatment (e.g., use of a bacteriostat). Under these circumstances, samples of air taken before and after treatment can be compared directly (using a simple scale of similarity) or indirectly (with appropriate verbal descriptors).

### Hedonics

The acceptability or pleasantness of an odor can be measured psychophysically in the same way as odor intensity. Both ratio and category scaling procedures can be adapted to odor acceptability.

Odors do not always cause adverse reactions. Products are manufactured to elicit favorable responses. Acceptance tests may involve product comparison (frequently used in the perfume industry) or a hedonic scale. The premise of acceptance tests is that the larger the segment of subjects accepting the odor, the better the odor. A hedonic scale that allows for negative as well as positive responses is likely to better answer the question of how acceptable the odor is.

All persons exposed to a given odor are not likely to agree on its acceptability. Acceptability of a given odor to a person is based on a complex combination of associations and is not simply a characteristic of the odor itself (Beck and Day 1991). Responses to odors are determined by both **bottom-up factors** (attributes or properties of the odorant) and **top-down factors** (expectations, attitudes, and

associations from prior experience stored in memory, and appropriateness of the odor in its present context). Both of these factors are activated when an individual detects an odor, and the individual's ultimate response (e.g., perception of intensity, hedonics, irritation, or symptoms) is a joint function of both (Dalton 1996; Dalton et al. 1997). In some cases, the interpretation provided by the top-down process appears to override the outcome from the bottom-up process, resulting in complaints, symptoms, and reports of illness.

### DILUTION OF ODORS BY VENTILATION

The size of the exponent  $n$  in Stevens' law [Equation (1)] varies from one odorant to another, ranging from less than 0.2 to about 0.7 (Cain and Moskowitz 1974). This determines the slope or dose response of the odor intensity/odorant concentration function and has important consequences for malodor control. A low slope value indicates an odor that requires greater relative dilution for the odor to dissipate; a high slope value indicates an odor that can be more quickly reduced by ventilation. For example, an exponent of 0.7 implies that in order to reduce perceived intensity by a factor of 5, the concentration must be reduced by a factor of 10; an exponent of 0.2 implies that a reduction in perceived magnitude by a factor of 5 would require a reduction in concentration by a factor of more than 3000. Examples of compounds with low slope values include hydrogen sulfide, butyl acetate and amines. Compounds with high slope values include ammonia and aldehydes.

The ability of ventilation to control odors also depends on the strength of the source generating the odorant(s) and the nature of the odor. An odorant with a stronger source requires proportionately more ventilation to achieve the same reduction in concentration. Odors that are perceived as unpleasant may require substantially greater reduction before being perceived as acceptable. In addition, some sources, such as painted walls and flooring materials, may show increased emission rates in response to increased ventilation rates, which further complicates this picture (Gunnarsen 1997).

### ODOR CONCENTRATION

#### Analytical Measurement

Performance data on the control of specific odorants can be obtained using suitable analytical methods. Detectors permit detection of substances in amounts as little as 1 ng. Air contains many minor components, so gas chromatographic separation of the components must precede detection. Because odor thresholds for some compounds are low, preconcentration of the minor components is necessary. **Preconcentration** consists of adsorption or absorption by a stable, sufficiently nonvolatile material, followed by thermal desorption or extraction. The state of the art for sampling and analysis of VOCs in indoor air is reviewed in NIOSH (1993).

**Mass spectrometry** can be used with **gas chromatography** to identify constituents of complex mixtures. The chromatograph resolves a mixture into its constituents, and the spectrometer provides identification and concentration of selected constituents.

Several other detectors are sufficiently sensitive and specific to detect resolved components. **Hydrogen flame ionization detectors** respond adequately and nearly mass-proportionally to almost all organic compounds. **Flame photometric detectors** can pinpoint with equal sensitivity compounds that contain sulfur; many sulfur compounds are strongly odorous and are of interest in odor work. A **Coulson conductometric detector** is specifically and adequately sensitive to ammonia and organic nitrogen compounds. **Thermal conductivity detectors** are generally not sensitive enough for analytical work on odors.

Frequently, a **sniffing port** (Dravnieks and O'Donnell 1971; Dravnieks and Krotoszynski 1969) is installed in parallel with the detector(s). Part of the resolved effluent exhausts through the port and allows the components that are particularly odorous or carry

some relevant odor quality to be annotated. Usually, only a fraction of all components studied exhibits odors.

Airborne VOCs cause odors, but the correlation between indoor VOC concentrations and odor complaints in indoor environments is poor. Considerable work is being done on **artificial noses**, which may be the future of objective determination of odorants (Bartlett et al. 1997; Freund and Lewis 1995; Moy et al. 1994; Taubes 1996). However, because the physicochemical correlates of olfaction are poorly understood, no simple analytical means to predict the perceived quality and intensity of an odorant exists. Moreover, since acceptability of an odorant depends strongly on context, it is unlikely that analytical instruments will supplant human evaluation.

**Odor Units**

Odor concentration can be expressed as the number of unit volumes that a unit volume of odorous sample occupies when diluted to the odor threshold with nonodorous air. If a sample of odorous air can be reduced to threshold by a tenfold dilution with pure air, the concentration of the original sample is said to be 10 odor units. Hence, odor units are equivalent to multiples of threshold concentrations. Odor units are not units of perceived magnitude.

**Odor units** are widely used to express legal limits for emission of odoriferous materials. For example, the law may state that a factory operation may not cause the ambient odor level to exceed 15 odor units. For every odorant (chemical), odor units and parts per million (ppm) are proportional. The proportionality constant varies from one odorant to another, depending on the number of ppm needed to evoke a threshold response. Perceived odor magnitude (intensity), however, does not grow proportionally with concentration expressed in ppm. Therefore, it cannot grow proportionally with concentration expressed in odor units. For example, a sample of 20 odor units is always perceived as less than twice as strong as a sample of 10 odor units. Moreover, because the psychophysical function (slope) varies from one odorant to another, samples of two odorants, each at 20 odor units, may have unequal perceived intensities.

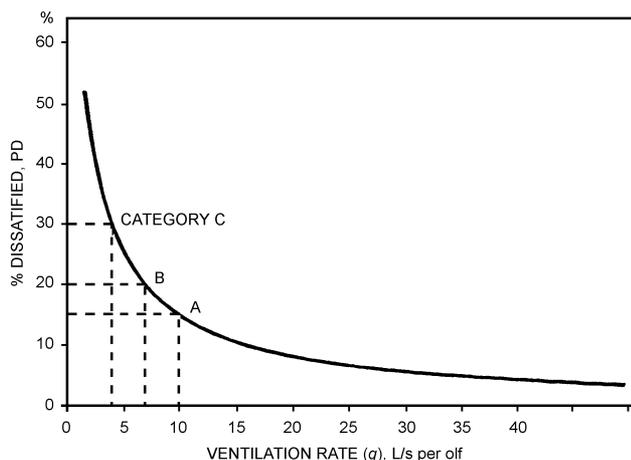

Although odor units are not equivalent to units of perceived magnitude, they can be useful. Most indoor and outdoor contaminants are complex mixtures, so that the actual concentration of the odoriferous portion of a sample cannot be expressed with certainty. Thus, the odor unit is a useful measure of concentration of the mixture when evaluating, for example, the efficiency of a filter or ventilation system to remove or dilute the odor.

**OLF UNITS**

Sometimes IAQ scientists cannot successfully resolve complaints about the air in offices, schools, and other nonindustrial environments. Customarily, complaints are attributed to elevated pollutant concentrations; frequently, however, such high concentrations are not found, yet complaints persist.

On the assumption that the inability to find a difference between air pollutant levels in buildings with registered complaints and those without complaints is due to inadequacies of prevailing measurement techniques, Fanger and others changed the focus from chemical analysis to sensory analysis (Fanger 1987, 1988; Fanger et al. 1988). Fanger quantified air pollution sources by comparing them with a well-known source: a sedentary person in thermal comfort. A new unit, the olf, was introduced. An **olf** is defined as the emission rate of air pollutants (bioeffluents) from a standard person. A **decipol** is one olf ventilated at a rate of 10 L/s of unpolluted air.

To use these units, Fanger generated a curve that relates the percentage of persons dissatisfied with air polluted by human bioeffluents as a function of the outdoor air ventilation rate and obtained the following expression:

**Fig. 5 Percentage of Dissatisfied Persons as a Function of Ventilation Rate per Standard Person (i.e., per Olf) (CEN 1998)**

**Table 3 Sensory Pollution Load from Different Pollution Sources**

Source	Sensory Load
Sedentary person (1 to 1.5 met)	1 olf
Person exercising	
Low level (3 met)	4 olf
Medium level (6 met)	10 olf
Children, kindergarten (3 to 6 yrs)	1.2 olf
Children, school (4 to 16 yrs)	1.3 olf
Low-polluting building	0.1 olf/m <sup>2</sup>
Non-low-polluting building	0.2 olf/m <sup>2</sup>

Source: CEN (1998).

$$\begin{aligned}
 D &= 395 \exp(-1.83q^{0.26}) && \text{for } q \geq 0.332 \\
 D &= 100 && \text{for } q < 0.332
 \end{aligned}
 \tag{2}$$

where

D = percentage of persons dissatisfied  
 q = ventilation-emission ratio, L/s per olf

This curve, which is shown in Figure 5, is based on experiments involving more than 1000 European subjects (Fanger and Berg-Munch 1983). Experiments with American (Cain et al. 1983) and Japanese (Iwashita et al. 1990) subjects show very similar results.

The idea behind the olf concept is that sensory sources other than humans also be expressed in equivalent standard persons (i.e., in olfs). A room should therefore be ventilated to handle the total sensory load from persons and building. The olf concept is used in European publications for ventilation (CEN 1998; ECA 1992) to determine the required ventilation and in several national standards (DIN 1994; Norwegian Building Code 1996). Table 3 shows the sensory loads from different pollution sources used in CEN (1998).

**Example.** Office, low-polluting building, occupancy 0.07 persons/m<sup>2</sup>

Occupants	0.07 olf/m <sup>2</sup>
Building	0.1 olf/m <sup>2</sup>
<b>Total sensory load</b>	<b>0.17 olf/m<sup>2</sup></b>

30% dissatisfied requires 4 L/s per olf ventilation rate (Figure 5)  
 Required ventilation: 4 × 0.17 = 0.7 L/(s·m<sup>2</sup>)

The sensory load on the air in a space can be determined from Figure 5 by measuring the outdoor ventilation rate and determining the percent dissatisfied, using an untrained panel with a minimum of 20 impartial persons (ASHRAE *Standard 62*; Gunnarsen and Fanger 1992). The panel judges the acceptability of the air just after entering the space. The required ventilation rate depends on the desired percentage of occupant satisfaction. In ASHRAE *Standard 62*, 80% acceptability (20% dissatisfied) is the goal; European guidelines offer three quality levels: 15%, 20%, and 30% dissatisfied.

Although this system has much to offer from a theoretical standpoint, its use is controversial in some areas. Problems have been found in cultural differences among panel members and access to outdoor air for dilution (Aizlewood et al. 1996). The trend is now to use untrained panels as described in the previous paragraph. Knudsen et al. (1998) have shown that the curve giving the relation between percent dissatisfied and ventilation rate for some building materials is less steep than that in Figure 5, while other materials show a steeper curve. The sensory load in this case depends on the ventilation rate. The constant sensory loads given in Table 3 should therefore be seen as a first approximation.

**H**EATING, refrigerating, and air-conditioning engineers and technicians require instruments for both laboratory work and fieldwork. Precision is more essential in the laboratory, where research and development are undertaken, than in the field, where acceptance and adjustment tests are conducted. This chapter describes the characteristics and uses of some of these instruments.

## TERMINOLOGY

The following definitions are generally accepted.

**Accuracy.** The capability of an instrument to indicate the true value of measured quantity. This is often confused with inaccuracy, which is the departure from the true value to which all causes of error (e.g., hysteresis, nonlinearity, drift, temperature effect, and other sources) contribute.

**Amplitude.** The magnitude of variation from its zero value in an alternating quantity.

**Average.** The sum of a number of values divided by the number of values.

**Bandwidth.** The range of frequencies over which a given device is designed to operate within specified limits.

**Bias.** The tendency of an estimate to deviate in one direction from a true value (a systematic error).

**Calibration.** (1) The process of comparing a set of discrete magnitudes or the characteristic curve of a continuously varying magnitude with another set or curve previously established as a standard. Deviation between indicated values and their corresponding standard values constitutes the correction (or calibration curve) for inferring true magnitude from indicated magnitude thereafter; (2) the process of adjusting an instrument to fix, reduce, or eliminate the deviation defined in (1).

**Calibration curve.** (1) The path or locus of a point that moves so that its coordinates on a graph correspond to values of input signals and output deflections; (2) the plot of error versus input (or output).

**Confidence.** The degree to which a statement (measurement) is believed to be true.

**Dead band.** The range of values of the measured variable to which an instrument will not effectively respond.

**Deviate.** Any item of a statistical distribution that differs from the selected measure of control tendency (average, median, mode).

**Deviation, standard.** The square root of the average of the squares of the deviations from the mean (root mean square deviation). A measure of dispersion of a population.

**Distortion.** An unwanted change in wave form. Principal forms of distortion are inherent nonlinearity of the device, nonuniform response at different frequencies, and lack of constant proportionality between phase-shift and frequency. (A wanted or intentional change might be identical, but it is called **modulation**.)

**Drift.** A gradual, undesired change in output over a period of time that is unrelated to input, environment, or load. Drift is gradual; if variation is rapid, the fluctuation is referred to as **cycling**.

**Dynamic error band.** The spread or band of output-amplitude deviation incurred by a constant amplitude sine wave as its frequency is varied over a specified portion of the frequency spectrum (see *Static error band*).

**Error.** The difference between the true or actual value to be measured (input signal) and the indicated value (output) from the measuring system. Errors can be systematic or random.

**Error, accuracy.** See *Error, systematic*.

**Error, fixed.** See *Error, systematic*.

**Error, instrument.** The error of an instrument's measured value that includes random or systematic errors.

**Error, precision.** See *Error, random*.

**Error, probable.** An error with a 50% or higher chance of occurrence. A statement of probable error is of little value.

**Error, random.** A statistical error caused by chance and not recurring. This term is a general category for errors that can take values on either side of an average value. To describe a random error, its distribution must be known.

**Error, root mean square, or RMS.** An accuracy statement of a system comprising several items. For example, a laboratory potentiometer, volt box, null detector, and reference voltage source have individual accuracy statements assigned to them. These errors are generally independent of one another, so a system of these units displays an accuracy given by the square root of the sum of the squares of the individual limits of error. For example, four individual errors of 0.1% yield a calibrated accuracy of 0.4% but an RMS error of only 0.2%.

**Error, systematic.** A persistent error not due to chance; systematic errors are causal. A systematic error is likely to have the same magnitude and sign for every instrument constructed with the same components and procedures. Errors in calibrating equipment cause systematic errors because all instruments calibrated are biased in the direction of the calibrating equipment error. Voltage and resistance drifts over time are generally in one direction and are classed as systematic errors.

**Frequency response (flat).** The portion of the frequency spectrum over which the measuring system has a constant value of amplitude response and a constant value of time lag. Input signals that have frequency components within this range are indicated by the measuring system (without distortion).

The preparation of this chapter is assigned to TC 1.2, Instruments and Measurements.

**Hysteresis.** The summation of all effects, under constant environmental conditions, that cause the output of an instrument to assume different values at a given stimulus point when that point is approached with increasing stimulus and with decreasing stimulus. Hysteresis includes backlash. It is usually measured as a percent of full scale when input varies over the full increasing and decreasing range. In instrumentation, hysteresis and dead band are similar quantities.

**Linearity.** The straight-lineness of the transfer curve between an input and an output; that condition prevailing when output is directly proportional to input (see *Nonlinearity*).

**Loading error.** A loss of output signal from a device caused by a current drawn from its output. It increases the voltage drop across the internal impedance, where no voltage drop is desired.

**Mean.** See *Average*.

**Median.** The middle value in a distribution, above and below which lie an equal number of values.

**Noise.** Any unwanted disturbance or spurious signal that modifies the transmission, measurement, or recording of desired data.

**Nonlinearity.** The prevailing condition (and the extent of its measurement) under which the input-output relationship (known as the input-output curve, transfer characteristic, calibration curve, or response curve) fails to be a straight line. Nonlinearity is measured and reported in several ways, and the way, along with the magnitude, must be stated in any specification.

*Minimum-deviation-based nonlinearity.* The maximum departure between the calibration curve and a straight line drawn to give the greatest accuracy; expressed as a percent of full-scale deflection.

*Slope-based nonlinearity.* The ratio of maximum slope error anywhere on the calibration curve to the slope of the nominal sensitivity line; usually expressed as a percent of nominal slope.

Most variations beyond these two definitions result from the many ways in which the straight line can be arbitrarily drawn. All are valid as long as construction of the straight line is explicit.

**Population.** A group of individual persons, objects, or items from which samples may be taken for statistical measurement.

**Precision.** The repeatability of measurements of the same quantity under the same conditions; not a measure of absolute accuracy. The precision of a measurement is used here to describe the relative tightness of the distribution of measurements of a quantity about their mean value. Therefore, precision of a measurement is associated more with its repeatability than its accuracy. It combines uncertainty caused by random differences in a number of identical measurements and the smallest readable increment of the scale or chart. Precision is given in terms of deviation from a mean value.

**Primary calibration.** A calibration procedure in which the instrument output is observed and recorded while the input stimulus is applied under precise conditions—usually from a primary external standard traceable directly to the National Institute of Standards and Technology (NIST).

**Range.** A statement of the upper and lower limits between which an instrument's input can be received and for which the instrument is calibrated.

**Reliability.** The probability that an instrument's precision and accuracy will continue to fall within specified limits.

**Repeatability.** See *Precision*.

**Reproducibility.** In instrumentation, the closeness of agreement among repeated measurements of the output for the same value of input made under the same operating conditions over a period of time, approaching from both directions; it is usually measured as a nonreproducibility and expressed as reproducibility in percent of span for a specified time period. Normally, this implies a long period of time, but under certain conditions, the period may be a short time so that drift is not included. Reproducibility includes hysteresis, dead band, drift, and repeatability. Between repeated measurements, the input may vary over the range, and operating conditions may vary within normal limits.

**Resolution.** The smallest change in input that produces a detectable change in instrument output. Resolution differs from precision in that it is a psychophysical term referring to the smallest increment of humanly perceptible output (rated in terms of the corresponding increment of input). The precision, the resolution, or both may be better than the accuracy. An ordinary six-digit (or dial) instrument has a resolution of one part per million (ppm) of full scale; however, it is possible that the accuracy is no better than 25 ppm (0.0025%). Note that the practical resolution of an instrument cannot be any better than the resolution of the indicator or detector, whether internal or external.

**Scale factor.** (1) The amount by which a measured quantity must change to produce unity output; (2) the ratio of real to analog values.

**Sensitivity.** The property of an instrument that determines scale factor. The word is often short for maximum sensitivity or the minimum scale factor with which an instrument can respond. The minimum input signal strength required to produce a desired value of output signal (e.g., full scale or unit output or the ratio of output to input values).

**Sensitivity inaccuracy.** The maximum error in sensitivity displayed as a result of the summation of the following: frequency response; attenuator inaccuracy; hysteresis or dead band; amplitude distortion (sensitivity nonlinearity); phase distortion (change in phase relationship between input signal and output deflection); and gain instability. Only by taking into account all these factors can nominal sensitivity, as indicated by the numeral on the attenuator readout, be discounted for accurate interpretation.

**Stability.** (1) Independence or freedom from changes in one quantity as the result of a change in another; (2) the absence of drift.

**Static error band.** (1) The spread of error present if the indicator (pen, needle) stopped at some value (e.g., at one-half of full scale). It is normally reported as a percent of full scale; (2) a specification or rating of maximum departure from the point where the indicator must be when an on-scale signal is stopped and held at a given signal level. This definition stipulates that the stopped position can be approached from either direction in following any random waveform. Therefore, it is a quantity that includes hysteresis and nonlinearity but excludes items such as chart paper accuracy or electrical drift (see *Dynamic error band*).

**Step-function response.** The characteristic curve or output plotted against time resulting from the input application of a step function (a function that is zero for all values of time before a certain instant, and a constant for all values of time thereafter).

**Threshold.** The smallest stimulus or signal that results in a detectable output.

**Time constant.** The time required for an exponential quantity to change by an amount equal to 0.632 times the total change required to reach steady state for first-order systems.

**Transducer.** A device for translating the changing magnitude of one kind of quantity into corresponding changes of another kind of quantity. The second quantity often has dimensions different from the first and serves as the source of a useful signal. The first quantity may be considered an input and the second an output. Significant energy may or may not transfer from the transducer's input to output.

**Uncertainty.** An estimated value for the error (i.e., what an error might be if it were measured by calibration). Although uncertainty may be the result of both systematic and precision errors, only precision error can be treated by statistical methods.

**Zero shift.** Drift in the zero indication of an instrument without any change in the measured variable.

## UNCERTAINTY ANALYSIS

### Uncertainty Sources

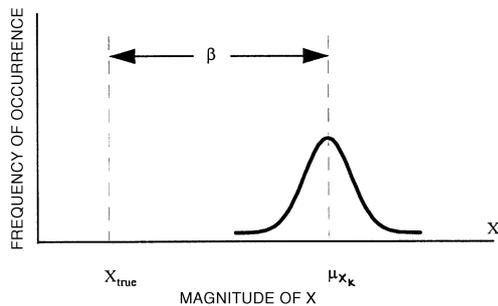

Measurement generally consists of a sequence of operations or steps. Virtually every step introduces a conceivable source of uncertainty, the effect of which must be assessed. The following list is representative of the most common, but not all, sources of uncertainty.

- Inaccuracy in the mathematical model that describes the physical quantity
- Inherent stochastic variability of the measurement process
- Uncertainties in measurement standards and calibrated instrumentation
- Time-dependent instabilities due to gradual changes in standards and instrumentation
- Effects of environmental factors such as temperature, humidity, and pressure
- Values of constants and other parameters obtained from outside sources
- Uncertainties arising from interferences, impurities, inhomogeneity, inadequate resolution, and incomplete discrimination
- Computational uncertainties and data analysis
- Incorrect specifications and procedural errors
- Laboratory practice, including handling techniques, cleanliness, and operator techniques, etc.
- Uncertainty in corrections made for known effects, such as installation effect corrections

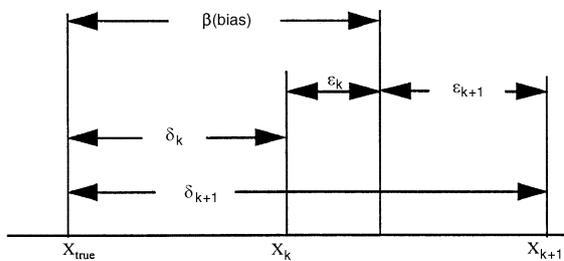

**Uncertainty of a Measured Variable**

For a measured variable  $X_i$ , the total error is caused by both **precision (random)** and **systematic (bias) errors**. This relationship is shown in Figure 1. The possible measurement values of the variable are scattered in a distribution around the parent population mean  $\mu_i$  (Figure 1A). The curve is the normal or Gaussian distribution and is the theoretical distribution function for the infinite population of measurements that generated  $X_i$ . The parent population mean differs from  $(X_i)_{true}$  by an amount called the systematic (or bias) error  $\beta_i$  (Figure 1B). The quantity  $\beta_i$  is the total fixed error that remains after all calibration corrections have been made. In general, there are several sources of bias error, such as calibration standard errors, data acquisition errors, data reduction errors, and test technique errors. There is usually no direct way to measure these errors. These errors are unknown and are assumed to be zero; otherwise, an additional correction would be applied to reduce them to as close to zero as possible.

The **precision uncertainty** for a variable, which is an estimate of the possible error associated with the repeatability of a particular

A. INFINITE NUMBER OF READINGS

B. TWO READINGS

**Fig. 1 Errors in the Measurement of a Variable X**

measurement, is determined from the sample standard deviation, or the estimate of the error associated with the repeatability of a particular measurement. Unlike the systematic error, the precision error varies from reading to reading. As the number of readings of a particular variable tends to infinity, the distribution of these possible errors becomes Gaussian.

For each bias error source, the experimenter must estimate a **systematic uncertainty**. Systematic uncertainties are usually estimated from previous experience, calibration data, analytical models, and engineering judgment. For a discussion on estimating systematic uncertainties (bias limits), see Coleman and Steele (1989).

For further information on measurement uncertainty, see ASME Standards MFC-2M and PTC 19.1 and Coleman and Steele (1995).

**TEMPERATURE MEASUREMENT**

Instruments for measuring temperature are listed in Table 1. Temperature sensor output must be related to an accepted temperature scale. This is achieved by manufacturing the instrument according to certain specifications or by calibrating it against a temperature standard. To help users conform to standard temperatures and temperature measurements, the International Committee of Weights and Measures (CIPM) has adopted the International Temperature Scale of 1990 (ITS-90).

The unit of temperature of the ITS-90 is the kelvin (K) and has a size equal to the fraction 1/273.16 of the thermodynamic temperature of the triple point of water.

The ITS-90 is maintained in the United States by the National Institute of Standards and Technology (NIST), and any laboratory may obtain calibrations from NIST based on this scale.

Benedict (1984), Considine (1985), Quinn (1990), Schooley (1986, 1992), and DeWitt and Nutter (1988) cover temperature measurement in more detail.

**Sampling and Averaging**

Although temperature is usually measured within, and is associated with, a relatively small volume (depending on the size of the thermometer), it can also be associated with an area (e.g., on a surface or in a flowing stream). To determine average stream temperature, the cross section must be divided into smaller areas and the temperature of each area measured. The temperatures measured are then combined into a weighted mass flow average by either (1) using equal areas and multiplying each temperature by the fraction of total mass flow in its area or (2) using areas of size inversely proportional to mass flow and taking a simple arithmetic average of the temperatures in each. A means of mixing or selective sampling may be preferable to these cumbersome procedures. While mixing can occur from turbulence alone, **transposition** is much more effective. In transposition, the stream is divided into parts determined by the type of stratification, and alternate parts pass through one another.

**Static Temperature Versus Total Temperature**

When a fluid stream impinges on a temperature-sensing element such as a thermometer or thermocouple, the element is at a temperature greater than the true stream temperature. The difference is a fraction of the temperature equivalent of the stream velocity  $t_e$ .

$$t_e = \frac{V^2}{2Jc_p} \tag{1}$$

where

$t_e$  = temperature equivalent of stream velocity, °C

$V$  = velocity of stream, m/s

$J$  = mechanical equivalent of heat, 1000 N·m/kJ

$c_p$  = specific heat of stream at constant pressure, kJ/(kg·K)

Table 1 Temperature Measurement

Measurement Means	Application	Approximate Range, °C	Uncertainty, K	Limitations
Liquid-in-glass thermometers				
Mercury-in-glass	Temperature of gases and liquids by contact	-38/550	0.03 to 2	In gases, accuracy affected by radiation
Organic	Temperature of gases and liquids by contact	-200/200	0.03 to 2	In gases, accuracy affected by radiation
Gas thermometer	Primary standard	-271/665	Less than 0.01	Requires considerable skill to use
Resistance thermometers				
Platinum	Precision; remote readings; temperature of fluids or solids by contact	-259/1000	Less than 0.0001 to 0.1	High cost; accuracy affected by radiation in gases
Rhodium-iron	Transfer standard for cryogenic applications	-273/-243	0.0001 to 0.1	High cost
Nickel	Remote readings; temperature by contact	-250/200	0.01 to 1	Accuracy affected by radiation in gases
Germanium	Remote readings; temperature by contact	-273/-243	0.0001 to 0.1	
Thermistors	Remote readings; temperature by contact	Up to 200	0.0001 to 0.1	
Thermocouples				
Pt-Rh/Pt (type S)	Standard for thermocouples on IPTS-68, not on ITS-90	0/1450	0.1 to 3	High cost
Au/Pt	Highly accurate reference thermometer for laboratory applications	-50/1000	0.05 to 1	High cost
Types K and N	General testing of high temperature; remote rapid readings by direct contact	Up to 1250	0.1 to 10	Less accurate than listed above thermocouples
Iron/Constantan (type J)	Same as above	Up to 750	0.1 to 6	Subject to oxidation
Copper/Constantan (type T)	Same as above, especially suited for low temperature	Up to 350	0.1 to 3	
Ni-Cr/Constantan (type E)	Same as above, especially suited for low temperature	Up to 900	0.1 to 7	
Beckman thermometers (metastatic)	For differential temperature in same applications as in glass-stem thermometer	0 to 100	0.005	Must be set for temperature to be measured
Bimetallic thermometers	For approximate temperature	-20/660	1, usually much more	Time lag; unsuitable for remote use
Pressure-bulb thermometers				
Gas-filled bulb	Remote testing	-75/660	2	Caution must be exercised so that installation is correct
Vapor-filled bulb	Remote testing	-5/250	2	Caution must be exercised so that installation is correct
Liquid-filled bulb	Remote testing	-50/1150	2	Caution must be exercised so that installation is correct
Optical pyrometers	For intensity of narrow spectral band of high-temperature radiation (remote)	800 and up	15	
Radiation pyrometers	For intensity of total high-temperature radiation (remote)	Any range		
Segger cones (fusion pyrometers)	Approximate temperature (within temperature source)	660/2000	50	
Triple points, freezing/melting points, and boiling points of materials	Standards	All except extremely high temperatures	Extremely precise	For laboratory use only

This fraction of the temperature equivalent of the velocity is the **recovery factor**, and it varies from 0.3 to 0.4 K for bare thermometers to 0.5 K for aerodynamically shielded thermocouples. For precise temperature measurement, each temperature sensor must be calibrated to determine its recovery factor. However, for most applications where air velocities are below 10 m/s, the recovery factor can be omitted.

Various temperature sensors are available for temperature measurement in fluid streams. The principal sensors are the **static temperature thermometer**, which indicates true stream temperature but is cumbersome, and the **thermistor**, used for accurate temperature measurement within a limited range.

### LIQUID-IN-GLASS THERMOMETERS

Any device that changes monotonically with temperature is a thermometer; however, the term usually signifies an ordinary liquid-in-glass temperature-indicating device. Mercury-filled thermometers have a useful range from  $-38.8^{\circ}\text{C}$ , the freezing point of mercury, to about  $550^{\circ}\text{C}$ , near which the glass usually softens. Lower temperatures can be measured with organic-liquid-filled thermometers (e.g., alcohol-filled), with ranges of  $-200$  to  $200^{\circ}\text{C}$ . During manufacture, thermometers are roughly calibrated for at least two temperatures, often the freezing and boiling points of water; space between the calibration points is divided into desired scale divisions. Thermometers that are intended for precise measurement applications have scales etched into the glass that forms their stems. The probable error for as-manufactured, etched-stem thermometers is  $\pm 1$  scale division. The highest quality mercury thermometers may have uncertainties of  $\pm 0.03$  to  $\pm 2$  K if they have been calibrated by comparison against primary reference standards.

Liquid-in-glass thermometers are used for many applications within the HVAC industry. Some of these uses include local temperature indication of process fluids related to HVAC systems, such as cooling and heating fluids and air.

The use of mercury-in-glass thermometers as temperature measurement standards is fairly common because of their relatively high accuracy and low cost. Such thermometers used as references must be calibrated on the ITS-90 by comparison in a uniform bath with a standard platinum resistance thermometer that has been calibrated either by the appropriate standards agency or by a laboratory that has direct traceability to the standards agency and the ITS-90. Such a calibration is necessary in order to determine the proper corrections to be applied to the scale readings. For application and calibration of liquid-in-glass thermometers, refer to NIST (1976, 1986).

Liquid-in-glass thermometers are calibrated by the manufacturer for total or partial stem immersion. If a thermometer calibrated for total immersion is used at partial immersion (i.e., with a portion of the liquid column at a temperature different from that of the bath), an emergent stem correction must be made. This correction can be calculated as follows:

$$\text{Stem correction} = Kn(t_b - t_s) \quad (2)$$

where

$K$  = differential expansion coefficient of mercury or other liquid in glass.  $K$  is 0.00016 for Celsius mercurial thermometers. For  $K$  values for other liquids and specific glasses, refer to Schooley (1992).

$n$  = number of degrees that liquid column emerges from bath

$t_b$  = temperature of bath,  $^{\circ}\text{C}$

$t_s$  = average temperature of emergent liquid column of  $n$  degrees,  $^{\circ}\text{C}$

### Sources of Thermometer Errors

A thermometer measuring gas temperatures can be affected by radiation from surrounding surfaces. If the gas temperature is

approximately the same as that of the surrounding surfaces, radiation effects can be ignored. If the temperature differs considerably from that of the surroundings, radiation effects should be minimized by shielding or aspiration (ASME *Standard* PTC 193). **Shielding** may be provided by highly reflective surfaces placed between the thermometer bulb and the surrounding surfaces such that air movement around the bulb is not appreciably restricted (Parmelee and Huebscher 1946). Improper shielding can increase errors. **Aspiration** results from passing a high-velocity stream of air or gas over the thermometer bulb.

When a **thermometer well** within a container or pipe under pressure is required, the thermometer should fit snugly and be surrounded with a high thermal conductivity material (oil, water, or mercury, if suitable). Liquid in a long, thin-walled well is advantageous for rapid response to temperature changes. The surface of the pipe or container around the well should be insulated to eliminate heat transfer to or from the well.

Industrial thermometers are available for permanent installation in pipes or ducts. These instruments are fitted with metal guards to prevent breakage and are useful for many other purposes. The considerable heat capacity and conductance of the guards or shields can cause errors, however.

Allowing ample time for the thermometer to attain temperature equilibrium with the surrounding fluid prevents excessive errors in temperature measurements. When reading a liquid-in-glass thermometer, the eye should be kept at the same level as the top of the liquid column to avoid parallax.

### RESISTANCE THERMOMETERS

Resistance thermometers depend on a change of the electrical resistance of a sensing element (usually metal) with a change in temperature; resistance increases with increasing temperature. The use of resistance thermometers largely parallels that of thermocouples, although readings are usually unstable above about  $550^{\circ}\text{C}$ . Two-lead temperature elements are not recommended because they do not permit correction for lead resistance. Three leads to each resistor are necessary to obtain consistent readings, and four leads are preferred. Wheatstone bridge circuits or 6-1/2-digit multimeters can be used for measurements.

A typical circuit used by several manufacturers is shown in Figure 2. In this design, a differential galvanometer is used in which coils L and H exert opposing forces on the indicating needle. Coil L is in series with the thermometer resistance AB, and coil H is in series with the constant resistance R. As the temperature falls, the resistance of AB decreases, allowing more current to flow through coil L than through coil H. This causes an increase in the force exerted by coil L, pulling the needle down to a lower reading. Likewise, as the temperature rises, the resistance of AB increases, causing less current to flow through coil L than through coil H. This forces the indicating needle to a higher reading. Rheostat S must be adjusted occasionally to maintain a constant current.

The resistance thermometer is more costly to make and likely to have considerably longer response times than thermocouples. A resistance thermometer gives best results when used to measure steady or slowly changing temperature.

### Resistance Temperature Devices

Resistance temperature devices (RTDs) are typically constructed from platinum, rhodium-iron, nickel, nickel-iron, tungsten, or copper. These devices are further characterized by their simple circuit designs, high degree of linearity, good sensitivity, and excellent stability. The choice of materials for an RTD usually depends on the intended application; temperature range, corrosion protection, mechanical stability, and cost are some of the selection criteria.

**Platinum RTDs.** Presently, for HVAC applications, RTDs constructed of platinum are the most widely used. Platinum is extremely

stable and corrosion-resistant. Platinum RTDs are highly malleable and can thus be drawn into fine wires; they can also be manufactured at low cost as thin films. They have a high melting point and can be refined to a high degree of purity, thus attaining highly reproducible results. Due to these properties, platinum RTDs are used to define the ITS-90 for the range of 13.8033 K (triple point of equilibrium hydrogen) to 1234.93 K (freezing point of silver).

Platinum resistance temperature devices can measure the widest range of temperatures and are the most accurate and stable temperature sensors. Their resistance-temperature relationship is one of the most linear. The higher the purity of the platinum, the more stable and accurate the sensor. With high-purity platinum, primary grade platinum RTDs are capable of achieving reproducibility of  $\pm 0.00001$  K, whereas the minimum uncertainty of a recently calibrated thermocouple is  $\pm 0.2$  K.

**Platinum RTD Design.** The most widely used RTD is designed with a resistance of  $100 \Omega$  at  $0^\circ\text{C}$  ( $R_0 = 100 \Omega$ ). Other RTDs are

available that use lower resistances at temperatures above  $600^\circ\text{C}$ . The lower the resistance value, the faster the response time for sensors of the same size.

**Thin-Film Platinum RTDs.** Thin-film  $1000 \Omega$  platinum RTDs are readily available. They have the excellent linear properties of lower resistance platinum RTDs and are more cost-effective because they are mass produced and have lower platinum purity. However, the problem with many platinum RTDs with  $R_0$  values of greater than  $100 \Omega$  is the difficulty in obtaining transmitters or electronic interface boards from sources other than the RTD manufacturer. In addition to a nonstandard interface, higher  $R_0$  value platinum RTDs may have higher self-heating losses if the excitation current is not controlled properly.

Thin-film RTDs have the advantages of lower cost and smaller sensor size. They are specifically adapted to surface mounting. Thin-film sensors tend to have an accuracy limitation of  $\pm 0.1\%$  or  $\pm 0.1$  K. This may prove to be adequate for most HVAC applications; only in tightly controlled facilities may users wish to install the standard wire-wound platinum RTDs with accuracies of  $0.01\%$  or  $\pm 0.01$  K (these are available upon special request for certain temperature ranges).

**Assembly and Construction.** Regardless of the  $R_0$  resistance value of RTDs, their assembly and construction are relatively simple. The electrical connections come in three basic types, depending on the number of wires to be connected to the resistance measurement circuitry. Two, three, or four wires are used for electrical connection using a Wheatstone bridge or a variation of it (Figure 3).

In the basic two-wire configuration, the resistance of the RTD is measured through the two connecting wires. Because the connecting wires extend from the site of the temperature measurement, any additional changes in resistivity due to a change in temperature may affect the measured resistance. Three- and four-wire assemblies are built to compensate for the connecting lead resistance values. The original three-wire circuit improved the resistance measurement by adding a compensating wire to the voltage side of the circuit. This helps reduce part of the connecting wire resistance. When more accurate measurements (better than  $\pm 0.1$  K) are required, the four-wire bridge is recommended. The four-wire bridge eliminates all connecting wire resistance errors.

All the bridges discussed here are direct current (dc) circuits and were used extensively until the advent of precision alternating current (ac) circuits using microprocessor-controlled ratio transformers, dedicated analog-to-digital converters, and other solid-state

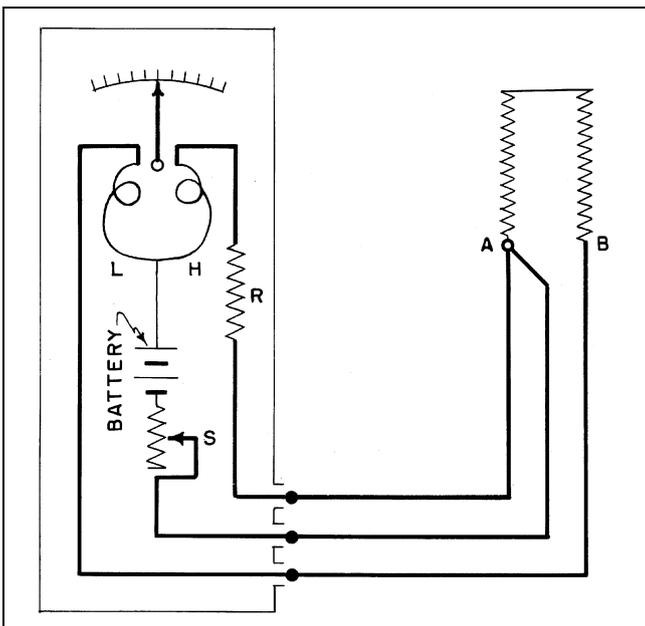

Fig. 2 Typical Resistance Thermometer Circuit

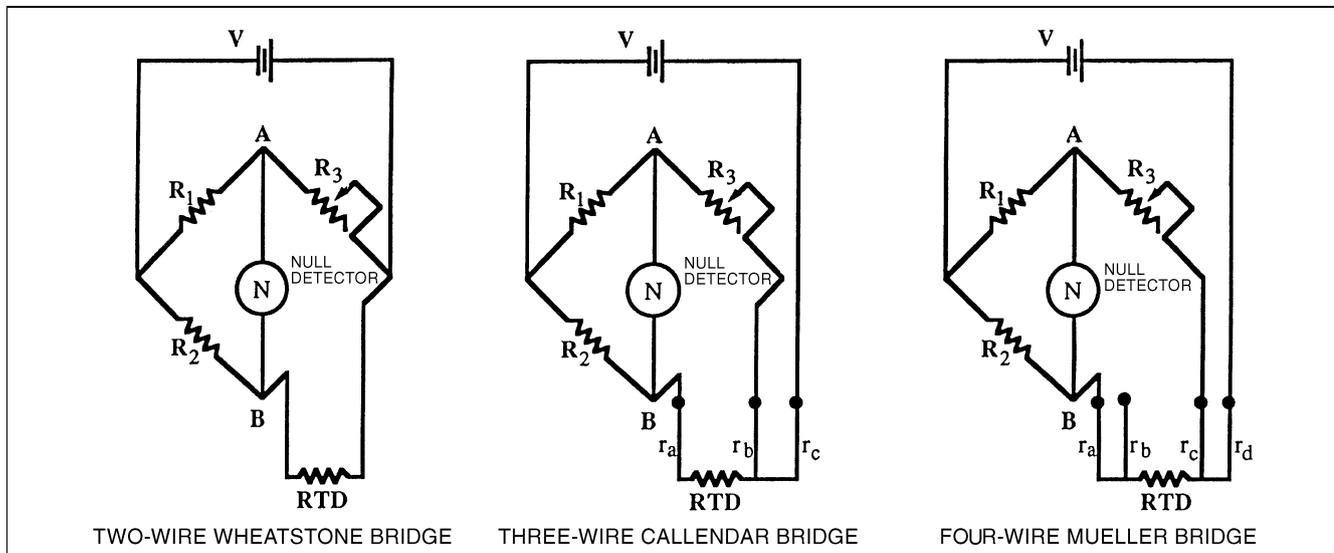

Fig. 3 Typical Resistance Temperature Device Bridge Circuits

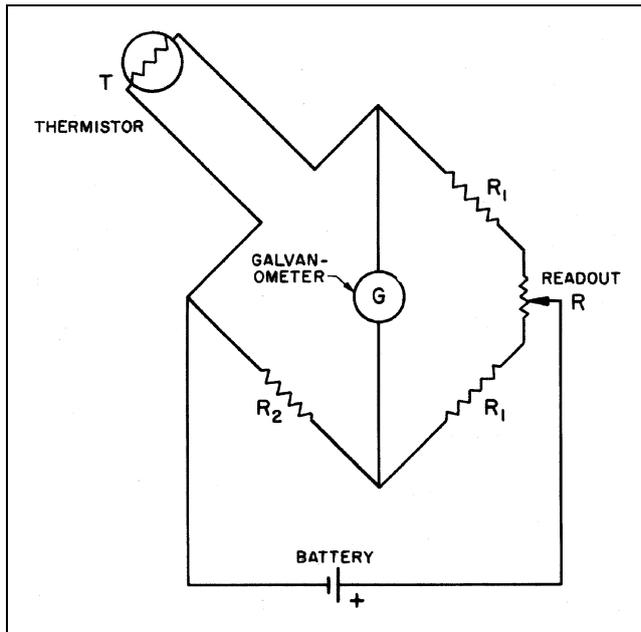

Fig. 4 Basic Thermistor Circuit

devices that measure resistance with uncertainties of less than 1 ppm. Resistance measurement technology now allows more portable thermometers, lower cost, ease of use, and high-precision temperature measurement in industrial uses.

### Thermistors

Certain semiconductor compounds (usually sintered metallic oxides) exhibit large changes in resistance with temperature, usually decreasing as the temperature increases. For use, the thermistor element may be connected by lead wires into a galvanometer bridge circuit and calibrated. Alternatively, a 6-1/2-digit multimeter and a constant-current source with a means for reversing the current to eliminate thermal electromotive force (emf) effects may also be used. This method of measurement is easier and faster, and it may be more precise and accurate. Thermistors are usually applied to electronic temperature compensation circuits, such as thermocouple reference junction compensation, or to other applications where high resolution and limited operating temperature ranges exist. Figure 4 illustrates a typical thermistor circuit.

### Semiconductor Devices

In addition to the positive resistance coefficient RTDs and the negative resistance coefficient thermistor, there are two other types of devices that vary resistance or impedance with temperature. Although the principle of their operation has long been known, their reliability was questioned due to imprecise manufacturing techniques. Improvements in silicon microelectronics manufacturing techniques have brought semiconductors to the point where low-cost, precise temperature sensors are commercially available.

**Elemental Semiconductors.** Due to controlled doping of impurities into elemental germanium, a germanium semiconductor is a reliable temperature sensor for cryogenic temperature measurement in the range of 1 to 84 K.

**Junction Semiconductors.** The first simple junction semiconductor device consisted of a single diode or transistor, in which the forward-connected base emitter voltage is very sensitive to temperature. Today the more common form is a pair of diode-connected transistors, which make the device suitable for ambient temperature measurement. Applications include thermocouple reference junction compensation.

The primary advantages of silicon transistor temperature sensors are their extreme linearity and exact  $R_0$  value. Another advantage is the incorporation of signal conditioning circuitry into the same device as the sensor element. As with thermocouples, these semiconductors require highly precise manufacturing techniques, extremely precise voltage measurements, multiple-point calibration, and temperature compensation to achieve an accuracy as high as  $\pm 0.01$  K, but with a much higher cost. Lower cost devices achieve accuracies of  $\pm 0.1$  K using mass manufacturing techniques and single-point calibration. A mass-produced silicon temperature sensor can be interchanged easily. If one device fails, only the sensor element need be changed. Electronic circuitry can be used to recalibrate the new device.

**Winding Temperature.** The winding temperature of electrical operating equipment is usually determined from the resistance change of these windings in operation. With copper windings, the relation between these parameters is

$$\frac{R_1}{R_2} = \frac{100 + t_1}{100 + t_2} \quad (3)$$

where

$$\begin{aligned} R_1 &= \text{winding resistance at temperature } t_1, \Omega \\ R_2 &= \text{winding resistance at temperature } t_2, \Omega \\ t_1, t_2 &= \text{winding temperatures, } ^\circ\text{C} \end{aligned}$$

The classical method of determining winding temperature is to measure the equipment when it is inoperative and temperature-stabilized at room temperature. After the equipment has operated sufficiently to cause temperature stabilization under load conditions, the winding resistance should be measured again. The latter value is obtained by taking resistance measurements at known short time intervals after shutdown. These values may be extrapolated to zero time to indicate the winding resistance at the time of shutdown. The obvious disadvantage of this method is that the device must be shut down to determine winding temperature. A circuit described by Seely (1955), however, makes it possible to measure resistances while the device is operating.

### THERMOCOUPLES

When two wires of dissimilar metals are joined by soldering, welding, or twisting, they form a thermocouple junction or **thermo-junction**. An emf that depends on the wire materials and the junction temperature exists between the wires. This is known as the **Seebeck voltage**.

Thermocouples for temperature measurement yield less precise results than platinum resistance thermometers, but except for glass thermometers, thermocouples are the most common instruments of temperature measurement for the range of 0 to 1000°C. Due to their low cost, moderate reliability, and ease of use, thermocouples continue to maintain widespread acceptance.

The most commonly used thermocouples in industrial applications are assigned letter designations. The tolerances of such commercially available thermocouples are given in Table 2.

Because the measured emf is a function of the difference in temperature and the type of dissimilar metals used, a known temperature at one junction is required, whereas the remaining junction temperature may be calculated. It is common practice to call the one with a known temperature the (cold) **reference** junction and the one with the unknown temperature the (hot) **measured** junction. The reference junction is typically kept at a reproducible temperature, such as the ice point of water.

Various systems are used to maintain the reference junction temperature—a mixture of ice and water contained in an insulated flask or commercially available thermoelectric coolers to maintain the ice point temperature automatically within a reference chamber. When

Table 2 Thermocouple Tolerances on Initial Values of Electromotive Force Versus Temperature

Thermocouple Type	Material Identification	Temperature Range, °C	Reference Junction Tolerance at 0°C <sup>a</sup>	
			Standard Tolerance (whichever is greater)	Special Tolerance (whichever is greater)
T	Copper versus Constantan	0 to 350	±1 K or ±0.75%	±0.5 K or ±0.4%
J	Iron versus Constantan	0 to 750	±2.2 K or ±0.75%	±1.1 K or ±0.4%
E	Nickel-10% Chromium versus Constantan	0 to 900	±1.7 K or ±0.5%	±1 K or ±0.4%
K	Nickel-10% Chromium versus 5% Aluminum, Silicon	0 to 1250	±2.2 K or ±0.75%	±1.1 K or ±0.4%
N	Nickel-14% Chromium, 1.5% Silicon versus Nickel-4.5% Silicon, 0.1% Magnesium	0 to 1250	±2.2 K or ±0.75%	±1.1 K or ±0.4%
R	Platinum-13% Rhodium versus Platinum	0 to 1450	±1.5 K or ±0.25%	±0.6 K or ±0.1%
S	Platinum-10% Rhodium versus Platinum	0 to 1450	±1.5 K or ±0.25%	±0.6 K or ±0.1%

K <sup>b</sup>	Nickel-10% Chromium versus 5% Aluminum, Silicon	-200 to 0	±2.2 K or ±2%	c

Source: ASTM Standard E 230, Temperature-Electromotive Force (EMF) Tables for Standardized Thermocouples.

<sup>a</sup>Tolerances in this table apply to new thermocouple wire, normally in the size range of 0.25 to 3 mm diameter and used at temperatures not exceeding the recommended limits. Thermocouple wire is available in two grades: standard and special.

<sup>b</sup>Thermocouples and thermocouple materials are normally supplied to meet the tolerance specified in the table for temperatures above 0°C. The same materials, however, may not fall within the tolerances given in the second section of the table when operated below freezing (0°C). If materials are required to meet tolerances at subfreezing temperatures, the purchase order must state so.

<sup>c</sup>Little information is available to justify establishing special tolerances for below-freezing temperatures. Limited experience suggests the following special tolerances for types E and T thermocouples:

Type E -200 to 0°C; ±1 K or ±0.5% (whichever is greater)

Type T -200 to 0°C; ±0.5 K or ±0.8% (whichever is greater)

These tolerances are given only as a guide for discussion between purchaser and supplier.

these systems cannot be used in an application, measuring instruments with automatic reference junction temperature compensation may be used.

As previously described, the principle for measuring temperature with a thermocouple is based on the accurate measurement of the Seebeck voltage. The acceptable dc voltage measurement methods are (1) millivoltmeter, (2) millivolt potentiometer, and (3) a high-input impedance digital voltmeter. Many digital voltmeters include built-in software routines for the direct calculation and display of temperature. Regardless of the method selected, many options to simplify the measurement process are available.

Solid-state digital readout devices in combination with a millivolt- or microvoltmeter, as well as packaged thermocouple readouts with built-in cold junction and linearization circuits, are available. The latter requires a proper thermocouple to provide direct meter reading of temperature. Accuracy approaching or surpassing that of potentiometers can be attained, depending on the instrument quality. This method is popular because it eliminates the null balancing requirement and reads temperature directly in a digital readout.

### Wire Diameter and Composition

Thermocouple wire is selected by considering the temperature to be measured, the corrosion protection afforded to the thermocouple, and the precision and service life required. Type T thermocouples are suitable for temperatures up to 350°C; type J, up to 750°C; and types K and N, up to 1250°C. Higher temperatures require noble metal thermocouples (type S, R, or B), which have a higher initial cost and do not develop as high an emf as the base metal thermocouples. Thermocouple wires of the same type have small compositional variation from lot to lot from the same manufacturer and especially among different manufacturers. Consequently, calibrating samples from each wire spool is essential for precision. Calibration data on wire may be obtained from the manufacturer.

Reference functions are available for relating temperature and emf of letter-designated thermocouple types. Such functions are easy to use with computers. The functions depend on thermocouple type and on the range of temperature; they are used to generate

reference tables of emf as a function of temperature but are not well suited for calculating temperatures directly from values of emf. Approximate inverse functions are available, however, for calculating temperature and are of the form

$$t = \sum_{i=0}^n a_i E^i \quad (4)$$

where  $t$  = temperature,  $a$  = thermocouple constant, and  $E$  = voltage. Burns et al. (1992) give the reference functions and approximate inverses for all letter-designated thermocouples.

The emf of a thermocouple, as measured with a high-input impedance device, is independent of the diameters of its constituent wires. Thermocouples with small-diameter wires respond faster to temperature changes and are less affected by radiation than larger ones. Large-diameter wire thermocouples, however, are necessary for high-temperature work when wire corrosion is a problem. For use in heated air or gases, thermocouples are often shielded and sometimes aspirated. An arrangement for avoiding error due to radiation involves using several thermocouples of different wire sizes and estimating the true temperature by extrapolating readings to zero diameter.

With thermocouples, temperatures can be indicated or recorded remotely on conveniently located instruments. Because thermocouples can be made of small-diameter wire, they can be used to measure temperatures within thin materials, within narrow spaces, or in otherwise inaccessible locations.

### Multiple Thermocouples

Thermocouples in series, with alternate junctions maintained at a common temperature, produce an emf that, when divided by the number of thermocouples, gives the average emf corresponding to the temperature difference between two sets of junctions. This series arrangement of thermocouples, often called a **thermopile**, is used to increase sensitivity and is often used for measuring small temperature changes and differences.

Connecting a number of thermocouples of the same type in parallel with a common reference junction is useful for obtaining an average temperature of an object or volume. In such measurements, however, it is important that the electrical resistances of the individual thermocouples be the same. The use of thermocouples in series and parallel arrangements is discussed in ASTM *Manual 12*.

### Surface Temperature Measurement

The thermocouple is useful in determining surface temperature. It can be attached to a metal surface in several ways. For permanent installations, soldering, brazing, or peening is suggested. For peening, a small hole is drilled and the thermocouple measuring junction is driven into it. For temporary arrangements, thermocouples can be attached by tape, adhesive, or putty-like material. For boiler or furnace surfaces, furnace cement should be used. To minimize the possibility of error caused by heat conduction along wires, a surface thermocouple should be made of fine wires placed in close contact with the surface being measured for about 25 mm from the junction to ensure good thermal contact. The wires must be insulated electrically from each other and from the metal surface (except at the junction).

### Thermocouple Construction

The thermocouple wires are typically insulated with fibrous glass, fluorocarbon resin, or ceramic insulators. In another form of thermocouple, the thermocouple wires are insulated with compacted ceramic insulation inside a metal sheath. This form of thermocouple provides both mechanical protection and protection from stray electromagnetic fields. The measuring junction may be exposed or enclosed within the metal sheath. An enclosed junction may be either grounded or ungrounded to the metal sheath.

For the exposed junction type, the measuring junction is in direct contact with the process stream; it is therefore subject to corrosion or contamination but provides a fast temperature response. The grounded enclosed junction type, in which the thermocouple wires are welded to the metal sheath, provides electrical grounding, as well as mechanical and corrosion protection. This type, however, has a slower response time than the exposed junction type. With the ungrounded enclosed junction construction, the response time is even slower, but the thermocouple wires are isolated electrically and are less susceptible to some forms of mechanical strain than those with grounded construction.

## INFRARED RADIOMETERS

Infrared radiation thermometers, also known as remote temperature sensors (Hudson 1969), permit noncontact measurement of surface temperature over a wide range. In these instruments, radiant flux from the observed object is focused by an optical system onto an infrared detector that generates an output signal proportional to the incident radiation that can be read from a meter or display unit. Point and scanning radiometers are available; the latter are able to display the temperature variation existing within the field of view.

Radiometers are usually classified according to the detector used—either thermal or photon. In thermal detectors, a change in electrical property is caused by the heating effect of the incident radiation. Examples of thermal detectors are the thermocouple, the thermopile, and metallic and semiconductor bolometers. In photon detectors, a change in electrical property is caused by the surface absorption of incident photons. Because these detectors do not require an increase in temperature for activation, their response time is much shorter than that of thermal detectors. Scanning radiometers usually use photon detectors.

A radiometer only measures the power level of the radiation incident on the detector; this incident radiation is a combination of the thermal radiation emitted by the object and the surrounding background radiation reflected from the surface of the object. An accurate measurement of the temperature, therefore, requires knowledge

of the long-wavelength emissivity of the object as well as the effective temperature of the thermal radiation field surrounding the object. Calibration against an internal or external source of known temperature and emissivity is required in order to obtain true surface temperature from the radiation measurements.

The temperature resolution of a radiometer decreases as the object temperature decreases. For example, a radiometer that can resolve a temperature difference of 0.25 K on an object near 20°C may only resolve a difference of 1 K on an object at 0°C.

## INFRARED THERMOGRAPHY

Infrared thermography is the discipline concerned with the acquisition and analysis of thermal information in the form of images from an infrared imaging system. An infrared imaging system consists of (1) an infrared television camera and (2) a display unit. The infrared television camera scans a surface and senses the self-emitted and reflected radiation viewed from the surface. The display unit contains either a cathode-ray tube (CRT) that displays a gray-tone or color-coded thermal image of the surface or a color liquid crystal display (LCD) screen. A photograph of the image on the CRT is called a **thermogram**. An introductory treatise on infrared thermography is given by Paljak and Pettersson (1972).

Thermography has been used successfully to detect missing insulation and air infiltration paths in building envelopes (Burch and Hunt 1978). Standard practices for conducting thermographic inspections of buildings are given in ASTM *Standard C 1060*. A technique for quantitatively mapping the heat loss in building envelopes is given by Mack (1986).

Aerial infrared thermography of buildings is effective in identifying regions of an individual built-up roof that have wet insulation (Tobiasson and Korhonen 1985), but it is ineffective in ranking a group of roofs according to their thermal resistance (Goldstein 1978, Burch 1980). In this latter application, the emittances of the separate roofs and outdoor climate (i.e., temperature and wind speed) throughout the microclimate often produce changes in the thermal image that may be incorrectly attributed to differences in thermal resistance.

Industrial applications include locating defective or missing pipe insulation in buried heat distribution systems, surveys of manufacturing plants to quantify energy loss from equipment, and locating defects in coatings (Bentz and Martin 1987).

## HUMIDITY MEASUREMENT

Any instrument capable of measuring the humidity or psychrometric state of air is a hygrometer, and many are available. The indication sensors used on the instruments respond to different moisture property contents. These responses are related to factors such as wet-bulb temperature, relative humidity, humidity (mixing) ratio, dew point, and frost point.

Table 3 lists instruments for measuring humidity. Each is capable of accurate measurement under certain conditions and within specific limitations. The following sections describe various instruments used to measure humidity.

### PSYCHROMETERS

A typical industrial psychrometer consists of a pair of matched electrical or mechanical temperature sensors, one of which is kept wet with a moistened wick. A blower aspirates the sensor, which lowers the temperature at the moistened temperature sensor. The lowest temperature depression occurs when the evaporation rate required to saturate the moist air adjacent to the wick is constant. This is a steady-state, open-loop, nonequilibrium process, which depends on the purity of the water, the cleanliness of the wick, the ventilation rate, radiation effects, the size and accuracy of the temperature sensors, and the transport properties of the gas.

Table 3 Humidity Sensor Properties

Type of Sensor	Sensor Category	Method of Operation	Approximate Range	Some Uses	Approximate Accuracy
Psychrometer	Evaporative cooling	Temperature measurement of wet bulb	0 to 80°C	Measurement, standard	±3 to ±7% rh
Adiabatic saturation psychrometer	Evaporative cooling	Temperature measurement of thermodynamic wet bulb	5 to 30°C	Measurement, standard	±0.2 to ±2% rh
Chilled mirror	Dew point	Optical determination of moisture formation	-75 to 95°C dp	Measurement, control, meteorology	±0.2 to ±2 K
Heated saturated salt solution	Water vapor pressure	Vapor pressure depression in salt solution	-30 to 70°C dp	Measurement, control, meteorology	±1.5 K
Hair	Mechanical	Dimensional change	5 to 100% rh	Measurement, control	±5% rh
Nylon	Mechanical	Dimensional change	5 to 100% rh	Measurement, control	±5% rh
Dacron thread	Mechanical	Dimensional change	5 to 100% rh	Measurement	±7% rh
Goldbeater's skin	Mechanical	Dimensional change	5 to 100% rh	Measurement	±7% rh
Cellulosic materials	Mechanical	Dimensional change	5 to 100% rh	Measurement, control	±5% rh
Carbon	Mechanical	Dimensional change	5 to 100% rh	Measurement	±5% rh
Dunmore type	Electrical	Impedance	7 to 98% rh at 5 to 60°C	Measurement, control	±1.5% rh
Ion exchange resin	Electrical	Impedance or capacitance	10 to 100% rh at -40 to 90°C	Measurement, control	±5% rh
Porous ceramic	Electrical	Impedance or capacitance	Up to 200°C	Measurement, control	±1 to ±1.5% rh
Aluminum oxide	Electrical	Capacitance	5 to 100% rh	Measurement, control	±3% rh
Aluminum oxide	Electrical	Capacitance	-80 to 60°C dp	Trace moisture measurement, control	±1 K dp
Electrolytic hygrometer	Electrical	Capacitance			
Coulometric	Electrolytic cell	Electrolyzes due to adsorbed moisture	1 to 1000 ppm	Measurement	
Infrared laser diode	Electrical	Optical diodes	0.1 to 100 ppm	Trace moisture measurement	±0.1 ppm
Surface acoustic wave	Electrical	SAW attenuation	85 to 98% rh	Measurement, control	±1% rh
Piezoelectric	Mass sensitive	Mass changes due to adsorbed moisture	-75 to -20°C	Trace moisture measurement, control	±1 to ±5 K dp
Radiation absorption	Moisture absorption	Moisture absorption of UV or IR radiation	-20 to 80°C dp	Measurement, control, meteorology	±2 K dp, ±5% rh
Gravimetric	Direct measurement of mixing ratio	Comparison of sample gas with dry airstream	120 to 20 000 ppm mixing ratio	Primary standard, research and laboratory	±0.13% of reading
Color change	Physical	Color changes	10 to 80% rh	Warning device	±10% rh

## Notes:

1. This table does not encompass all of the available technology for the measurement of humidity.

2. The approximate range for the device types listed is based on surveys of device manufacturers.

3. The approximate accuracy is based on manufacturers' data.

4. Presently, the National Institute of Standards and Technology (NIST) will only certify instruments whose operating range is within -75 to 100°C dew point.

ASHRAE *Standard* 41.6 recommends an airflow over both the wet and dry bulbs of 3 to 5 m/s for transverse ventilation and 1.5 to 2.5 m/s for axial ventilation.

The **slings psychrometer** consists of two thermometers mounted side by side in a frame fitted with a handle for whirling the device through the air. The thermometers are spun until their readings become steady. In the **ventilated** or **aspirated psychrometer**, the thermometers remain stationary, and a small fan, blower, or syringe moves the air across the thermometer bulbs. Various designs are used in the laboratory, and commercial models are available.

Other temperature sensors, such as thermocouples and thermistors, are also used and can be adapted for recording temperatures or for use where a small instrument is required. Small-diameter wet-bulb sensors operate with low ventilation rates.

Charts and tables showing the relationship between the temperatures and humidity are available. Data are usually based on a

barometric pressure equal to one standard atmosphere. To meet special needs, charts can be produced that apply to nonstandard pressure (e.g., the ASHRAE 2250 m psychrometric chart). Alternatively, mathematical calculations can be made (Kusuda 1965). Uncertainties of 3 to 7% rh are typical for psychrometer-based derivation. The degree of uncertainty is a function of the accuracy of the temperature measurements, wet and dry bulb, knowledge of the barometric pressure, and conformance to accepted operational procedures such as those outlined in ASHRAE *Standard* 41.6.

In air temperatures below 0°C, the water on the wick may either freeze or supercool. Because the wet-bulb temperature is different for ice and water, the state must be known and the proper chart or table used. Some operators remove the wick from the wet-bulb for freezing conditions and dip the bulb in water a few times; this allows water to freeze on the bulb between dips, forming a film of ice. Because the wet-bulb depression is slight at low temperatures,

precise temperature readings are essential. A psychrometer can be used at high temperatures, but if the wet-bulb depression is large, the wick must remain wet and water supplied to the wick must be cooled so as not to influence the wet-bulb temperature by carrying sensible heat to it (Richardson 1965, Worrall 1965).

Greenspan and Wexler (1968) and Wentzel (1961) developed devices to measure adiabatic saturation temperature.

## DEW-POINT HYGROMETERS

### Condensation Dew-Point Hygrometers

The condensation (chilled mirror) dew-point hygrometer is an accurate and reliable instrument with a wide humidity range. However, these features are obtained through an increase in complexity and cost compared to the psychrometer. In the condensation hygrometer, a surface is cooled (thermoelectrically, mechanically, or chemically) until dew or frost begins to condense out. The condensate surface is maintained electronically in vapor pressure equilibrium with the surrounding gas, while surface condensation is detected by optical, electrical, or nuclear techniques. The measured surface temperature is then the dew-point temperature.

The largest source of error in a condensation hygrometer stems from the difficulty in measuring condensate surface temperature accurately. Typical industrial versions of the instrument are accurate to  $\pm 0.5$  K over wide temperature spans. With proper attention to the condensate surface temperature measuring system, errors can be reduced to about  $\pm 0.2$  K. Condensation hygrometers can be made surprisingly compact using solid-state optics and thermoelectric cooling.

Wide span and minimal errors are two of the main features of this instrument. A properly designed condensation hygrometer can measure dew points from  $95^{\circ}\text{C}$  down to frost points of  $-75^{\circ}\text{C}$ . Typical condensation hygrometers can cool to 80 K below the ambient temperature, establishing lower limits of the instrument to dew points corresponding to approximately 0.5% rh. Accuracies for measurements above  $-40^{\circ}\text{C}$  can be  $\pm 1$  K or better, deteriorating to  $\pm 2$  K at lower temperatures.

The response time of a condensation dew-point hygrometer is usually specified in terms of its cooling/heating rate, typically 2 K/s for thermoelectric cooled mirrors. This makes it somewhat faster than a heated salt hygrometer. Perhaps the most significant feature of the condensation hygrometer is its fundamental measuring technique, which essentially renders the instrument self-calibrating. For calibration, it is necessary only to manually override the surface cooling control loop, causing the surface to heat, and witness that the instrument recools to the same dew point when the loop is closed. Assuming that the surface temperature measuring system is correct, this is a reasonable check on the instrument's performance.

Although condensation hygrometers can become contaminated, they can easily be cleaned and returned to service with no impairment to performance.

### Salt-Phase Heated Hygrometers

Another instrument in which the temperature varies with ambient dew-point temperature is variously designated as a self-heating salt-phase transition hygrometer or a heated electrical hygrometer. This device usually consists of a tubular substrate covered by glass fiber fabric, with a spiral bifilar winding for electrodes. The surface is covered with a salt solution, usually lithium chloride. The sensor is connected in series with a ballast and a 24 V (ac) supply. When the instrument is in operation, electrical current flowing through the salt film heats the sensor. The electrical resistance characteristics of the salt are such that a balance is reached with the salt at a critical moisture content corresponding to a saturated solution. The sensor temperature adjusts automatically so that the water vapor pressures of the salt film and ambient atmosphere are equal.

With lithium chloride, this sensor cannot be used to measure relative humidity below approximately 12% (the equilibrium relative humidity of this salt), and it has an upper dew-point limit of about  $70^{\circ}\text{C}$ . The regions of highest precision are between  $-23$  and  $34^{\circ}\text{C}$ , and above  $40^{\circ}\text{C}$  dew point. Another problem is that the lithium chloride solution can be washed off when exposed to water. In addition, this type of sensor is subject to contamination problems, which limits its accuracy. Its response time is also very slow; it takes approximately 2 min for a 67% step change.

## MECHANICAL HYGROMETERS

Many organic materials change in dimension with changes in humidity; this action is used in a number of simple and effective humidity indicators, recorders, and controllers (see Chapter 15). They are coupled to pneumatic leak ports, mechanical linkages, or electrical transduction elements to form hygrometers.

Commonly used organic materials are human hair, nylon, Dacron, animal membrane, animal horn, wood, and paper. Their inherent nonlinearity and hysteresis must be compensated for within the hygrometer. These devices are generally unreliable below  $0^{\circ}\text{C}$ . The response is generally inadequate for monitoring a changing process. Responses can be affected significantly by exposure to extremes of humidity. Mechanical hygrometers require initial calibration and frequent recalibration; however, they are useful because they can be arranged to read relative humidity directly, and they are simpler and less expensive than most other types.

## ELECTRICAL IMPEDANCE AND CAPACITANCE HYGROMETERS

Many substances adsorb or lose moisture with changing relative humidity and exhibit corresponding changes in electrical impedance or capacitance.

### Dunmore Hygrometers

This sensor consists of dual electrodes on a tubular or flat substrate; it is coated with a film containing salt, such as lithium chloride, in a binder to form an electrical connection between windings. The relation of sensor resistance to humidity is usually represented by graphs. Because the sensor is highly sensitive, the graphs are a series of curves, each for a given temperature, with intermediate values found by interpolation. Several resistance elements, called Dunmore elements, cover a standard range. Systematic calibration is essential because the resistance grid varies with time and contamination as well as with exposure to temperature and humidity extremes.

### Polymer Film Electronic Hygrometers

These devices consist of a hygroscopic organic polymer deposited by means of thin or thick film processing technology on a water-permeable substrate. Both capacitance and impedance sensors are available. The impedance devices may be either ionic or electronic conduction types. These hygrometers typically have integrated circuits that provide temperature correction and signal conditioning. The primary advantages of this sensor technology are small size; low cost; fast response times (on the order of 1 to 120 s for 64% change in relative humidity); and good accuracy over the full range, including the low end (1 to 15% h), where most other devices are less accurate.

### Ion Exchange Resin Electric Hygrometers

A conventional ion exchange resin consists of a polymer having a high relative molecular mass and polar groups of positive or negative charge in cross-link structure. Associated with these polar groups are ions of opposite charge that are held by electrostatic forces to the fixed polar groups. In the presence of water or water

vapor, the electrostatically held ions become mobile; thus, when a voltage is impressed across the resin, the ions are capable of electrolytic conduction. The **Pope cell** is one example of an ion exchange element. It is a wide-range sensor, typically covering 15 to 95% rh; therefore, one sensor can be used where several Dunmore elements would be required. The Pope cell, however, has a nonlinear characteristic from approximately 1000  $\Omega$  at 100% rh to several megohms at 10% rh.

### Impedance-Based Porous Ceramic Electronic Hygrometers

Using the adsorption characteristics of oxides, humidity-sensitive ceramic oxide devices employ either ionic or electronic measurement techniques to relate adsorbed water to relative humidity. Ionic conduction is produced by dissociation of water molecules forming surface hydroxyls. The dissociation causes migration of protons such that the impedance of the device decreases with increasing water content. The ceramic oxide is sandwiched between porous metal electrodes that connect the device to an impedance-measuring circuit for linearizing and signal conditioning. These sensors have excellent sensitivity, are resistant to contamination and high temperature (up to 200°C), and may get fully wet without sensor degradation. These sensors are accurate to about  $\pm 1.5\%$  rh, and  $\pm 1\%$  rh when temperature compensated. These sensors have a moderate cost.

### Aluminum Oxide Capacitive Sensor

This sensor consists of an aluminum strip that is anodized by a process that forms a porous oxide layer. A very thin coating of cracked chromium or gold is then evaporated over this structure. The aluminum base and the cracked chromium or gold layer form the two electrodes of what is essentially an aluminum oxide capacitor.

Water vapor is rapidly transported through the cracked chromium or gold layer and equilibrates on the walls of the oxide pores in a manner functionally related to the vapor pressure of water in the atmosphere surrounding the sensor. The number of water molecules adsorbed on the oxide structure determines the capacitance between the two electrodes.

## ELECTROLYTIC HYGROMETERS

In electrolytic hygrometers, air is passed through a tube, where moisture is adsorbed by a highly effective desiccant (usually phosphorous pentoxide) and electrolyzed. The airflow is regulated to 1.65 mL/s at a standard temperature and pressure. As the incoming water vapor is absorbed by the desiccant and electrolyzed into hydrogen and oxygen, the current of electrolysis determines the mass of water vapor entering the sensor. The flow rate of the entering gas is controlled precisely to maintain a standard sample mass flow rate into the sensor. The instrument is usually designed for use with moisture-air ratios in the range of less than 1 ppm to 1000 ppm but can be used with higher humidities.

## PIEZOELECTRIC SORPTION

This hygrometer compares the changes in frequency of two hygroscopically coated quartz crystal oscillators. As the mass of the crystal changes due to the absorption of water vapor, the frequency changes. The amount of water sorbed on the sensor is a function of relative humidity (i.e., partial pressure of water as well as ambient temperature).

A commercial version uses a hygroscopic polymer coating on the crystal. The humidity is measured by monitoring the change in the vibration frequency of the quartz crystal when the crystal is alternately exposed to wet and dry gas.

## SPECTROSCOPIC (RADIATION ABSORPTION) HYGROMETERS

Radiation absorption devices operate on the principle that selective absorption of radiation is a function of frequency for different media. Water vapor absorbs **infrared** radiation at 2 to 3  $\mu\text{m}$  wavelengths and **ultraviolet** radiation centered about the Lyman-alpha line at 0.122  $\mu\text{m}$ . The amount of absorbed radiation is directly related to the absolute humidity or water vapor content in the gas mixture according to Beer's law. The basic unit consists of an energy source and optical system for isolating wavelengths in the spectral region of interest and a measurement system for determining the attenuation of radiant energy caused by the water vapor in the optical path. The absorbed radiation is measured extremely quickly and independent of the degree of saturation of the gas mixture. Response times of 0.1 to 1 s for 90% change in moisture content are common. Spectroscopic hygrometers are primarily used where a noncontact application is required; this may include atmospheric studies, industrial drying ovens, and harsh environments. The primary disadvantages of this device are its high cost and relatively large size.

## GRAVIMETRIC HYGROMETERS

Humidity levels can be measured by extracting and finding the mass of water vapor in a known quantity or atmosphere. For precise laboratory work, powerful desiccants, such as phosphorous pentoxide and magnesium perchlorate, are used for the extraction process; for other purposes, calcium chloride or silica gel is satisfactory.

When the highest level of accuracy is required, the gravimetric hygrometer, developed and maintained by NIST, is the ultimate in the measurement hierarchy. The gravimetric hygrometer gives the absolute water vapor content, where the mass of the absorbed water and the precise measurement of the gas volume associated with the water vapor determine the mixing ratio or absolute humidity of the sample. This system has been chosen as the primary standard because the required measurements of mass, temperature, pressure, and volume can be made with extreme precision. However, its complexity and required attention to detail limit the usefulness of the gravimetric hygrometer.

## CALIBRATION

For many hygrometers, the need for recalibration depends on the accuracy required, the stability of the sensor, and the conditions to which the sensor is being subjected. Many hygrometers should be calibrated regularly by exposure to an atmosphere maintained at a known humidity and temperature, or by comparison with a transfer standard hygrometer. Complete calibration usually requires observation of a series of temperatures and humidities. Methods for producing known humidities include saturated salt solutions (Greenspan 1977, Huang and Whetstone 1985); sulfuric acid solutions, and mechanical systems, such as the divided flow, two-pressure (Amdur 1965); two-temperature (Till and Handegord 1960); and NIST two-pressure humidity generator (Hasegawa 1976). All these systems rely on precise methods of temperature and pressure control within a controlled environment to produce a known humidity, usually with accuracies of 0.5 to 1.0%. The operating range for the precision generator is typically 5 to 95% rh.

## PRESSURE MEASUREMENT

Pressure is the force exerted per unit area by a medium, generally a liquid or gas. Pressure so defined is sometimes called **absolute pressure**. Thermodynamic and material properties are expressed in terms of absolute pressures; thus, the properties of a refrigerant will be given in terms of absolute pressures. **Vacuum** refers to pressures below atmospheric.

**Differential pressure** is the difference between two absolute pressures. In many cases, the differential pressure can be very small compared to either of the absolute pressures (these are often referred to as low-range, high-line differential pressures). A common example of differential pressure is the pressure drop, or difference between inlet and outlet pressures, across a filter or flow element.

**Gage pressure** is a special case of differential pressure where one of the pressures (the reference pressure) is atmospheric pressure. Many pressure gages, including most refrigeration test sets, are designed to make gage pressure measurements, and there are probably more gage pressure measurements made than any other. Gage pressure measurements are often used as surrogates for absolute pressures. However, because of variations in atmospheric pressure due to elevation (atmospheric pressure in Denver, Colorado, is about 81% of sea-level pressure) and weather changes, the measurement of gage pressures to determine absolute pressures can significantly restrict the accuracy of the measured pressure, unless corrections are made for the local atmospheric pressure at the time of the measurement.

Pressures can be further classified as static or dynamic. **Static pressures** have a small or undetectable change with time; **dynamic pressures** include a significant pulsed, oscillatory, or other time-dependent component. Static pressure measurements are the most common, but equipment such as blowers and compressors can generate significant oscillatory pressures at discrete frequencies. Flow in pipes and ducts can generate resonant pressure changes, as well as turbulent “noise” that can span a wide range of frequencies.

## Units

A plethora of pressure units, many of them poorly defined, are in common use. The international (SI) unit is the newton per square metre, called the pascal (Pa). While the bar and the standard atmosphere are used, they should not be introduced where they are not used at present.

## Types of Pressure-Measuring Instruments

Broadly speaking, pressure instruments can be divided into three different categories—standards, mechanical gages, and electromechanical transducers. Standards instruments are used for the most accurate calibrations. The liquid-column manometer, which is the most common and potentially the most accurate standard, is used for a variety of applications, including field applications. Mechanical pressure gages are generally the least expensive and the most common pressure instruments. However, electromechanical transducers have become much less expensive and are easier to use, so they are being used more often.

## PRESSURE STANDARDS

**Liquid-column manometers** measure pressure by determining the vertical displacement of a liquid of known density in a known gravitational field. Typically they are constructed as a U-tube of transparent material (glass or plastic). The pressure to be measured is applied to one side of the U-tube. If the other (reference) side is evacuated (zero pressure), the manometer measures absolute pressure; if the reference side is open to the atmosphere, it measures gage pressure; if the reference side is connected to some other pressure, the manometer measures the differential between the two pressures. Manometers filled with water and different oils are often used to measure low-range differential pressures. In some low-range instruments, one tube of the manometer is inclined in order to enhance the readability. Mercury-filled manometers are used for higher range differential and absolute pressure measurements. In the latter case, the reference side is evacuated, generally with a

mechanical vacuum pump. Typical full-scale ranges for manometers vary from 2.5 kPa (250 mm of water) to 300 kPa.

For pressures above the range of manometers, standards are generally of the piston-gage, pressure-balance, or deadweight-tester type. These instruments apply pressure to the bottom of a vertical piston, which is surrounded by a close-fitting cylinder (typical clearances are micrometres). The pressure generates a force approximately equal to the pressure times the area of the piston. This force is balanced by weights stacked on the top of the piston. If the mass of the weights, the local acceleration of gravity, and the area of the piston (or more properly, the “effective area” of the piston and cylinder assembly) are known, the applied pressure can be calculated. Piston gages generally generate gage pressures with respect to the atmospheric pressure above the piston. They can be used to measure absolute pressures either indirectly by separately measuring the atmospheric pressure and adding it to the gage pressure determined by the piston gage, or directly by surrounding the top of the piston and weights with an evacuated bell jar. Piston gage full-scale ranges vary from 35 kPa to 1.4 GPa.

At the other extreme, very low absolute pressures (below about 100 Pa), a number of different types of standards are used. These tend to be specialized and expensive instruments found only in major standards laboratories. However, one low-pressure standard, the **McLeod gage**, has been used for field applications. Unfortunately, although the theory of the McLeod gage is simple and straightforward, it is difficult to make accurate measurements with this instrument, and major errors can occur when it is used to measure gases that condense or are adsorbed (e.g., water). In general, gages other than the McLeod gage should be used for most low-pressure or vacuum applications.

## MECHANICAL PRESSURE GAGES

Mechanical pressure gages couple a pressure sensor to a mechanical readout, typically a pointer and dial. The most common type employs a **Bourdon tube** sensor, which is essentially a coiled metal tube of circular or elliptical cross section. Increasing pressure applied to the inside of the tube causes it to uncoil. A mechanical linkage translates the motion of the end of the tube to the rotation of a pointer. In most cases, the Bourdon tube is surrounded by atmospheric pressure, so that the gages measure gage pressure. A few instruments surround the Bourdon tube with a sealed enclosure that can be evacuated for absolute measurements or connected to another pressure for differential measurements. Available instruments vary widely in cost, size, pressure range, and accuracy. Full-scale ranges can vary from 35 kPa to 700 MPa. Accuracy of properly calibrated and used instruments can vary from 0.1 to 10% of full scale. Generally there is a strong correlation between size, accuracy, and price; larger instruments are more accurate and expensive.

To achieve better sensitivity, some low-range mechanical gages, sometimes called **aneroid gages**, employ corrugated diaphragms or capsules as sensors. The capsule is basically a short bellows sealed with end caps. These sensors are more compliant than a Bourdon tube, and a given applied pressure will cause a larger deflection of the sensor. The inside of a capsule can be evacuated and sealed in order to measure absolute pressures or connected to an external fitting to allow differential pressures to be measured. Typically, these gages are used for low-range measurements of 100 kPa or less. In instruments of better quality, accuracies of 0.1% of reading or better can be achieved.

## ELECTROMECHANICAL TRANSDUCERS

Mechanical pressure gages are generally limited by inelastic behavior of the sensing element, friction in the readout mechanism, and limited resolution of the pointer and dial. These effects can be eliminated or reduced by using electronic techniques to sense the

distortion or stress of a mechanical sensing element and electronically convert that stress or distortion to a pressure reading. A wide variety of sensors is used, including Bourdon tubes, capsules, diaphragms, and different resonant structures whose vibration frequency varies with the applied pressure. Capacitive, inductive, and optical lever sensors are used to measure the displacement of the sensor element. In some cases, feedback techniques may be used to constrain the sensor in a null position, minimizing distortion and hysteresis of the sensing element. Temperature control or compensation is often included. Readout may be in the form of a digital display, analog voltage or current, or a digital code. Size varies, but in the case of transducers employing a diaphragm fabricated as part of a silicon chip, the sensor and signal-conditioning electronics can be contained in a small transistor package, and the largest part of the device is the pressure fitting. The best of these instruments achieve long-term instabilities of 0.01% or less of full scale, and corresponding accuracies when properly calibrated. Performance of the less expensive instruments can be more on the order of several percent.

While the dynamic response of most mechanical gages is limited by the sensor and readout, the response of some electromechanical transducers can be much faster, allowing measurements of dynamic pressures at frequencies up to 1 kHz and beyond in the case of transducers specifically designed for dynamic measurements. Manufacturers' literature should be consulted as a guide to the dynamic response of specific instruments.

As the measured pressure is reduced below about 10 kPa, it becomes increasingly difficult to sense mechanically. A variety of gages have been developed that measure some other property of the gas that is related to the pressure. In particular, thermal conductivity gages, known as thermocouple, thermistor, Pirani, and convection gages, are used for pressures down to about 0.1 Pa. These gages have a sensor tube with a small heated element and a temperature sensor; the temperature of the heated element is determined by the thermal conductivity of the gas, and the output of the temperature sensor is displayed on an analog or digital electrical meter contained in an attached electronics unit. The accuracy of thermal conductivity gages is limited by their nonlinearity, dependence on gas species, and tendency to read high when contaminated. Oil contamination is a particular problem. However, these gages are small, reasonably rugged, and relatively inexpensive; in the hands of a typical user, they will give far more reliable results than a McLeod gage. They can be used to check the base pressure in a system that is being evacuated prior to being filled with refrigerant. They should be checked periodically for contamination by comparing the reading with that from a new, clean sensor tube.

### GENERAL CONSIDERATIONS

Accurate values of atmospheric or barometric pressure are required for weather prediction and aircraft altimetry. In the United States, a network of calibrated instruments, generally accurate to within 0.1% of reading and located at airports, is maintained by the National Weather Service, the Federal Aviation Administration, and local airport operating authorities. These agencies are generally cooperative in providing current values of atmospheric pressure that can be used to check the calibration of absolute pressure gages or to correct gage pressure readings to absolute pressures. However, the pressure readings generally reported for weather and altimetry purposes are not the true atmospheric pressure, but rather a value adjusted to an equivalent sea level pressure. Therefore, unless the location is near sea level, it is important to ask for the station or true atmospheric pressure rather than using the adjusted values broadcast by radio stations. Further, the atmospheric pressure decreases with increasing elevation at a rate (near sea level) of about 10 Pa/m, and corresponding corrections should be made to account for the difference in elevation between the instruments being compared.

As noted before, gage-pressure instruments are sometimes used to measure absolute pressures, and the accuracy of these measurements can be compromised by uncertainties in the atmospheric pressure. This error can be particularly serious when gage-pressure instruments are used to measure a vacuum (negative gage pressures). For all but the most crude measurements, absolute-pressure gages should be used for vacuum measurements; for pressures below about 100 Pa, a thermal conductivity gage should be used.

All pressure gages are susceptible to temperature errors. Several techniques are used to minimize these errors—sensor materials are generally chosen to minimize temperature effects, mechanical readouts can include temperature compensation elements, electromechanical transducers may include a temperature sensor and compensation circuit, and some transducers are operated at a controlled temperature. Clearly, temperature effects are of greater concern for field applications, and it is prudent to check the manufacturers' literature for the temperature range over which the specified accuracy can be maintained. Abrupt temperature changes can also cause large transient errors that may take some time to decay.

The readings of some electromechanical transducers with a resonant or vibrating sensor can depend on the gas species. Although some of these units can achieve calibrated accuracies of the order of 0.01% of reading, they are typically calibrated with dry air or nitrogen, and the readings for other gases can be in error by several percent, quite possibly much more for refrigerants and other high-density gases. High-accuracy readings can be maintained by calibrating these devices with the gas to be measured. Manufacturer's literature should be consulted.

The measurement of dynamic pressures is limited not just by the frequency response of the pressure gage, but also by the hydraulic or pneumatic time constant of the connection between the gage and the system to be monitored. As a general rule, the longer the connecting lines and the smaller their diameter, the lower the frequency response of the system. Further, even if only the static component of the pressure is of interest, and a gage with a low-frequency response is used, a significant pulsating or oscillating pressure component can cause significant errors in pressure gage readings and, in some cases, can damage the gage, particularly gages with a mechanical readout mechanism. In these cases, a filter or snubber should be used to reduce the higher frequency components.

## VELOCITY MEASUREMENT

HVAC engineers measure the flow of air more often than any other gas, and the air is usually measured at or near atmospheric pressure. Under this condition, the air can be treated as an incompressible fluid, and simple formulas give sufficient precision to solve many problems. Instruments that measure fluid velocity and their application range and precision are listed in Table 4.

### AIRBORNE TRACER TECHNIQUES

Tracer techniques are suitable for measuring velocity in an open space. Typical tracers include smoke, feathers, pieces of lint, and radioactive or nonradioactive gases. Measurements are made by timing the rate of movement of solid tracers or by monitoring the change in concentration level of gas tracers.

Smoke is a useful qualitative tool in studying air movements. Smoke can be obtained from titanium tetrachloride (irritating to nasal membranes) or by mixing potassium chlorate and powdered sugar (a nonirritating smoke) and firing the mixture with a match. The latter process produces considerable heat and should be confined to a pan away from flammable materials. Titanium tetrachloride smoke works well for spot tests, particularly for leakage

**Table 4 Velocity Measurement**

Measurement Means	Application	Range, m/s	Precision	Limitations
Smoke puff or airborne solid tracer	Low air velocities in rooms; highly directional	0.025 to 0.25	10 to 20%	Awkward to use but valuable in tracing air movement
Deflecting vane anemometer	Air velocities in rooms, at outlets, etc.; directional	0.15 to 120	5%	Needs periodic check calibration
Revolving vane anemometer	Moderate air velocities in ducts and rooms; somewhat directional	0.5 to 15	2 to 5%	Extremely subject to error with variations in velocities with space or time; easily damaged; needs periodic calibration
Hot-wire anemometer	a. Low air velocities; directional and nondirectional available	0.005 to 5	2 to 5%	Requires accurate calibration at frequent intervals. Some are relatively costly.
	b. High air velocities	Up to 300	0.2 to 5%	
	c. Transient velocity and turbulence			
Pitot tube	Standard instrument for measuring duct velocities	0.9 to 50 with micromanometer; 3 to 50 with draft gages; 50 up with manometer	1 to 5%	Accuracy falls off at low end of range
Impact tube and sidewall or other static tap	High velocities, small tubes and where air direction may be variable	0.6 to 50 with micromanometer; 3 to 50 with draft gages; 50 up with manometer	1 to 5%	Accuracy depends on constancy of static pressure across stream section
Cup anemometer	Meteorological	Up to 60	2 to 5%	Poor accuracy at low air velocity (<2.5 m/s)
Laser Doppler velocimeter	Calibration of air velocity instruments	0.005 to 30	1 to 3%	High cost and complexity limit LDVs to laboratory applications

through casings and ducts, because it can be handled easily in a small, pistol-like ejector.

The fumes of ammonia water and sulfuric acid, if permitted to mix, form a white precipitate. Two bottles, one containing ammonia water and the other containing acid, are connected to a common nozzle by rubber tubing. A syringe forces air over the liquid surfaces in the bottles; the two streams mix at the nozzle and form a white cloud.

A satisfactory test smoke also can be made by bubbling an airstream through ammonium hydroxide and then hydrochloric acid (Nottage et al. 1952). Smoke tubes, smoke candles, and smoke bombs are available for studying airflow patterns.

## ANEMOMETERS

### Deflecting Vane Anemometers

The deflecting vane anemometer consists of a pivoted vane enclosed in a case. Air exerts pressure on the vane as it passes through the instrument from an upstream to a downstream opening. A hair spring and a damping magnet resist vane movement. The instrument gives instantaneous readings of directional velocities on an indicating scale. With fluctuating velocities, it is necessary to average the needle swings visually to obtain average velocities. This instrument is useful for studying air motion in a room; locating objectionable drafts; measuring air velocities at supply and return diffusers and grilles; and measuring laboratory hood face velocities.

### Propeller or Revolving Vane Anemometers

The propeller anemometer consists of a light, revolving wind-driven wheel connected through a gear train to a set of recording dials that read linear metres of air passing in a measured length of time. It is made in various sizes—75, 100, and 150 mm are the most common. Each instrument requires individual calibration. At low velocities, the friction drag of the mechanism is considerable. To compensate for this, a gear train that overspeeds is commonly used. For this reason, the correction is often additive at the lower range

and subtractive at the upper range, with the least correction in the middle range of velocities. The best of these instruments have starting speeds of 0.25 m/s or higher; therefore, they cannot be used below that air speed. Electronic revolving vane anemometers, with optical or magnetic pickups to sense the rotation of the vane, are available. Sizes for the vanes range as small as 13 mm in diameter for the electronic versions.

### Cup Anemometers

The cup anemometer is primarily used to measure outdoor, meteorological wind speeds. It consists of three or four hemispherical cups mounted radially from a vertical shaft. Wind from any direction with a vector component in the plane of cup rotation causes the cups and shaft to rotate. Because the primary use of this anemometer is to make meteorological wind speed measurements, the instrument is usually constructed so that wind speeds can be recorded or indicated electrically at a remote point.

### Thermal Anemometers

The thermal or hot-wire anemometer consists of a heated RTD, thermocouple junction, or thermistor sensor constructed at the end of a probe; it is designed to provide a direct, simple method of determining air velocity at a point in the flow field. The probe is placed into an airstream, and the movement of air past the electrically heated velocity sensor tends to cool the sensor in proportion to the speed of the airflow. The electronics and sensor are commonly combined into a portable, hand-held device that interprets the sensor signal and provides a direct reading of air velocity in either analog or digital display format. Often the sensor probe also incorporates an ambient temperature-sensing RTD or thermistor, in which case the indicated air velocity is “temperature compensated” to “standard” air density conditions (typically 1.20 kg/m<sup>3</sup>).

Hot-wire anemometers have long been used in the fluid flow research field. Research anemometer sensors have been constructed using very fine wires in configurations that allow the researcher to characterize fluid flows in one, two, and three dimensions with

sensor/electronics response rates up to several hundred kilohertz. This technology has been incorporated into more ruggedized sensors suitable for measurements in the HVAC field, primarily for unidirectional airflow measurement. Omnidirectional sensing instruments suitable for thermal comfort studies are also available.

The principal advantages of thermal anemometers are their wide dynamic range and their ability to sense extremely low velocities. Typical accuracy (including repeatability) of 2 to 5% of reading over the entire velocity range is often achieved in commercially available portable instruments.

Among the limitations of thermal anemometers are the following: (1) the unidirectional sensor must be carefully aligned in the airstream (typically to within  $\pm 20^\circ$  rotation) to achieve accurate results; (2) the velocity sensor must be kept clean because contaminant buildup will cause the calibration to change; and (3) due to the inherent high speed of response of thermal anemometers, measurements in turbulent flows can yield fluctuating velocity measurements. Electronically controlled time-integrated functions are now available in many digital air velocity meters to help smooth these turbulent flow measurements.

In the HVAC field, thermal anemometers are suitable for use in a variety of applications. They are particularly well-suited to the low velocities associated with laboratory fume hood face velocity measurements (typically in the 0.3 to 1 m/s range). Thermal anemometers can also be used for taking multipoint traverse measurements in ventilation ductwork.

### Laser Doppler Velocimeters (or Anemometers)

The laser Doppler velocimeter (LDV) or laser Doppler anemometer (LDA) is an extremely complex system that collects scattered light produced by a particle passing through the intersection volume of two intersecting laser beams of the same light frequency (Mease et al. 1992). The scattered light consists of bursts containing a regularly spaced fringe pattern whose frequency is linearly proportional to the speed of the particle. Due to the cost and complexity of these systems, they are usually not suitable for in situ field measurements. Rather, the primary application of LDV systems in the HVAC industry is the calibration of systems used to calibrate other air velocity instruments.

The greatest advantage of an LDV is its performance at low air speeds. It is capable of reading air speeds as low as 0.075 m/s with uncertainty levels of 1% or less (Mease et al. 1992). In addition, it is nonintrusive in the flow—only optical access is required. It can be used to measure fluctuating components as well as mean speeds and is available in one-, two-, and even three-dimensional configurations. Its biggest disadvantages are its high cost and extreme technological complexity, which requires highly skilled operators. Modern fiber optic systems require less-skilled operators but at a considerable increase in cost.

### PITOT-STATIC TUBES

The pitot-static tube, in conjunction with a suitable manometer or differential pressure transducer, provides a simple method of determining air velocity at a point in a flow field. Figure 5 shows the construction of a standard pitot tube (ASHRAE *Standard 51*) and the method of connecting it with inclined manometers to display both static pressure and velocity pressure. The equation for determining air velocity from measured velocity pressure is

$$V = \sqrt{\frac{2p_w}{\rho}} \quad (5)$$

where

$V$  = velocity, m/s

$p_w$  = velocity pressure (pitot-tube manometer reading), Pa

$\rho$  = density of air,  $\text{kg/m}^3$

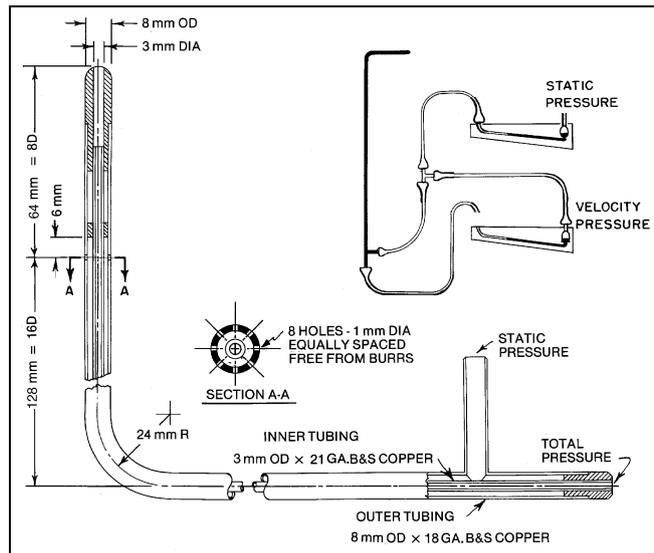

Fig. 5 Standard Pitot Tube

The type of manometer or differential pressure transducer used with a pitot-static tube depends on the magnitude of velocity pressure being measured and on the desired accuracy. At velocities greater than 7.5 m/s, a draft gage of appropriate range is usually satisfactory. If the pitot-static tube is used to measure air velocities lower than 7.5 m/s, a precision manometer or comparable pressure differential transducer is essential.

Other pitot-static tubes have been used and calibrated. To meet special conditions, various sizes of pitot-static tubes geometrically similar to the standard tube can be used. For relatively high velocities in ducts of small cross-sectional area, total pressure readings can be obtained with an impact (pitot) tube. Where static pressure across the stream is relatively constant, as in turbulent flow in a straight duct, a sidewall tap to obtain static pressure can be used with the impact tube to obtain the velocity pressure. One form of impact tube is a small streamlined tube with a fine hole in its upstream end and with its axis placed parallel to the stream.

If the Mach number of the flow is greater than about 0.3, the effects of compressibility should be included in the computation of the air speed from pitot-static and impact (stagnation or pitot) tube measurements (Mease et al. 1992).

### MEASURING FLOW IN DUCTS

Because velocity in a duct is seldom uniform across any section, and a pitot tube reading or thermal anemometer indicates velocity at only one location, a traverse is usually made to determine average velocity. Generally, velocity is lowest near the edges or corners and greatest at or near the center.

To determine the velocity in a traverse plane, a straight average of individual point velocities will give satisfactory results when point velocities are determined by the **log-Tchebycheff rule** (ISO *Standard 3966*) or, if care is taken, by the **equal area method**. Figure 6 shows suggested sensor locations for traversing round and rectangular ducts. The log-Tchebycheff rule provides the greatest accuracy because its location of traverse points accounts for the effect of wall friction and the fall-off of velocity near wall ducts. This method is now recommended for rectangular ducts, although for circular ducts the log-Tchebycheff and log-linear traverse methods are similar. Log-Tchebycheff minimizes the positive error (measured greater than actual) caused by the failure to account for

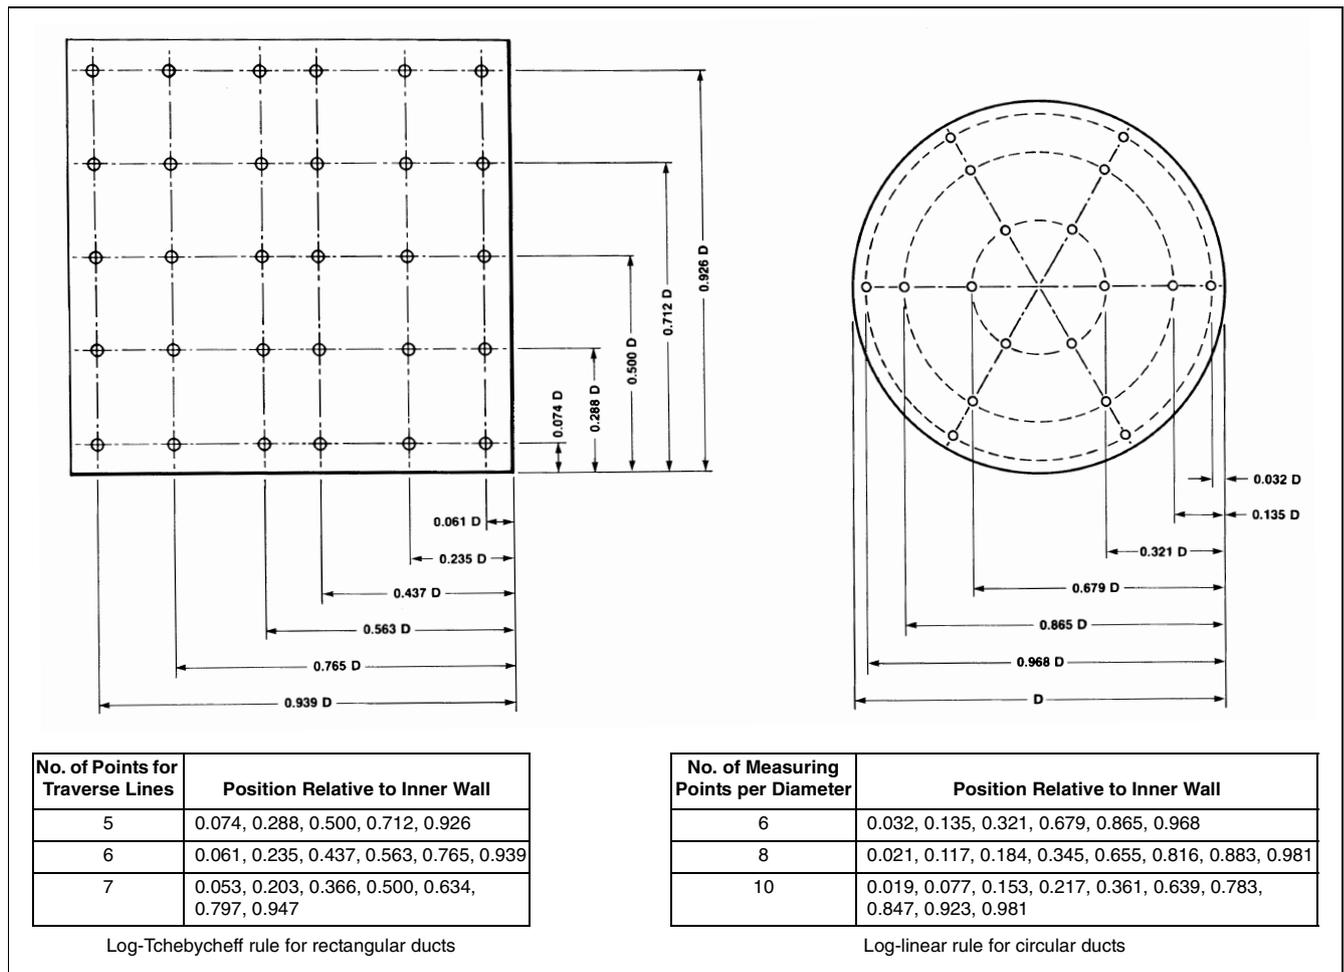

Fig. 6 Measuring Points for Rectangular and Round Duct Traverse

losses at the duct wall. This error can occur when using the older method of equal subareas to traverse rectangular ducts.

For a rectangular duct traverse, a minimum of 25 points should be measured. For a duct size less than 450 mm, the points should be located at the center of equal areas not more than 150 mm apart, and a minimum of 2 points per side should be used. For a duct side greater than 1400 mm, the maximum distance between points is 200 mm. For a circular duct traverse, the log-linear rule and three symmetrically disposed diameters may be used (Figure 6). Points on two perpendicular diameters may be used where access is limited.

If possible, measuring points should be located at least 7.5 diameters downstream and 3 diameters upstream from a disturbance (e.g., caused by a turn). Compromised traverses as close as 2 diameters downstream and 1 diameter upstream can be performed with an increase in measurement error. Because field-measured airflows are rarely steady and uniform, particularly near disturbances, accuracy can be improved by increasing the number of measuring points. Straightening vanes (ASHRAE Standard 51) located 1.5 duct diameters ahead of the traverse plane improve measurement precision.

When velocities at a traverse plane fluctuate, the readings should be averaged on a time-weighted basis. Two traverse readings in short succession also help to average out velocity variations that occur with time. If negative velocity pressure readings are encountered, they are considered a measurement value of zero and calculated in the average velocity pressure. ASHRAE Standard 111 has further information on measuring flow in ducts.

## FLOW RATE MEASUREMENT

Various means of measuring fluid flow rate are listed in Table 5. The values for volumetric or mass flow rate measurement (ASME Standard PTC 19.5, Benedict 1984) are often determined by measuring pressure difference across an orifice, nozzle, or venturi tube. The various meters have different advantages and disadvantages. For example, the orifice plate is more easily changed than the complete nozzle or venturi tube assembly. However, the nozzle is often preferred to the orifice because its discharge coefficient is more precise. The venturi tube is a nozzle followed by an expanding recovery section to reduce net pressure loss. Differential pressure-type flow measurement has benefited through workshops addressing fundamental issues, textbooks, research, and improved standards (Miller 1983, DeCarlo 1984, Mattingly 1984, ASME Standard B40.1, ASME Standard MFC-9M, ASME Standard MFC-10M, ASME Standard MFC-1M).

Fluid meters use a wide variety of physical techniques to make flow measurements (ASME Standard PTC 19.5, Miller 1983, DeCarlo 1984); those more prevalently used are described in this section. To assure and validate the accuracy of flow rate measurement instruments, appropriate calibration procedures should include documentation of traceability to the calibration facility. The calibration facility should, in turn, provide documentation of traceability to national standards.

Table 5 Volumetric or Mass Flow Rate Measurement

Measurement Means	Application	Range	Precision	Limitations
Orifice and differential pressure measurement system	Flow through pipes, ducts, and plenums for all fluids	Above Reynolds number of 5000	1 to 5%	Discharge coefficient and accuracy influenced by installation conditions
Nozzle and differential pressure measurement system	Flow through pipes, ducts, and plenums for all fluids	Above Reynolds number of 5000	0.5 to 2.0%	Discharge coefficient and accuracy influenced by installation conditions
Venturi tube and differential pressure measurement system	Flow through pipes, ducts, and plenums for all fluids	Above Reynolds number of 5000	0.5 to 2.0%	Discharge coefficient and accuracy influenced by installation conditions
Timing given mass or volumetric flow	Liquids or gases; used to calibrate other flowmeters	Any	0.1 to 0.5%	System is bulky and slow
Rotameters	Liquids or gases	Any	0.5 to 5.0%	Should be calibrated for fluid being metered
Displacement meter	Relatively small volumetric flow with high pressure loss	As high as 500 L/s depending on type	0.1 to 2.0% depending on type	Most types require calibration with fluid being metered
Gasometer or volume displacement	Short-duration tests; used to calibrate other flowmeters	Total flow limited by available volume of containers	0.5 to 1.0%	—
Thomas meter (temperature rise of stream due to electrical heating)	Elaborate setup justified by need for good accuracy	Any	1%	Uniform velocity; usually used with gases
Element of resistance to flow and differential pressure measurement system	Used for check where system has calibrated resistance element	Lower limit set by readable pressure drop	1 to 5%	Secondary reading depends on accuracy of calibration
Turbine flowmeters	Liquids or gases	Any	0.25 to 2.0%	Uses electronic readout
Instrument for measuring velocity at point in flow	Primarily for installed systems with no special provision for flow measurement	Lower limit set by accuracy of velocity measurement	2 to 4%	Accuracy depends on uniformity of flow and completeness of traverse
Heat input and temperature changes with steam and water coil	Check value in heater or cooler tests	Any	1 to 3%	—
Laminar flow element and differential pressure measurement system	Measure liquid or gas volumetric flow rate; nearly linear relationship with pressure drop; simple and easy to use	50 mm <sup>3</sup> /s to 1 m <sup>3</sup> /s	1%	Fluid must be free of dirt, oil, and other impurities that could plug meter or affect its calibration
Magnetohydrodynamic flowmeter (electromagnetic)	Measures electrically conductive fluids, slurries; meter does not obstruct flow; no moving parts	0.006 to 600 L/s	1%	At present state of the art, conductivity of fluid must be greater than 5 μmho/cm
Swirl flowmeter and vortex shedding meter	Measure liquid or gas flow in pipe; no moving parts	Above Reynolds number of 10 <sup>4</sup>	1%	—

## Flow Measurement Methods

**Direct.** Both gas and liquid flow can be measured quite accurately by timing a collected amount of fluid that is measured gravimetrically or volumetrically. While this method is commonly used for calibrating other metering devices, it is particularly useful where the flow rate is low or intermittent and where a high degree of accuracy is required. These systems are generally large and slow, but in their simplicity, they can be considered primary devices.

The variable area meter or rotameter is a convenient direct-reading flowmeter for liquids and gases. This is a vertical, tapered tube in which the flow rate is indicated by the position of a float suspended in the upward flow. The position of the float is determined by its buoyancy and the upwardly directed fluid drag.

Displacement meters measure total liquid or gas flow over time. The two major types of displacement meters used for gases are the conventional gas meter, which uses a set of bellows, and the wet test meter, which uses a water displacement principle.

**Indirect.** The **Thomas meter** is used in laboratories to measure high gas flow rates with low pressure losses. The gas is heated by electric heaters, and the temperature rise is measured by two resistance thermometer grids. When the heat input and temperature rise are known, the mass flow of gas is calculated as the

quantity of gas that will remove the equivalent heat at the same temperature rise.

A velocity traverse (made using a pitot tube or other velocity-measuring instrument) measures airflow rates in the field or calibrates large nozzles. This method can be imprecise at low velocities and impracticable where many test runs are in progress.

Another field-estimating method measures the pressure drop across elements with known pressure drop characteristics, such as heating and cooling coils or fans. If the pressure drop/flow rate relationship has been calibrated, the results can be precise. If the method depends on rating data, it should be used for check purposes only.

## VENTURI, NOZZLE, AND ORIFICE FLOWMETERS

Flow in a pipeline can be measured by a venturi meter (Figure 7), flow nozzle (Figure 8), or orifice plate (Figure 9). American Society of Mechanical Engineers (ASME) *Standard* MFC-3M describes measurement of fluid flow in pipes using the orifice, nozzle, and venturi; ASME *Standard* PTC 19.5 specifies their construction.

Assuming an incompressible fluid (liquid or slow-moving gas), uniform velocity profile, frictionless flow, and no gravitational

effects, the principle of conservation of mass and energy can be applied to the venturi and nozzle geometries to give

$$w = \rho V_1 A_1 = \rho V_2 A_2 = A_2 \sqrt{\frac{2\rho(p_1 - p_2)}{1 - \beta^4}} \quad (6)$$

where

- $w$  = mass flow rate, kg/s
- $V$  = velocity of stream, m/s
- $A$  = flow area, m<sup>2</sup>
- $\rho$  = density of fluid, kg/m<sup>3</sup>
- $p$  = absolute pressure, Pa
- $\beta = (D_2/D_1)$  for venturi and sharp edge orifice and  $d/D$  for flow nozzle

Note: Subscript 1 refers to the entering conditions; subscript 2 refers to the throat conditions.

Because the flow through the meter is not frictionless, a correction factor  $C$  is defined to account for friction losses. If the fluid is at a high temperature, an additional correction factor  $F_a$  should be included to account for thermal expansion of the primary element. Because this amounts to less than 1% at 260°C, it can usually be omitted. Equation (6) then becomes

$$w = CA_2 \sqrt{\frac{2\rho(p_1 - p_2)}{1 - \beta^4}} \quad (7)$$

where  $C$  is the friction loss correction factor.

The factor  $C$  is a function of geometry and Reynolds number. Values of  $C$  are given in ASME Standard PTC 19.5. The jet passing through an orifice plate contracts to a minimum area at the vena contracta located a short distance downstream from the orifice plate. The contraction coefficient, friction loss coefficient  $C$ , and approach factor  $1/(1 - \beta^4)^{0.5}$  can be combined into a single constant  $K$ , which is a function of geometry and Reynolds number. The orifice flow rate equations then become

$$Q = KA_2 \sqrt{\frac{2(p_1 - p_2)}{\rho}} \quad (8)$$

where

- $Q$  = discharge flow rate, m<sup>3</sup>/s
- $A_2$  = orifice area, m<sup>2</sup>
- $p_1 - p_2$  = pressure drop as obtained by pressure taps, Pa

Values of  $K$  are shown in ASME Standard PTC 19.5.

Valves, bends, and fittings upstream from the flowmeter can cause errors. Long, straight pipes should be installed upstream and downstream from the flow devices to assure fully developed flow for proper measurement. ASHRAE Standard 41.8 specifies upstream

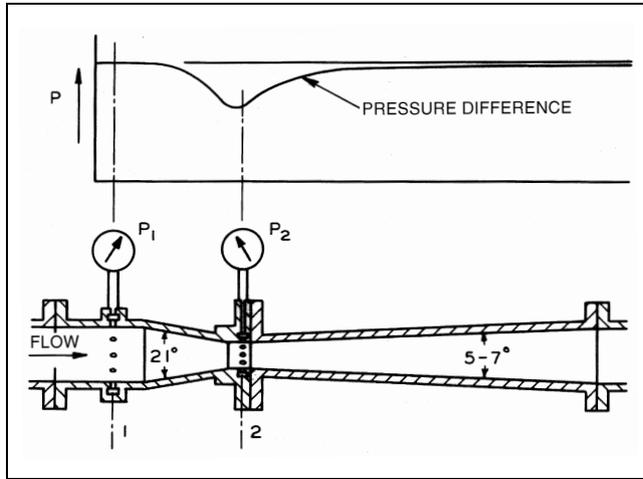

Fig. 7 Typical Herschel Type Venturi Meter

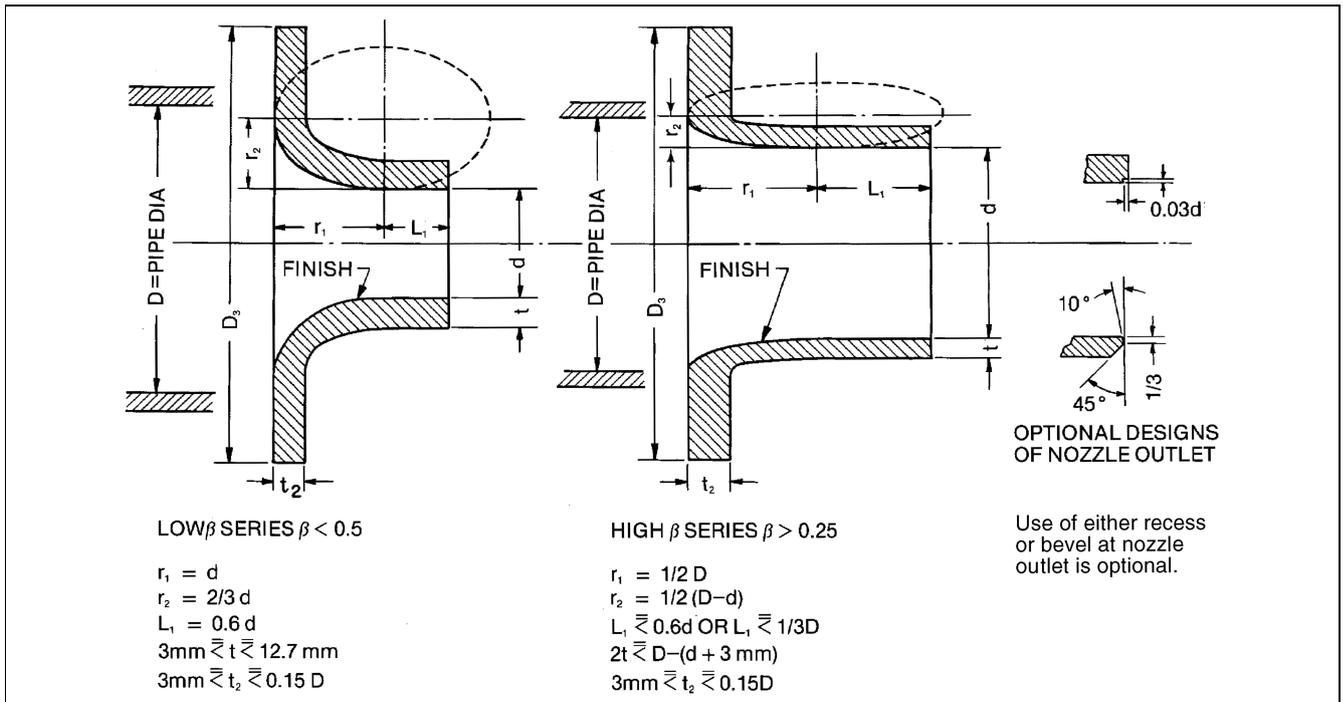

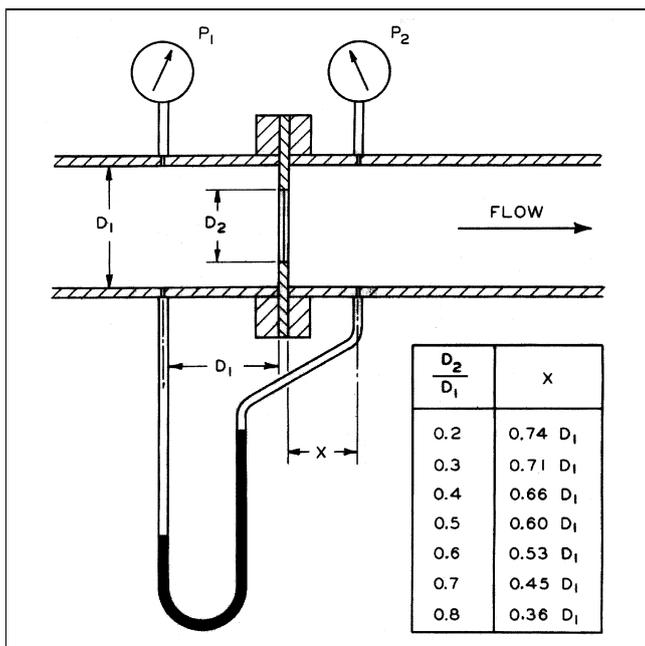

Fig. 8 Dimensions of ASME Long-Radius Flow Nozzles

**Fig. 9 Sharp Edge Orifice with Pressure Tap Locations**

From ASME PTC 19.5. Reprinted with permission of ASME.

and downstream pipe lengths for measuring flow of liquids with an orifice plate. ASME *Standard* PTC 19.5 gives the piping requirements between various fittings and valves and the venturi, nozzle, and orifice. If these conditions cannot be met, flow conditioners or straightening vanes can be used (ASME *Standard* PTC 19.5, ASME *Standard* MFC-10M, Mattingly 1984, Miller 1983).

Compressibility effects must be considered for gas flow if the pressure drop across the measuring device is more than a few percent of the initial pressure.

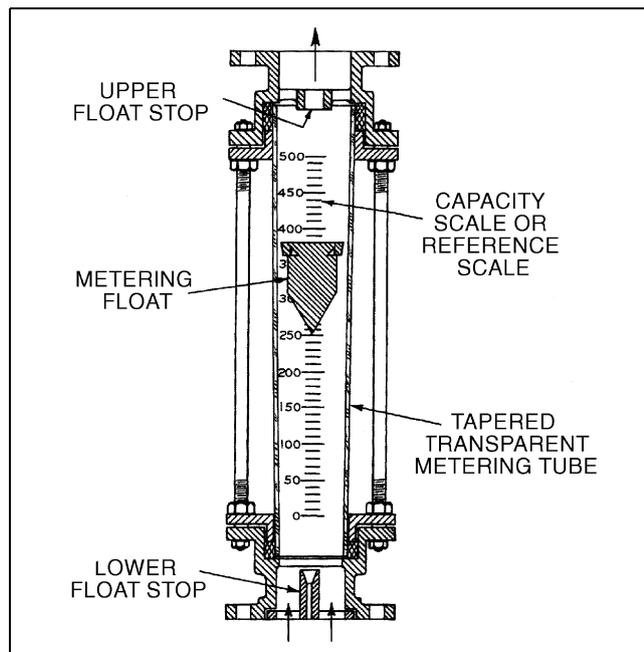

Nozzles are sometimes arranged in parallel pipes from a common manifold; thus, the capacity of the testing equipment can be changed by shutting off the flow through one or more nozzles. An apparatus designed for testing airflow and capacity of air-conditioning equipment is described by Wile (1947), who also presents pertinent information on nozzle discharge coefficients, Reynolds numbers, and resistance of perforated plates. Some laboratories refer to this apparatus as a code tester.

### VARIABLE AREA FLOWMETERS (ROTAMETERS)

In permanent installations where high precision, ruggedness, and operational ease are important, the variable area flowmeter is satisfactory. It is frequently used to measure liquids or gases in small-diameter pipes. For ducts or pipes over 150 mm in diameter, the expense of this meter may not be warranted. In larger systems, however, the meter can be placed in a bypass line and used with an orifice.

The variable area meter (Figure 10) commonly consists of a float that is free to move vertically in a transparent tapered tube. The fluid to be metered enters at the narrow bottom end of the tube and moves upward, passing at some point through the annulus formed between the float and the inside wall of the tube. At any particular flow rate, the float assumes a definite position in the tube; a calibrated scale on the tube shows the float's location and the fluid flow rate.

The position of the float is established by a balance between the fluid pressure forces across the annulus and gravity on the float. The buoyant force supporting the float,  $v_f(\rho_f - \rho)g$ , is balanced by the pressure difference acting on the cross-sectional area of the float

**Fig. 10 Variable Area Flowmeter**

$A_f \Delta p$ , where  $\rho_f$ ,  $A_f$ , and  $v_f$  are, respectively, the float density, float cross-sectional area, and float volume. The pressure difference across the annulus is

$$\Delta p = \frac{v_f(\rho_f - \rho)g}{A_f} \quad (9)$$

The mass flow follows from Equation (8) as

$$w = KA_2 \sqrt{\frac{2v_f(\rho_f - \rho)g\rho}{A_f}} \quad (10)$$

The flow for any selected fluid is nearly proportional to the area, so that calibration of the tube is convenient. To use the meter for different fluids, the flow coefficient variation for any float must be known. Float design can reduce variation of the flow coefficient with Reynolds number; float materials can reduce the dependence of mass flow calibration on fluid density.

### POSITIVE DISPLACEMENT METERS

Many positive displacement meters are available for measuring total liquid or gas volumetric flow rates. The fluid measured in these meters flows progressively into compartments of definite size. As the compartments are filled, they are rotated so that the fluid discharges from the meter. The flow rate through the meter is equal to the product of the compartment volume, the number of compartments, and the rotation rate of the rotor. Most of these meters have a mechanical register calibrated to show total flow.

### TURBINE FLOWMETERS

Turbine flowmeters are volumetric flow rate sensing meters with a magnetic stainless steel turbine rotor suspended in the flow stream of a nonmagnetic meter body. The fluid stream exerts a force on the blades of the turbine rotor, setting it in motion and converting the fluid's linear velocity to an angular velocity. Design motivation for turbine meters is to have the rotational speed of the turbine proportional to the average fluid velocity and

thus to the volume rate of fluid flow (Miller 1983, DeCarlo 1984, Mattingly 1992).

The rotational speed of the rotor is monitored by an externally mounted pickoff assembly. Magnetic and radio frequency are the most commonly used pickoffs. The magnetic pickoff contains a permanent magnet and coil. As the turbine rotor blades pass through the field produced by the permanent magnet, a shunting action induces ac voltage in the winding of the coil wrapped around the magnet. A sine wave with a frequency proportional to the flow rate develops. With the radio frequency pickoff, an oscillator applies a high-frequency carrier signal to a coil in the pickoff assembly. The rotor blades pass through the field generated by the coil and modulate the carrier signal by shunting action on the field shape. The carrier signal is modulated at a rate corresponding to the rotor speed, which is proportional to the flow rate. With both pickoffs, frequency of the pulses generated becomes a measure of flow rate, and the total number of pulses measures total volume (Woodring 1969, Shafer 1961, Mattingly 1992).

Because output frequency of the turbine flowmeter is proportional to flow rate, every pulse from the turbine meter is equivalent to a known volume of fluid that has passed through the meter; the sum of these pulses yields total volumetric flow. Summation is accomplished by electronic counters designed for use with turbine flowmeters; they combine a mechanical or electronic register with the basic electronic counter.

Turbine flowmeters should be installed with straight lengths of pipe upstream and downstream from the meter. The length of the inlet and outlet pipes should be according to manufacturers' recommendations or pertinent standards. Where recommendations of standards cannot be accommodated, the meter installation should be calibrated. Some turbine flowmeters can be used in bidirectional flow applications. A fluid strainer, used with liquids of poor or marginal lubricity, minimizes bearing wear.

The lubricity of the process fluid and the type and quality of rotor bearings determine whether the meter is satisfactory for the particular application. When choosing turbine flowmeters for use with fluorocarbon refrigerants, attention must be paid to the type of bearings used in the meter and to the oil content of the refrigerant. For these applications, sleeve-type rather than standard ball bearings are recommended. The amount of oil in the refrigerant can severely affect calibration and bearing life.

In metering liquid fluorocarbon refrigerants, the liquid must not flash to a vapor (cavitate). This would cause a tremendous increase in flow volume. Flashing results in erroneous measurements and rotor speeds that can damage the bearings or cause a failure. Flashing can be avoided by maintaining an adequate back pressure on the downstream side of the meter (Liptak 1972).

### AIRFLOW-MEASURING HOODS

Flow-measuring hoods are portable instruments designed to measure supply or exhaust airflow through diffusers and grilles in HVAC systems. A flow-measuring hood assembly typically consists of a fabric hood section, a plastic or metal base, an airflow-measuring manifold, a meter, and handles for carrying and holding the hood in place.

For volumetric airflow measurements, the flow-measuring hood is placed over a diffuser or grille. The fabric hood captures and directs airflow from the outlet or inlet across the flow-sensing manifold in the base of the instrument. The manifold consists of a number of tubes containing upstream and downstream holes in a grid pattern designed to simultaneously sense and average multiple velocity points across the base of the flow-measuring hood. Air from the upstream holes flows through the tubes past a sensor and then exits through the downstream holes. Sensors employed by different manufacturers include swinging vane anemometers, electronic micromanometers, and thermal anemometers. In the case of

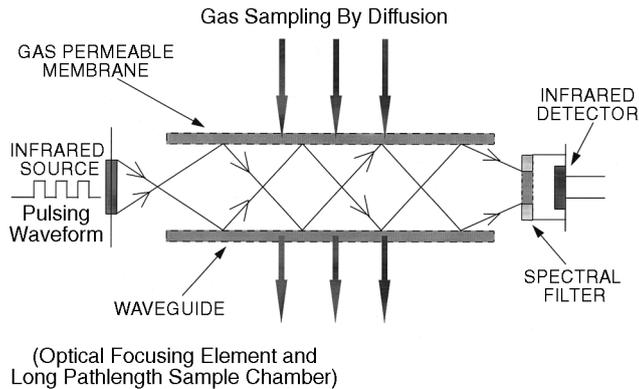

the electronic micromanometer sensor, air does not actually flow through the manifold, but the airtight sensor senses the pressure differential from the upstream to downstream series of holes. The meter on the base of the flow-measuring hood interprets the signal from the sensor and provides a direct reading of volumetric flow in either an analog or digital display format.

As a performance check in the field, the indicated flow of a measuring hood can be compared to a duct traverse flow measurement (using a pitot-tube or a thermal anemometer). All flow-measuring hoods induce some back pressure on the air-handling system because the hood restricts the flow coming out of the diffuser. This added resistance alters the true amount of air coming out of the diffuser. In most cases, this error is negligible and is less than the accuracy of the instrument. For proportional balancing, this error need not be taken into account because all similar diffusers will have about the same amount of back pressure. To determine whether back pressure is significant, a velocity traverse can be made in the duct ahead of the diffuser with and without the flow-measuring hood in place. The difference in the average velocity of the traverse indicates the degree of back-pressure compensation required on similar diffusers in the system. For example, if the average velocity is 4.0 m/s with the hood in place and 4.1 m/s without the hood, the indicated flow reading can be multiplied by 1.025 on similar diffusers in the system ( $4.1/4.0 = 1.025$ ). As an alternative, the designer of the air-handling system can predict the reduction in airflow due to the additional pressure of the hood by using a curve supplied by the flow-measuring hood manufacturer. This curve indicates the pressure drop through the hood for different flow rates.

## AIR INFILTRATION, AIRTIGHTNESS, AND OUTDOOR AIR VENTILATION RATE MEASUREMENT

Two major characteristics describe air infiltration in buildings—air exchange rate and envelope air leakage. The measurement approaches used to determine these factors are described in Chapter 26. The air exchange rate of a building refers to the rate at which outdoor air enters the building under normal weather and ventilation system operation. In general, the air change rate includes both outdoor air taken in through the air handlers and air leakage through the building envelope (infiltration). The outdoor air intake rate is determined by the design, installation, and operation of the mechanical ventilation system. Infiltration is determined by the extent and distribution of leaks over the building envelope and the pressure differences across these leaks. These pressure differences are induced by wind, inside-outside temperature differences, and the operation of building mechanical equipment. To fully characterize the air exchange performance of a building, the air exchange rate must be measured over a range of weather and equipment operation.

The outdoor air ventilation rate is an indicator of the rate of dilution of occupant- and building-generated contaminants. Building air exchange rates can be measured by injecting a tracer gas into a building and monitoring and analyzing the tracer gas concentration response. The equipment required for tracer testing includes (1) a means of injecting the tracer gas and (2) a tracer gas monitor. A variety of tracer gas techniques are used. They are distinguished by their injection strategy and analysis approach. These techniques include the constant concentration (equilibrium tracer), tracer decay (ASTM *Standard E 741*), and outside air fraction (air ratio) methods. Tracer decay is the simplest and most accurate of these techniques (as per Chapter 26), but the other methods may be satisfactory if care is taken. Carbon dioxide is often used as a tracer gas because CO<sub>2</sub> gas monitors are relatively inexpensive and easy to use, and occupant-generated CO<sub>2</sub> can be used for most tracer gas techniques. Bottled CO<sub>2</sub> or CO<sub>2</sub> fire extinguishers are also readily available for tracer gas injection.

**Fig. 11 Nondispersive Infrared Carbon Dioxide Sensor**

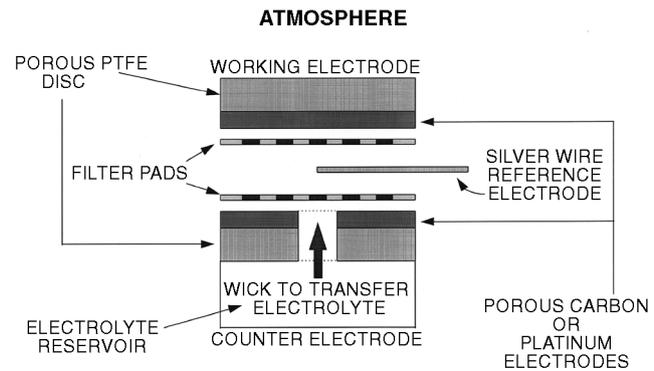

The airtightness of a building envelope can be measured relatively quickly using building pressurization techniques, which are described in Chapter 26. In the pressurization technique, a large fan or blower mounted in a door or window induces a large and roughly uniform pressure difference across the building shell. The airflow required to maintain this pressure difference is then measured. The more leakage in the building, the more airflow is required to induce a specific indoor-outdoor pressure difference. The building airtightness is characterized by the airflow rate at a reference pressure, normalized by the building volume or surface area. Under proper test conditions, the results of a pressurization test are independent of weather conditions. The instrumentation requirements for pressurization testing include air-moving equipment, a device to measure airflow, and a differential pressure gage.

## CARBON DIOXIDE MEASUREMENT

Carbon dioxide has become an important measurement parameter for air-conditioning, heating, and refrigerating engineers, particularly for use in indoor air quality (IAQ) applications. Although CO<sub>2</sub> is generally not of concern as a specific toxin in indoor air, it is used as a surrogate indicator of odor related to human occupancy. ASHRAE *Standard 62* states that maintaining CO<sub>2</sub> concentrations below 1000 ppm (based on a differential of 700 ppm between indoor and outdoor CO<sub>2</sub> concentrations) usually results in conditions conducive to comfort and reduced odor from human-generated pollutants. *Standard 62* also recommends specific minimum outdoor air ventilation rates to ensure adequate indoor air quality. Carbon dioxide is often used as a tracer gas when quantifying outdoor air ventilation rates. Carbon dioxide sensors are also used in building control strategies to optimize ventilation as a function of occupancy.

### NONDISPERSIVE INFRARED CO<sub>2</sub> DETECTORS

The technology in most widespread use for IAQ applications is the nondispersive infrared (NDIR) sensor (Figure 11). This device makes use of the strong absorption band that CO<sub>2</sub> produces at 4.2 μm when excited by an infrared light source. Indoor air quality-specific NDIR instruments, when calibrated between 0 and 5000 ppm, are typically accurate within 150 ppm, but the accuracy of some sensors can be improved to within 50 ppm if the instrument is calibrated for a narrower range. Portable NDIR meters are available with direct-reading digital displays; however, response time varies significantly among different instruments. While most NDIR cell designs facilitate very rapid CO<sub>2</sub> sample diffusion, some of the instruments now in widespread use for indoor air quality measurement exhibit slower sensor response, resulting in stabilization times greater than 5 min (up to 15 min), which may complicate walk-through inspections.

**Fig. 12 Amperometric Carbon Dioxide Sensor**

### Calibration

In a clean, stable environment, NDIR sensors can hold calibration for months, but condensation, dust, dirt, and mechanical shock may offset calibration. As with all other CO<sub>2</sub> sensor technologies, NDIR sensor readings are proportional to pressure due to the change in density of the gas molecules that results from a change in the sample pressure. This leads to errors in CO<sub>2</sub> readings when the barometric pressure changes from the calibration pressure. Weather-induced errors will be small, but all CO<sub>2</sub> instruments should be recalibrated if used at an altitude that is significantly different from the calibration altitude. Some NDIR sensors are sensitive to cooling effects when placed in an airstream. This is an important consideration when locating a fixed sensor or when using a portable system to evaluate air-handling system performance because airflow in supply and return ducts may significantly shift readings.

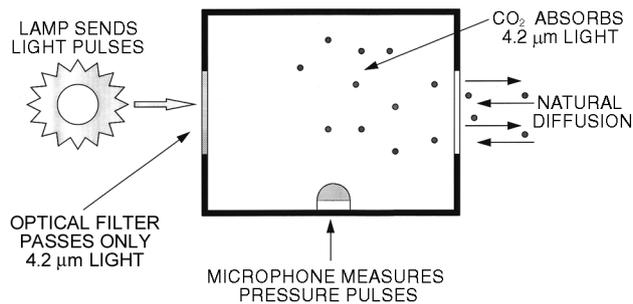

### Applications

Nondispersive infrared sensors are well suited for equilibrium tracer and tracer decay ventilation studies, and faster response models are ideal for a quick, basic evaluation of human-generated pollution and ventilation adequacy. When properly located, these sensors are also appropriate for continuous monitoring and for control strategies using equilibrium tracer and air fraction tracer calculations.

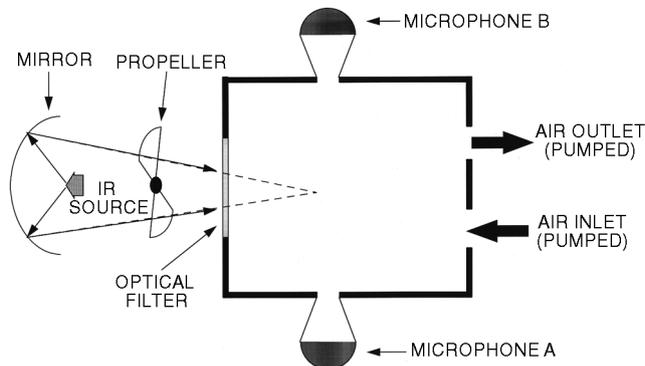

## AMPEROMETRIC ELECTROCHEMICAL CO<sub>2</sub> DETECTORS

Amperometric electrochemical CO<sub>2</sub> sensors (Figure 12) use a measured current driven between two electrodes by the reduction of CO<sub>2</sub> that diffuses across a porous membrane. Unlike NDIR sensors, which normally last the lifetime of the instrument, electrochemical CO<sub>2</sub> sensors may change in electrolyte chemistry over time (typically 12 to 18 months); so sensors should be replaced periodically. These sensors typically hold their calibration for several weeks, but they may drift more if exposed to low humidity; this drift makes them less suitable for continuous monitoring applications. At low humidity (below 30% rh), the sensors must be kept moist to maintain specified accuracy.

Amperometric electrochemical sensors have a lower power requirement than NDIR sensors, usually operating continuously for weeks where NDIR instruments typically operate for 6 hours (older models) to 150 hours (newer models). The longer battery life can be advantageous for spot checks and walk-throughs and for measuring CO<sub>2</sub> distribution throughout a building and within a zone. Unlike most NDIR sensors, amperometric electrochemical sensors are not affected by high humidity, although readings may be affected if condensate is allowed to form on the sensor.

**Fig. 13 Open-Cell Photoacoustic Carbon Dioxide Sensor**

**Fig. 14 Closed-Cell Photoacoustic Carbon Dioxide Sensor**

## PHOTOACOUSTIC CO<sub>2</sub> DETECTORS

Both open- and closed-cell photoacoustic sensors are available.

### Open-Cell Sensors

Open-cell photoacoustic CO<sub>2</sub> sensors (Figure 13) operate as air diffuses through a permeable membrane into a chamber that is pulsed with filtered light at the characteristic CO<sub>2</sub> absorption frequency of 4.2 μm. The light energy absorbed by the CO<sub>2</sub> heats the sample chamber, causing a pressure pulse, which is sensed by a piezoresistor. Open-cell photoacoustic CO<sub>2</sub> sensors are presently unavailable in portable instruments, in part because any vibration that might occur during transportation would affect calibration and might affect the signal obtained for a given concentration of CO<sub>2</sub>. Ambient acoustical noise may also influence readings. For continuous monitoring, vibration is a concern, as are temperature and airflow cooling effects. However, if a sensor is located properly and if the optical filter is kept relatively clean, photoacoustic CO<sub>2</sub> sensors may be very stable. Commercially available open-cell photoacoustic transmitters do not allow recalibration to adjust for pressure differences, so an offset should be incorporated in any control system using these sensors at an altitude or duct pressure other than calibration conditions.

### Closed-Cell Sensors

Closed-cell photoacoustic sensors (Figure 14) operate under the same principle as the open-cell version, except that samples are pumped into a sample chamber that is sealed and environmentally stabilized. Two acoustic sensors are sometimes used in the chamber to minimize vibration effects. Closed-cell units, available as portable or fixed monitors, come with particle filters that are easily replaced (typically at 3- to 6-month intervals) if dirt or dust accumulates on them. Closed-cell photoacoustic monitors permit recalibration to correct for drift, pressure effects, or other environmental factors that might influence accuracy.

## POTENTIOMETRIC ELECTROCHEMICAL CO<sub>2</sub> DETECTORS

Potentiometric electrochemical CO<sub>2</sub> sensors use a porous fluorocarbon membrane that is permeable to CO<sub>2</sub>, which diffuses into a carbonic acid electrolyte, changing the electrolyte pH. This pH change is monitored by a pH electrode inside the cell. The pH electrode isopotential drift prohibits long-term monitoring to the accuracy and resolution required for continuous measurement or control or for detailed IAQ evaluations, although accuracy within 100 ppm, achievable short-term over the 2000 ppm range, may be adequate for basic ventilation and odor evaluations. In addition, this type of sensor exhibits slow response, which increases the operator time necessary for field applications or for performing a walk-through of a building.

## COLORIMETRIC DETECTOR TUBES

Colorimetric detector tubes contain a chemical compound that discolors in the presence of CO<sub>2</sub> gas, with the amount of discoloration related to the CO<sub>2</sub> concentration. These detector tubes are often used to spot check CO<sub>2</sub> levels; when used properly, they are accurate to within 25%. If numerous samples are taken (i.e., six or more), uncertainty may be reduced; this may render the tubes, if used in the late afternoon, adequate as a very basic determination of odor and discomfort related to human occupation. However, CO<sub>2</sub> detector tubes are generally not appropriate for specific ventilation assessment because of their inaccuracy and inability to record concentration changes over time.

## LABORATORY MEASUREMENTS

Laboratory techniques for measuring CO<sub>2</sub> concentration include mass spectroscopy, thermal conductivity, infrared spectroscopy, and gas chromatography. These techniques typically require taking on-site **grab samples** for laboratory analysis. Capital costs for each piece of equipment are high, and significant training is required. A considerable drawback to grab sampling is that CO<sub>2</sub> levels change significantly during the day and over the course of a week, making it sensible to place sensors on site with an instrument capable of recording or data logging measurements continuously over the course of a workweek. An automated grab sampling system capturing many samples of data would be quite cumbersome and expensive if designed to provide CO<sub>2</sub> trend information over time. However, an advantage to laboratory techniques is that they can be highly accurate. A mass spectrometer, for example, can measure CO<sub>2</sub> concentration to within 5 ppm from 0 to 2000 ppm. All laboratory measurement techniques are subject to errors resulting from interfering agents. A gas chromatograph is typically used in conjunction with the mass spectrometer to eliminate interference from nitrous oxide (N<sub>2</sub>O), which has an equivalent mass, if samples are collected in a hospital or in another location where N<sub>2</sub>O might be present.

## ELECTRIC MEASUREMENT

### Ammeters

Ammeters are low-resistance instruments for measuring current. They should be connected in series with the circuit being measured (Figure 15). Ideally, they have the appearance of a short circuit, but in practice, all ammeters have a nonzero input impedance that influences the measurement to some extent.

Ammeters often have several ranges, and it is good practice when measuring unknown currents to start with the highest range and then reduce the range to the appropriate value to obtain the most sensitive reading. Ammeters with range switches maintain circuit continuity during switching. On some older instruments, it

may be necessary to short-circuit the ammeter terminals when changing the range.

Current transformers are often used to increase the operating range of ammeters. They may also provide isolation and thus protection from a high-voltage line. Current transformers have at least two separate windings on a magnetic core (Figure 16). The primary winding is connected in series with the circuit in which the current is measured. In the case of a clamp-on probe, the transformer core is actually opened and then connected around a single conductor carrying the current to be measured. That conductor serves as the primary winding. The secondary winding carries a scaled-down version of the primary current, which is connected to an ammeter. Depending on the type of instrument, the ammeter reading may have to be multiplied by the ratio of the transformer.

When using an auxiliary current transformer, the secondary circuit must not be open when current is flowing in the primary winding; dangerous high voltage may exist across the secondary terminals. A short-circuiting blade between the secondary terminals should be closed before the secondary circuit is opened at any point.

Transformer accuracy can be impaired by the residual magnetism in the core when the primary circuit is opened at an instant when the flux is large. The transformer core may be left magnetized, resulting in ratio and phase angle errors. The primary and secondary windings should be short-circuited before making changes.

### Voltmeters

Voltmeters are high-resistance instruments that should be connected across the load (in parallel), as shown in Figure 17. Ideally they have the appearance of an open circuit, but in practice all voltmeters have some finite impedance that influences the measurement to some extent.

Voltage transformers are often used to increase the operating range of a voltmeter (Figure 18). They also provide isolation from high voltages and prevent injury to the operator. Like current transformers, voltage transformers consist of two or more windings on a magnetic core. The primary winding is generally connected across the high voltage to be measured, and the secondary winding is connected to the voltmeter. It is important not to short-circuit the secondary winding of a voltage transformer.

### Wattmeters

Wattmeters are instruments that measure the active power of an ac circuit, which equals the voltage multiplied by that part of the current in phase with the voltage. There are generally two sets of terminals—one to connect the load voltage and the other to connect in series with the load current. Current and voltage transformers can be used to extend the range of a wattmeter or to isolate it from high voltage. Figure 19 and Figure 20 show connections for single-phase wattmeters, and Figure 21 shows use of current and voltage transformers with a single-phase wattmeter.

Wattmeters with multiple current and voltage elements are available to measure polyphase power. Polyphase wattmeter connections are shown in Figure 22 and Figure 23.

### Power-Factor Meters

Power-factor meters measure the ratio of the active power to the apparent power (product of the voltage and current). The connections for power-factor meters and wattmeters are similar, and current and voltage transformers can be used to extend their range. Connections for single-phase and polyphase power-factor meters are shown in Figure 24 and Figure 25, respectively.

## ROTATIVE SPEED MEASUREMENT

### Tachometers

Tachometers, or direct-measuring rpm counters, vary from hand-held mechanical or electric meters to shaft-driven and electronic pulse counters. They are used in general laboratory and shop work to check the rotative speeds of motors, engines, and turbines.

### Stroboscopes

Optical rpm counters work by producing a controlled high-speed electronic flashing light. The operator directs the light on a rotating member and increases the rate of flashes until the optical effect of stopping rotation of the member is achieved. At this point, the rpm measured is equal to the flashes per minute emitted by the strobe unit. Care must be taken to start at the bottom of the instrument scale and work up because multiples of the rpm produce almost the same optical effect as true synchronism. Multiples can be indicated by positioning suitable marks on the shaft, such as a bar on one side and a circle on the opposite side. If, for example, the two are seen superimposed, then the strobe light is flashing at an even multiple of the true rpm.

### AC Tachometer-Generators

A tachometer-generator consists of a rotor and a stator. The rotor is a permanent magnet driven by the equipment. The stator is a winding with a hole through the center for the rotor. Concentricity is not critical; bearings are not required between rotor and stator. The output can be a single-cycle-per-revolution signal whose voltage is a linear function of rotor speed. The polypole configuration that generates 10 cycles per revolution permits measurement of speeds as low as 20 rpm without causing the indicating needle to flutter. The output of the ac tachometer-generator is rectified and connected to a dc voltmeter.

## SOUND AND VIBRATION MEASUREMENT

Measurement systems for determining sound pressure, sound intensity, and mechanical vibration generally involve the use of transducers to convert mechanical signals into electrical signals, which are then processed electronically in order to characterize the measured mechanical signals. These measurement systems contain one or more of the following elements, which may or may not be contained in a single instrument:

1. A transducer, or an assembly of transducers, to convert sound pressure, sound intensity, or mechanical vibration (time-varying strain, displacement, velocity, acceleration, or force) into an electrical signal that is quantitatively related to the mechanical quantity being measured.
2. Amplifiers and networks to provide such functions as electrical impedance matching, signal conditioning, integration, differentiation, frequency weighting, and gain.
3. Signal-processing equipment to detect and quantify those aspects of the signal that are being measured (peak value, rms value, time-weighted average level, power spectral density, or magnitude or phase of a complex linear spectrum or transfer function).
4. A device such as a meter, oscilloscope, digital display, or level recorder to display the signal or the aspects of it that are being quantified.

The relevant range of sound and vibration signals can vary over more than 12 orders of magnitude in amplitude and more than 8 orders of magnitude in frequency, depending on the application. References on instrumentation, measurement procedures, and signal analysis are given in the section on Bibliography. Product and

application notes, technical reviews, and books published by instrumentation manufacturers are an excellent source of additional reference material. See Chapter 46 of the 1999 *ASHRAE Handbook—Applications* and Chapter 7 of this volume for further information on sound and vibration.

## SOUND MEASUREMENT

### Microphones

A microphone is an electroacoustical transducer that transforms an acoustical signal into an electrical signal. The two predominant transduction principles used in the measurement of sound (as opposed to broadcasting or recording) are the electrostatic and the piezoelectric. **Electrostatic (capacitor) microphones** are available either as electric microphones, which do not require an external polarizing voltage, or as condenser microphones, which do require an external polarizing voltage, typically in the range of 28 to 200 V (dc). **Piezoelectric microphones** may be manufactured using either natural piezoelectric crystals or poled ferroelectric crystals. The types of response characteristics of measuring microphones are pressure, free field, and random incidence (diffuse field).

A microphone with a uniform pressure response characteristic maintains uniform sensitivity over its operating frequency range when exposed to a sound pressure that is uniform over the surface of the sensing element. A microphone with a uniform free-field response characteristic maintains uniform sensitivity over its operating frequency range when exposed to a plane progressive sound wave at a specified angle of incidence to the surface of the sensing element. A microphone with a uniform random-incidence response characteristic maintains uniform sensitivity over its operating frequency range when exposed to a diffuse sound field.

The sensitivity and the frequency range over which the microphone has uniform sensitivity (flat frequency response) vary with both the diameter (surface area) of the sensing element and the microphone type. Other factors that may critically affect the performance or response of a measuring microphone and preamplifier in a given measurement application are atmospheric pressure, temperature, relative humidity, external magnetic and electrostatic fields, mechanical vibration, and radiation. A microphone should be selected based on its long- and short-term stability; the match between its performance characteristics (e.g., sensitivity, frequency response, amplitude linearity, self-noise) and the expected amplitude of sound pressure, frequency, range of analysis, and expected environmental conditions of measurement; and any other pertinent considerations, such as size and directional characteristics.

### Sound Measurement Systems

Microphone preamplifiers, amplifiers, weighting networks (see Chapter 7), filters, and displays are available either separately or integrated into a measuring instrument such as a sound level meter, personal noise exposure meter, measuring amplifier, or real-time fractional octave or Fourier [e.g., fast Fourier transform (FFT)] signal analyzer. The instrument(s) included in a sound measurement system depends on the purpose of the measurement and the frequency range and resolution of signal analysis. In the case of community and industrial noise measurements for regulatory purposes, the instrument, signal processing, and quantity to be measured are usually dictated by the pertinent regulation. The optimal set of instruments generally varies for measurement of different characteristics such as sound power in HVAC ducts, sound power emitted by machinery, noise criteria (NC) numbers, sound absorption coefficients, sound transmission loss of building partitions, and reverberation times ( $T_{60}$ ).

### Frequency Analysis

Measurement criteria often dictate the use of filters to analyze the signal in order to indicate the spectrum of the sound being measured. Filters of different bandwidths for different purposes include fractional octave band (one, one-third, one-twelfth, etc.), constant percentage bandwidth, and constant (typically narrow) bandwidth. The filters may be analog or digital and, if digital, may or may not be capable of real-time data acquisition during the measurement period, depending on the bandwidth of frequency analysis. FFT signal analyzers are generally used in situations that require very narrow band signal analysis when the amplitudes of the sound spectra vary significantly with respect to frequency. This may occur in regions of resonance or when it is necessary to identify narrow-band or discrete sine-wave signal components of a spectrum in the presence of other such components or of broadband noise.

### Sound Chambers

Special rooms and procedures are required in order to characterize and calibrate sound sources and receivers. The rooms are generally classified into three types—anechoic, semianechoic, and reverberant. The ideal **anechoic** room or chamber would have boundary surfaces that completely absorb sound energy at all frequencies. The ideal **semianechoic** room or chamber would be identical to the ideal anechoic room, except that one surface would totally reflect sound energy at all frequencies. The ideal **reverberant** room or chamber would have boundary surfaces that totally reflect sound energy at all frequencies.

Anechoic chambers are used to perform measurements under conditions approximating those of a free sound field. They can be used in calibrating and characterizing individual microphones, microphone arrays, acoustic intensity probes, reference sound power sources, loudspeakers, sirens, and other individual or complex sources of sound.

Semianechoic chambers are built with a hard reflecting floor in order to accommodate heavy machinery or to simulate large factory floor or outdoor conditions. They can be used in calibrating and characterizing reference sound power sources, obtaining sound power levels of noise sources, and characterizing the sound output of emergency vehicle sirens when mounted on an emergency motor vehicle.

Reverberation chambers are used to perform measurements under conditions approximating those of a diffuse sound field. They can be used in calibrating and characterizing random-incidence microphones and reference sound power sources, obtaining sound power ratings of equipment and sound power levels of noise sources, measuring sound absorption coefficients of building materials and panels, and measuring the transmission loss through building partitions and components such as doors and windows.

### Calibration

A measurement system should be calibrated as a system from microphone or probe to indicating device before it is used to perform absolute measurements of sound. Acoustic calibrators and pistonphones of fixed or variable frequency and amplitude are available for this purpose. These calibrators should be used at a frequency low enough that the pressure, free-field, and random-incidence response characteristics of the measuring microphone(s) are, for practical purposes, equivalent, or at least related in a known quantitative manner for that specific measurement system. In general, the sound pressure produced by these calibrators may vary, depending on the microphone type, whether the microphone has a protective grid, atmospheric pressure, temperature, and relative humidity. Correction factors and coefficients are required for conditions of use that differ from those existing during the calibration of the acoustic calibrator or pistonphone. For demanding applications, precision sound sources and measuring microphones should period-

ically be sent to the manufacturer, a private testing laboratory, or a national standards laboratory for calibration.

### VIBRATION MEASUREMENT

With the exception of seismic instruments that record or indicate vibration directly via a mechanical or optomechanical device connected to the test surface, vibration measurements involve the use of an electromechanical or interferometric vibration transducer. Here, the term vibration transducer refers to a generic mechanical vibration transducer. Electromechanical and interferometric vibration transducers belong to a large and varied group of transducers that detect mechanical motion and furnish an electrical signal that is quantitatively related to a particular physical characteristic of the motion. Depending on the design of the transducer, the electrical signal may be related to mechanical strain, displacement, velocity, acceleration, or force. The operating principles of vibration transducers may involve optical interference; electrodynamic coupling; piezoelectric (including poled ferroelectric) or piezoresistive crystals; or variable capacitance, inductance, reluctance, or resistance. A considerable variety of vibration transducers with a wide range of sensitivities and bandwidths is commercially available. Vibration transducers may be contacting (e.g., seismic transducers) or non-contacting (e.g., interferometric or capacitive).

#### Transducers

Seismic transducers use a spring mass resonator within the transducer. At frequencies much greater than the fundamental natural frequency of the mechanical resonator, the relative displacement between the base and the seismic mass of the transducer is nearly proportional to the displacement of the transducer base. At frequencies much lower than the fundamental resonant frequency, the relative displacement between the base and the seismic mass of the transducer is nearly proportional to the acceleration of the transducer base. Therefore, seismic displacement transducers and seismic electrodynamic velocity transducers tend to have a relatively compliant suspension with a low resonant frequency; piezoelectric accelerometers and force transducers have a relatively stiff suspension with a high resonant frequency.

Strain transducers include the metallic resistance gage and the piezoresistive strain gage. For dynamic strain measurements, these are usually of the bonded type, where the gages are bonded directly to the test surface. The accuracy with which a bonded strain gage replicates strain occurring in the test structure is largely a function of how well the strain gage was oriented and bonded to the test surface.

Displacement transducers include the capacitance gage, fringe-counting interferometer, seismic displacement transducer, and linear variable differential transformer (LVDT). Velocity transducers include the reluctance (magnetic) gage, laser Doppler interferometer, and seismic electrodynamic velocity transducer. Accelerometers and force transducers include the piezoelectric, piezoresistive, and force-balance servo.

#### Vibration Measurement Systems

The sensitivity, frequency limitations, bandwidth, and amplitude linearity of vibration transducers vary greatly with the transduction mechanism and the manner in which the transducer is applied in a given measurement apparatus. The performance of contacting transducers can be significantly affected by the mechanical mounting methods and points of attachment of the transducer and connecting cable and by the mechanical impedance of the structure loading the transducer. Amplitude linearity varies significantly over the operating range of the transducer, with some transducer types or configurations being inherently more linear than others. Other factors that may critically affect the performance or response of a vibration transducer in a given measurement application are

temperature; relative humidity; external acoustic, magnetic, and electrostatic fields; transverse vibration; base strain; chemicals; and radiation. A vibration transducer should be selected based on its long- and short-term stability; the match between its performance characteristics (e.g., sensitivity, frequency response, amplitude linearity, self-noise) and the expected amplitude of vibration, frequency range of analysis, and expected environmental conditions of measurement; and any other pertinent considerations (e.g., size, mass, and resonant frequency).

**Vibration exciters**, or **shakers**, are used in structural analysis, vibration analysis of machinery, fatigue testing, mechanical impedance measurements, and vibration calibration systems. Vibration exciters have a table or moving element with a drive mechanism that may be mechanical, electrodynamic, piezoelectric, or hydraulic. They range from relatively small, low-power units for calibrating transducers such as accelerometers to relatively large, high-power units for structural and fatigue testing.

Conditioning amplifiers, power supplies, preamplifiers, charge amplifiers, voltage amplifiers, power amplifiers, filters, controllers, and displays are available either separately or integrated into a measuring instrument or system, such as a structural analysis system, vibration analyzer, vibration monitoring system, vibration meter, measuring amplifier, multichannel data-acquisition and modal analysis system, or real-time fractional-octave or FFT signal analyzer. The choice of instrument(s) to include in a vibration measurement system depends on the mechanical quantity to be determined, the purpose of the measurement, and the frequency range and resolution of signal analysis. In the case of vibration measurements, the signal analysis is relatively narrow in bandwidth and may be relatively low in frequency in order to accurately characterize structural resonances. Accelerometers with internal integrated circuitry are available to provide impedance matching or servo control for measuring very low frequency acceleration (servo accelerometers). Analog integration and differentiation of vibration signals is available through integrating and differentiating networks and amplifiers, and digital is available through FFT analyzers. Vibration measurements made for different purposes (e.g., machinery diagnostics and health monitoring, balancing rotating machinery, analysis of torsional vibration, analysis of machine-tool vibration, modal analysis, analysis of vibration isolation, stress monitoring, industrial control) will generally each dictate different mechanical measurement requirements and a different optimal set of instrumentation.

#### Calibration

Because of their inherent long- and short-term stability, amplitude linearity, wide bandwidth, wide dynamic range, low noise, and wide range of sensitivities, seismic accelerometers have traditionally been used as a reference standard for dynamic mechanical measurements. A measurement system should be calibrated as a system from transducer to indicating device before it is used to perform absolute dynamic measurements of mechanical quantities. Calibrated reference vibration exciters, standard reference accelerometers, precision conditioning amplifiers, and precision calibration exciters are available for this purpose. These exciters and standard reference accelerometers can be used to transfer a calibration to another transducer. For demanding applications, either a calibrated exciter or a standard reference accelerometer with connecting cable and conditioning amplifier should periodically be sent to the manufacturer, a private testing laboratory, or a national standards laboratory for calibration.

## LIGHTING MEASUREMENT

Light level, or illuminance, is usually measured with a photocell made from a semiconductor such as silicon or selenium. Such photocells produce an output current proportional to incident luminous flux; when linked with a microammeter, color- and

cosine-corrected filters, and multirange switches, they are used in inexpensive hand-held light meters and more precise instruments. Different cell heads allow multirange use in precision meters.

Cadmium sulfide photocells, in which the resistance varies with illumination, are also used in light meters. Both gas-filled and vacuum photoelectric cells are in use.

Small survey-type meters are not as accurate as laboratory meters; their readings should be considered approximate, although consistent, for a given condition. Their range is usually from 50 to 50 000 lux. Precision low-level meters have cell heads with ranges down to 0 to 20 lux.

A photometer installed in a revolving head is called a goniophotometer and is used to measure the distribution of light sources or luminaires. To measure total luminous flux, the luminaire is placed in the center of a sphere painted inside with a high-reflectance white with a near perfect diffusing matte surface. Total light output is measured through a small baffled window in the sphere wall.

To measure irradiation from germicidal lamps, a filter of fused quartz with fluorescent phosphor is placed over the light meter cell.

If meters are used to measure the number of lumens per unit area diffusely leaving a surface, luminance ( $\text{cd/m}^2$ ) instead of illumination (lux) is read. Light meters can be used to measure luminance; or electronic lux meters containing a phototube, an amplifier, and a microammeter can read luminance directly.

## THERMAL COMFORT MEASUREMENT

Thermal comfort depends on the combined influence of clothing, activity, air temperature, air velocity, mean radiant temperature, and air humidity. Thermal comfort is influenced by heating or cooling of particular body parts. This is due to radiant temperature asymmetry (plane radiant temperature), draft (air temperature, air velocity, turbulence), vertical air temperature differences, and floor temperature (surface temperature).

A general description of thermal comfort is given in Chapter 8, and guidelines for an acceptable thermal environment are given in *ASHRAE Standard 55* and *ISO Standard 7730*. *ASHRAE Standard 55* also includes required measuring accuracy. In addition to specified accuracy, *ISO Standard 7726* includes recommended measuring locations and a detailed description of instruments and methods.

### Clothing and Activity Level

These values are estimated from tables (Chapter 8, *ISO Standard 9920*, *ISO Standard 8996*). The thermal insulation of clothing ( $\text{m}^2 \cdot \text{K/W}$ ) can be measured on a thermal mannequin (McCullough et al. 1985, Olesen 1985). The activity ( $\text{W/m}^2$ ) can be estimated from measuring  $\text{CO}_2$  and  $\text{O}_2$  in a person's expired air.

### Air Temperature

Various types of thermometers may be used to measure air temperature. Placed in a room, the sensor registers a temperature between air temperature and mean radiant temperature. One way of reducing the radiant error is to make the sensor as small as possible because the convective heat transfer coefficient increases as the size decreases while the radiant heat transfer coefficient is constant. A smaller sensor also provides a favorably low time constant. The radiant error can also be reduced by using a shield (an open, polished aluminum cylinder) around the sensor, by using a sensor with a low-emittance surface, or by artificially increasing the air velocity around the sensor (aspirating air through a tube in which the sensor is placed).

### Air Velocity

In occupied zones, air velocities are usually small (0 to 0.5 m/s) but have an effect on human thermal sensation. Because the velocity fluctuates, the mean value should be measured over a suitable period, typically 3 min. Velocity fluctuations with frequencies up to 1 Hz significantly increase human discomfort due to draft, which is a function of air temperature, mean air velocity, and turbulence (see Chapter 8). The fluctuations can be given as the standard deviation of the air velocity over the measuring period (3 min) or as the turbulence intensity (standard deviation divided by mean air velocity). Velocity direction may change and is difficult to identify at low air velocities. An omnidirectional sensor with a short response time should be used. A thermal anemometer is suitable. If a hot-wire anemometer is used, the direction of the flow being measured must be perpendicular to the hot wire. Smoke puffs can be used to identify the direction.

### Plane Radiant Temperature

This refers to the uniform temperature of an enclosure in which the radiant flux on one side of a small plane element is the same as in the actual nonuniform environment. It describes the radiation in one direction. The plane radiant temperature can be calculated from the surface temperatures of the environment (half-room) and the angle factors between the surfaces and a plane element (*ASHRAE Standard 55*). The plane radiant temperature may also be measured by a net-radiometer or a radiometer with a sensor consisting of a reflective disk (polished) and an absorbent disk (painted black) (Olesen et al. 1989).

### Mean Radiant Temperature

This is the uniform temperature of an imaginary black enclosure in which an occupant would exchange the same amount of radiant heat as in the actual nonuniform enclosure. The mean radiant temperature can be calculated from measured surface temperatures and the corresponding angle factors between the person and the surfaces (Chapter 8).

The mean radiant temperature can also be determined from the plane radiant temperature in six opposite directions weighted according to the projected area factors for a person (Chapter 8).

Because of its simplicity, the instrument most commonly used to determine the mean radiant temperature is a **black globe thermometer** (Vernon 1932, Bedford and Warner 1935). This thermometer consists of a hollow sphere usually 150 mm in diameter coated in flat black paint with a thermocouple or thermometer bulb at its center. The temperature assumed by the globe at equilibrium results from a balance between heat gained and lost by radiation and convection.

The mean radiant temperatures are calculated from

$$\bar{t}_r = \left[ (t_g + 273)^4 + \frac{1.10 \times 10^8 V_a^{0.6}}{\epsilon D^{0.4}} (t_g - t_a) \right]^{1/4} - 273 \quad (11)$$

where

- $\bar{t}_r$  = mean radiant temperature, °C
- $t_g$  = globe temperature, °C
- $V_a$  = air velocity, m/s
- $t_a$  = air temperature, °C
- $D$  = globe diameter, m
- $\epsilon$  = emissivity (0.95 for black globe)

According to Equation (11), air temperature and air velocity around the globe must also be determined. The globe thermometer is spherical, while mean radiant temperature is defined in relation to the human body. For sedentary people, the globe represents a good approximation. For people who are standing, the globe, in a radiant nonuniform environment, overestimates the radiation from floor or

ceiling. An ellipsoid-shaped sensor gives a closer approximation to the human shape. A black globe will also overestimate the influence of short-wave radiation (e.g., sunshine). A flat gray color better represents the radiant characteristic of normal clothing (Olesen et al. 1989). The hollow sphere is usually made of copper, which results in an undesirable high time constant. This can be overcome by using lighter materials (e.g., a thin plastic bubble).

### Air Humidity

The water vapor pressure (absolute humidity) is usually uniform in the occupied zone of a space; therefore, it is sufficient to measure absolute humidity at one location. Many of the instruments listed in Table 3 are applicable. At ambient temperatures that provide comfort or slight discomfort, the thermal effect of humidity is only moderate, and highly accurate humidity measurements are unnecessary.

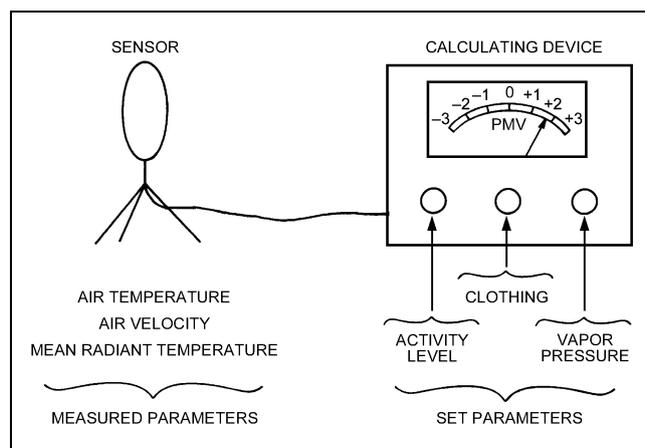

## CALCULATING THERMAL COMFORT

When the thermal parameters have been measured, their combined effect can be calculated by the thermal indices in Chapter 8. For example, the effective temperature (Gage et al. 1971) can be determined from air temperature and humidity. Based on the four environmental parameters and an estimation of clothing and activity, the **predicted mean vote (PMV)** can be determined with the aid of tables (Fanger 1982, ISO *Standard 7730*, Chapter 8). The PMV is an index predicting the average thermal sensation that a group of occupants may experience in a given space.

For certain types of normal activity and clothing, the environmental parameters measured can be compared directly with those described in ASHRAE *Standard 55* or ISO *Standard 7730*.

## INTEGRATING INSTRUMENTS

Several instruments have been developed to evaluate the combined effect of two or more thermal parameters on human comfort. Madsen (1976) developed an instrument that gives information on the occupants' expected thermal sensation by direct measurement of the PMV value. The comfort meter has a heated ellipsoid-shaped sensor that simulates the body (Figure 26). The estimated clothing (insulation value), activity in the actual space, and humidity are set on the instrument. The sensor then integrates the thermal effect of the air temperature, mean radiant temperature, and air velocity in approximately the same way the body does. The electronic instrument gives the measured operative and equivalent temperature, calculated PMV, and predicted percentage of dissatisfied (PPD).

**Fig. 26 Madsen's Comfort Meter**  
(Madsen 1976)

## MOISTURE CONTENT AND TRANSFER MEASUREMENT

Little off-the-shelf instrumentation exists to measure the moisture content of porous materials or the moisture transfer through those materials. However, many measurements can be set up with a small investment of time and money. Three moisture properties are most commonly sought—(1) the sorption isotherm, a measure of the amount of water vapor a hygroscopic material will adsorb from humid air; (2) vapor permeability, a measure of the rate at which water vapor will pass through a given material; and (3) liquid diffusivity, a measure of the rate at which liquid water will pass through a porous material.

### Sorption Isotherm

A sorption isotherm relates the **equilibrium moisture content (EMC)** of a hygroscopic material to the ambient relative humidity under conditions of constant temperature. Moisture content is the ratio of the total mass of water in a sample to the dry mass of the sample. Determining a sorption isotherm involves exposing a sample of material to a known relative humidity at a known temperature and then measuring the sample's moisture content after a sufficient period of time has elapsed for the sample to reach equilibrium with its surroundings. Hysteresis in the sorption behavior of most hygroscopic materials requires that measurements be made both for increasing relative humidity (the adsorption isotherm) and for decreasing relative humidity (the desorption isotherm).

The ambient relative humidity can be controlled using saturated salt solutions or mechanical refrigeration equipment (Tveit 1966, Cunningham and Sprott 1984, Carotenuto et al. 1991). Precise measurements of the relative humidity produced by various salt solutions have been reported by Greenspan (1977). ASTM *Standard E 104* describes the use of saturated salt solutions. The EMC of a sample is usually determined gravimetrically using a precision balance. The sample dry mass, necessary to calculate moisture content, can be found by oven drying or desiccant drying. Oven dry mass may be lower than desiccant dry mass because of the loss of volatiles other than water in the oven (Richards et al. 1992).

A major difficulty in the measurement of the sorption isotherms of engineering materials is the long time required for many materials to reach equilibrium—often as long as weeks or months. The rate-limiting mechanism for these measurements is usually the slow process of vapor diffusion into the pores of the material. The use of smaller samples can help reduce the diffusion time.

### Vapor Permeability

The diffusive transfer of water vapor through porous materials is often described by a modified form of Fick's law:

$$w_v'' = -\mu \frac{dp}{dx} \quad (12)$$

where

$$w_v'' = \text{mass of vapor diffusing through unit area in unit time, mg/(s} \cdot \text{m}^2\text{)}$$

$$dp/dx = \text{vapor pressure gradient, kPa/m}$$

$$\mu = \text{vapor permeability, mg/(s} \cdot \text{m} \cdot \text{kPa)}$$

In engineering practice, permeance may be used instead of permeability. **Permeance** is simply permeability divided by the material thickness in the direction of the flow of vapor; thus, while permeability is a material property, permeance depends on thickness.

Measurement of permeability is made with wet-cup, dry-cup, or modified cup tests. Wet- and dry-cup tests are described in Chapter 23.

For many engineering materials, vapor permeability is a strong function of mean relative humidity. Wet and dry cups cannot adequately characterize this dependence on relative humidity. Instead,

a modified cup method can be used (McLean et al. 1990, Burch et al. 1992). In the modified cup method, the pure water or desiccant within a cup is replaced with a saturated salt solution. A second saturated salt solution is used to condition the environment external to the cup. With such an arrangement, the relative humidities on both sides of the sample material can be varied from 0 to 100%. Several cups with a range of mean relative humidities are used to map out the dependence of vapor permeability on relative humidity.

In measuring materials of high permeability, the finite rate of vapor diffusion through air in the cup may become a factor. The air-film resistance could then be a significant fraction of the resistance to vapor flow presented by the sample material. An accurate measurement of high-permeability materials may require an accounting of diffusive rates across all air gaps (Fanney et al. 1991).

### Liquid Diffusivity

The transfer of liquid water through porous materials may be characterized as a diffusion-like process:

$$w_l'' = -\rho D_l \frac{d\gamma}{dx} \quad (13)$$

where

$w_l''$  = mass of liquid transferred through unit area per unit time, kg/(s·m<sup>2</sup>)

$\rho$  = liquid density, kg/m<sup>3</sup>

$D_l$  = liquid diffusivity, m<sup>2</sup>/s

$d\gamma/dx$  = moisture content gradient, m<sup>-1</sup>

$D_l$  typically shows a strong dependence on moisture content.

Transient measurement methods deduce the functional form of  $D_l\gamma$  by observing the evolution of a one-dimensional moisture content profile over time. An initially dry specimen is brought into contact with liquid water. The free water will migrate into the specimen, drawn in by surface tension. The resulting moisture content profile, which changes with time, must be differentiated to find the liquid diffusivity of the material (Bruce and Klute 1956).

Determining the transient moisture content profile typically involves the use of a noninvasive and nondestructive method of measuring local moisture content. Gamma ray absorption (Freitas et al. 1991, Kumaran and Bomberg 1985, Quenard and Sallee 1989), X-ray radiography (Ambrose et al. 1990), neutron radiography (Prazak et al. 1990), and nuclear magnetic resonance (NMR) (Gummerson et al. 1979) have all been employed.

Uncertainty in the resulting measurement of the liquid diffusivity is often large because of the necessity to differentiate noisy experimental data.

## HEAT TRANSFER THROUGH BUILDING MATERIALS

### Thermal Conductivity

The thermal conductivity of a heat insulator, as defined in Chapter 23, is a unit heat transfer factor. Two methods of determining the thermal conductivity of flat insulation are the **guarded hot plate** and the **heat flow meter apparatus**, according to ASTM *Standards* C 177 and C 518, respectively. Both methods use parallel isothermal plates to induce a steady temperature gradient across the thickness of the specimen(s). The guarded hot plate is considered an absolute method for determining thermal conductivity. The heat flow meter apparatus requires calibration with a specimen having a known thermal conductivity, usually determined in the guarded hot plate. The heat flow meter apparatus is calibrated by determining the voltage output of its heat flux transducer(s) as a function of the heat flux through the transducer(s).

The basic design of the guarded hot plate consists of an electrically heated plate and two liquid-cooled plates. Two similar specimens of a material are required for a test; one is mounted on each side of the hot plate. A cold plate is then pressed against the outside of each specimen by a clamp screw. The heated plate consists of two sections separated by a small gap. During tests, the central (metering) section and the outer (guard) section are maintained at the same temperature to minimize errors caused by edge effects. The electric energy required to heat the metering section is measured carefully and converted to heat flow. The thermal conductivity of the material can be calculated under steady-state conditions using this heat flow quantity, the area of the metering section, the temperature gradient, and the specimen thickness. The thermal conductivity of cylindrical or pipe insulation (Chapter 23) is determined in a similar manner, but an equivalent thickness must be calculated to account for the cylindrical shape (ASTM *Standard* C 335). Transient methods have been developed by D'Eustachio and Schreiner (1952), Hooper and Lepper (1950), and Hooper and Chang (1953) using a line heat source within a slender probe. These instruments are available commercially and have the advantages of rapidity and a small test specimen requirement. The probe is a useful research and development tool, but it has not been as accepted as the guarded hot plate, heat flow meter apparatus, or pipe insulation apparatus.

### Thermal Conductance and Resistance

Thermal conductances (C-factors) and resistances (R-values) of many building assemblies can be calculated from the conductivities and dimensions of their components, as described in Chapter 25. Test values can also be determined experimentally using large specimens representative of the building assemblies tested in the hot box apparatus described in ASTM *Standards* C 236 and C 976. This laboratory apparatus allows measurement of heat transfer through a specimen under controlled air temperature, air velocity, and radiation conditions. It is specially suited for large nonhomogeneous specimens.

For in situ measurements, heat flux and temperature transducers are useful in measuring the dynamic or steady-state behavior of opaque building components (ASTM *Standard* C 1046). A heat flux transducer is simply a differential thermopile within a core or substrate material. Two types of construction are used: (1) multiple thermocouple junctions wrapped around a core material, or (2) printed circuits with a uniform array of thermocouple junctions. The transducer is calibrated by determining its voltage output as a function of the heat flux through the transducer. For in situ measurements, the transducer is installed in either the wall or roof, or mounted on an exterior surface with tape or adhesive. The data obtained can be used to compute the thermal conductance or resistance of the building component (ASTM *Standard* C 1155).

## AIR CONTAMINANT MEASUREMENT

Three measures of particulate air contamination include the number, projected area, and mass of particles per unit volume of air (ASTM Volume 11.03). Each requires an appropriate sampling technique.

Particles are counted by capturing them in impingers, impactors, membrane filters, or thermal or electrostatic precipitators. Counting may be done by microscope, using stage counts if the sample covers a broad range of sizes.

Electronic particle counters can give rapid data on particle size distribution and concentration. However, their accuracy depends on careful calibration, appropriate maintenance, and proper application. Particle counters have been used in indoor office environments as well as in clean rooms.

Projected area determinations are usually made by sampling onto a filter paper and comparing the light transmitted or scattered by this filter to a standard filter. The staining ability of dusts depends on the projected area and refractive index per unit volume. For sampling, filters must collect the minimum sized particle of interest. In this respect, membrane or glass fiber filters are recommended.

To determine particle mass, a measured quantity of air is drawn through filters, preferably of membrane or glass fiber, and the filter mass is compared to the mass before sampling. Electrostatic or thermal precipitators and various impactors have also been used. For further information, see ACGIH (1983), Lundgren et al. (1979), and Lodge (1989).

Chapter 44 of the 1999 *ASHRAE Handbook—Applications* presents information on measuring and monitoring gaseous contaminants. Relatively costly analytical equipment, which must be calibrated and operated carefully by experienced personnel, is needed. Numerous methods of sampling the contaminants, as well as the laboratory analysis techniques used after sampling, are specified. Some of the analytical methods are specific to a single pollutant; others are capable of presenting a concentration spectrum for many compounds simultaneously.

## COMBUSTION ANALYSIS

Two approaches are used to measure the thermal output or capacity of a boiler, furnace, or other fuel-burning device. The direct or **calorimetric test** measures change in enthalpy or heat content of the fluid, air, or water heated by the device, and multiplies this by the flow rate to arrive at the unit's capacity. The indirect test or **flue gas analysis** method determines the heat losses in the flue gases and the jacket and deducts them from the heat content (higher heating value) of the measured fuel input to the appliance. A **heat balance** simultaneously applies both tests to the same device. The indirect test usually indicates the greater capacity, and the difference is credited to radiation from the casing or jacket and unaccounted-for losses.

With small equipment, the expense of the direct test is usually not justified, and the indirect test is used with an arbitrary radiation and unaccounted-for loss factor.

### FLUE GAS ANALYSIS

The flue gases from burning fossil fuels generally contain carbon dioxide ( $\text{CO}_2$ ), water, and hydrogen ( $\text{H}_2$ ) with some small amounts of carbon monoxide (CO), nitrogen oxides ( $\text{NO}_x$ ), sulfur oxides ( $\text{SO}_x$ ), and unburned hydrocarbons. However, generally only  $\text{CO}_2$  (or  $\text{O}_2$ ) and CO are measured to determine completeness of combustion and efficiency.

In the laboratory, the instruments most commonly used to measure CO and  $\text{CO}_2$  are nondispersive infrared (NDIR) analyzers. The NDIR instruments have several advantages: (1) they are not very sensitive to flow rate, (2) no wet chemicals are required, (3) they have a relatively fast response, (4) measurements can be made over a wide range of concentrations, and (5) they are not sensitive to the presence of contaminants in the ambient air.

In the laboratory, oxygen is generally measured with an instrument that makes use of the paramagnetic properties of oxygen. The paramagnetic instruments are generally used because of their excellent accuracy and because they can be made specific to the measurement of oxygen.

For field testing and burner adjustment, portable combustion testing equipment is available. These instruments generally measure  $\text{O}_2$  and CO with electrochemical cells. The  $\text{CO}_2$  is then calculated by an on-board microprocessor and, together with temperature, is used to calculate thermal efficiency. If a less expensive approach is required, a portable Orsat apparatus can be used to measure  $\text{CO}_2$ , and a length-of-stain tube to measure CO.

## DATA ACQUISITION AND RECORDING

Almost every type of transducer and sensor is available with the necessary interface system to make it computer-compatible. The transducer itself begins to lose its identity when integrated into a system that incorporates such features as linearization, offset correction, self-calibration, and so forth. This has eliminated the concern regarding the details of signal conditioning and amplification of basic transducer outputs. The personal computer is integrated into every aspect of data recording, including sophisticated graphics, acquisition and control, and analysis. Modems connected to the Internet or an internal network allow easy access to remote personal computer-based data-recording systems from virtually any locale.

Other means of recording, such as chart recorders, which can be either multipurpose or specifically designed for a given sensor, are available. Chart recorders provide a visual indication and a hard copy record of the data. Rarely is the output of a chart recorder used to process data. Simple indicators and readouts are used mostly to monitor the output of a sensor visually. In most situations, analog indicators such as d'Arsonval movement meters have been rendered obsolete by modern digital indicators. Industrial environments commonly employ signal transmitters for control or computer data-handling systems to convert the signal output of the primary sensor into a compatible common signal span (e.g., the standard 4-20 mA current loop). All signal conditioning (ranging, zero suppression, reference-junction compensation) is provided at the transmitter. Thus, all recorders and controllers in the system can have an identical electrical span, with variations only in charts and scales offering the advantages of interchangeability and economy in equipment cost. Long signal transmission lines can be used, and receiving devices can be added to the loop without degrading performance.

The vast selection of available hardware, an often confusing set of terminology, and the challenge of optimizing the performance/cost ratio for a specific application make the task of configuring a data acquisition system difficult. A system specifically configured to meet a particular measurement need can quickly become obsolete if it has inadequate flexibility. Memory size, recording speed, and signal processing capability are major considerations in determining the correct recording system. Thermal, mechanical, electromagnetic interference, portability, and meteorological factors also influence the selection.

### Digital Recording

A digital data acquisition system must contain an interface, which is a system involving one or several analog-to-digital converters, and in the case of multichannel inputs, circuitry for multiplexing. The interface may also provide excitation for transducers, calibration, and conversion of units. The digital data are arranged into one or several standard digital bus formats. Many data acquisition systems are designed to acquire data rapidly and store large records of data for later recording and analysis. Once the input signals have been digitized, the digital data are essentially immune to noise and can be transmitted over great distances.

Information is transferred to a computer/recorder from the interface as a pulse train, which can be transmitted as 4-, 8-, 12-, 16-, or 32-bit words. An 8-bit word is a byte; many communications methods are rated according to their bytes per second transfer rate. Digital data are transferred in either serial or parallel mode. Serial transmission means that the data are sent as a series of pulses, one bit at a time. Although slower than parallel systems, serial interfaces require only two wires, which lowers their cabling cost. The speed of serial transmissions is rated according to the symbols per second rate, or baud rate. In parallel transmission, the entire data word is transmitted at one time. To do this, each bit of a data word has to have its own transmission line; other lines are needed for clocking

and control. Parallel mode is used for short distances or when high data transmission rates are required. Serial mode must be used for long-distance communications where wiring costs are prohibitive.

The two most popular interface bus standards currently used for data transmission are the IEEE 488, or general-purpose interface bus (GPIB), and the RS232 serial interface. The IEEE 488 bus system feeds data down eight parallel wires, one data byte at a time. This parallel operation allows it to transfer data rapidly at up to 1 million characters per second. However, the IEEE 488 bus is limited to a cable length of 20 m and requires an interface connection on every meter for proper termination. The RS232 system feeds data serially down two wires, one bit at a time. An RS232 line may be over 300 m long. For longer distances, it may feed a modem to send data over standard telephone lines. A local area network (LAN) may be available in a facility for transmitting information. With appropriate interfacing, transducer data are available to any computer connected to the network.

Bus measurements can greatly simplify three basic applications—data gathering, automated limit testing, and computer-controlled processes. In data gathering applications, readings are collected over time. The most common applications include aging tests in quality control, temperature tests in quality assurance, and testing for intermittents in service. A controller can monitor any output indefinitely and then display the data directly on its screen or record it on magnetic tape or disks for future use.

In automated limit testing, the computer simply compares each measurement with programmed limits. The controller converts the readings to a good/bad readout. Automatic limit testing becomes highly cost-effective when working with large number of parameters of a particular unit under test.

In computer-controlled processes, the IEEE 488 bus system becomes a permanent part of a larger, completely automated system. For example, a large industrial process may require many electrical sensors that feed a central computer controlling many parts of the manufacturing process. An IEEE 488 bus controller collects readings from several sensors and saves the data until asked to dump an entire batch of readings to a larger central computer at one time. Used in this manner, the IEEE 488 bus controller serves as a slave of the central computer.

Dynamic range and accuracy are two important parameters that must be considered in a digital recording system. **Dynamic range** refers to the ratio of the maximum input signal for which the system is useful to the noise floor of the system. The **accuracy** figure for a system is impacted by the signal noise level, nonlinearity, temperature, time, crosstalk, and so forth. In selecting an 8-, 12-, or 16-bit analog-to-digital converter, the designer cannot assume that the system accuracy will necessarily be determined by the resolution of the encoders (i.e., 0.4%, 0.025%, and 0.0016%, respectively). If the sensor preceding the converter is limited to 1% full-scale accuracy, for example, no significant benefits are gained by using a 12-bit system over an 8-bit system and suppressing the least significant bit. However, a greater number of bits may be required to cover a larger dynamic range.

### Data Logging Devices

Data loggers digitally store electrical signals (analog or digital) to an internal memory storage component. The signal from connected sensors is typically stored to memory at timed intervals ranging from MHz to hourly sampling. Some data loggers store data based on an event (e.g., button push, contact closure). Many data loggers can perform linearization, scaling, or other signal conditioning and permit logged readings to be either instantaneous or averaged values. Most data loggers have built-in clocks that record the time and date together with transducer signal information. Data loggers range from single-channel input to 256 or more channels. Some are general-purpose devices that will accept a multitude of analog and/or digital inputs, while others are more specialized to a specific

measurement (e.g., a portable anemometer with built-in data logging capability) or for a specific application (e.g., a temperature, relative humidity, CO<sub>2</sub>, and CO monitor with data logging for IAQ applications). Stored data are generally downloaded using a serial interface with a temporary direct connection to a personal computer. Remote data loggers may also download via modem through telephone lines. Some data loggers are designed to allow downloading directly to a printer.

With the reduction in size of personal computers (laptops, notebooks, hand-held PCs, and palmtops), the computer itself is now being used as the data logger. These “mobile” computers may be left in the field storing measurements from sensors directly interfaced into the computer.

### Chart Recorders

Chart recorders convert electrical signals (analog or digital) to records of the data versus time on a hard copy, usually paper. Mechanical styluses use ink, hot wire, pressure, or electrically sensitive paper to provide a continuous trace. They are useful up to a few hundred hertz. Thermal and ink recorders are confined to chart speeds of several centimetres per second for recording relatively slow processes. Newer advances in portable recorders provide multichannel inputs and up to 25 kHz real-time frequency response without using a pen or pen motor. Both *x-y* recorders and plotters allow two variables to be recorded with respect to one another. Their response times are generally limited to that of thermal and ink recorders. Oscillographic recorders have largely been made obsolete by digital oscilloscopes.

Specifying BAS Networks .....	15.15
Approaches to Interoperability .....	15.15
COMMISSIONING .....	15.15
Tuning .....	15.16

**A**UTOMATIC HVAC control systems are designed to maintain temperature, humidity, pressure, flow, power, lighting levels, and safe levels of indoor contaminants. Automatic control primarily modulates, stages, or sequences mechanical and electrical equipment to meet load requirements and provide safe operation of the equipment. It can use digital, pneumatic, mechanical, electrical, and electric control devices; human intervention is limited to starting and stopping equipment and adjusting control set points.

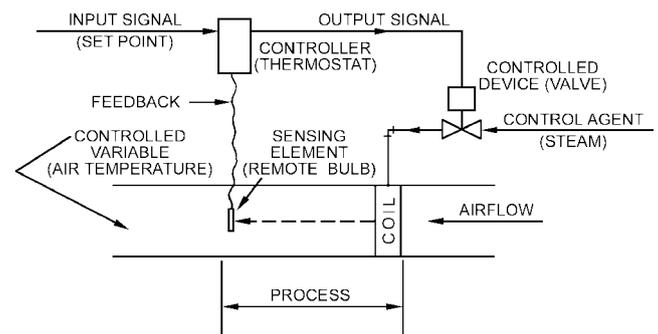

This chapter focuses on the fundamental concepts and devices normally used by a control system designer. It covers (1) control fundamentals, including terminology; (2) the types of control components; (3) the methods of connecting these components to form various individual control loops or subsystems; and (4) commissioning, operation, and maintenance. Chapter 45 of the 1999 *ASHRAE Handbook—Applications* discusses the design of controls for specific HVAC applications.

### TERMINOLOGY

A **closed loop** or **feedback** control measures actual changes in the controlled variable and actuates the controlled device to bring about a change. The corrective action continues until the variable is brought to a desired value within the design limitations of the controller. This arrangement of having the controller sense the value of the controlled variable is known as **feedback**. Figure 1 shows a feedback control.

An **open loop** control does not have a direct link between the value of the controlled variable and the controller. An open loop control anticipates the effect of an external variable on the system and adjusts the set point to avoid excessive offset. An example is an outdoor thermostat arranged to control heat to a building in proportion to the calculated load caused by changes in outdoor temperature. In essence, the designer presumes a fixed relationship between outside air temperature and the heat requirement of the building and specifies control action based on the outdoor air temperature. The actual space temperature has no effect on this controller. Because there is no feedback on the controlled variable (space temperature), the control is an open loop.

Figure 1 illustrates the components of the typical **control loop**. The **sensor** measures the controlled variable and transmits to the controller a signal (pneumatic, electric, or electronic) having a pressure, voltage, or current value proportional to the value of the variable being measured. The **controller** compares this value with the set point and signals to the controlled device for corrective action. A controller can be hardware or software. A **hardware controller** is an analog device that continuously receives

**Fig. 1 Discharge Air Temperature Control**  
(Example of Feedback Control)

and acts on data. Thermostats, humidistats, and pressure controls are examples of hardware controllers. A **software controller** is a digital device that receives and acts on data on a sample-rate basis. Digital algorithms are examples of software controllers.

The **set point** is the desired value of the controlled variable. The controller seeks to maintain this set point. The **controlled device** reacts to signals received from the controller to vary the control agent. The controlled device may be a valve, a damper, a heating element, or a motor driving a pump or a fan.

The **control agent** is the medium manipulated by the controlled device. It may be air or gas flowing through a damper; gas, steam, or water flowing through a valve; or an electric current.

The **process** is the air-conditioning apparatus being controlled. It reacts to the output of the control agent and effects the change in the controlled variable. It may be a coil, fan, or humidifier.

The **controlled variable** is the temperature, humidity, pressure, etc., being controlled.

A control loop can be represented in the form of a **block diagram**, in which each component is modeled and represented in its own block. Figure 2 is a block diagram of the control loop shown in Figure 1. The flow of information from one component to the next is shown by lines between the blocks. The figure shows the set point being compared to the controlled variable. The difference is the **offset error**, also known as offset drift, deviation, droop, or steady-state error. The offset error is fed into the controller, which sends a control signal to the controlled device. In this case, the controlled device is a valve that can change the amount of steam flow through the coil of Figure 1. The amount of steam flow is the input to the next block, which represents the process. From the process block comes the controlled variable, which is temperature. The controlled variable is sensed by the sensing element and fed to the controller as feedback, completing the loop.

The preparation of this chapter is assigned to TC 1.4, Control Theory and Application.

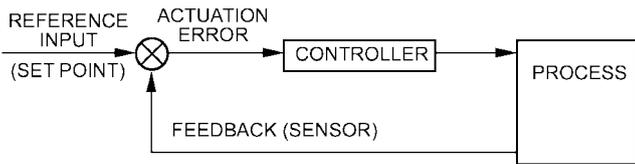

Fig. 2 Block Diagram of Discharge Air Temperature Control

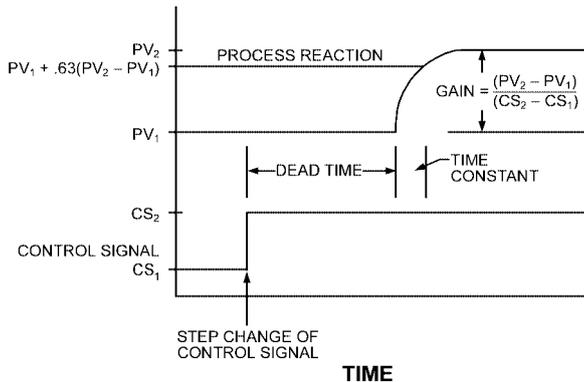

Fig. 3 Process Subjected to a Step Input

Each component of Figure 2 can be represented by a **transfer function**, which is an idealized mathematical representation of the relationship between the input and the output variables of the component. The transfer function must be sufficiently detailed to cover both the dynamic and static characteristics of the device. The dynamics of the component are represented in the time domain by a differential equation. In environmental control, the transfer function of many of the components can be adequately described by a first-order differential equation, implying that the dynamic behavior is dominated by a single capacitance factor. For a solution, the differential equation is converted to its Laplace transform or  $z$ -transform.

The **time constant** is defined as the time it takes for the output to reach 63.2% of its final value when a step change in the input is effected. Components with small time constants alter their output rapidly to reflect changes in the input; conversely, components with a larger time constant are sluggish in responding to changes in the input.

**Dead time** is a phase shift that can cause control and modeling problems. Dead time (or **time lag**) is the time between a change in the process input and when the change affects the output of the process. Dead time can occur in the control loop of Figure 1 due to the transportation time of the air from the coil to the space. After a coil temperature is changed, there is dead time while the affected supply air travels the distribution system and finally reaches the sensor in the space. The mass of air within the space further delays detection of the coil temperature change. Dead time can also be caused by a slow sensor, or a time lag in the signal from the controller. If the dead time is small, it may be ignored in the model of the control; if it is significant, it must be considered.

The **gain** of a transfer function is the amount the output of the component changes for a given change of input under steady-state conditions. If the element is linear, its gain remains constant. However, many control components are nonlinear, and have gains that depend on the operating conditions. Figure 3 shows the response of the first-order-plus-dead-time process to a step change of the input signal. Notice that the process shows no reaction during the dead time, followed by a response that resembles a first order exponential.

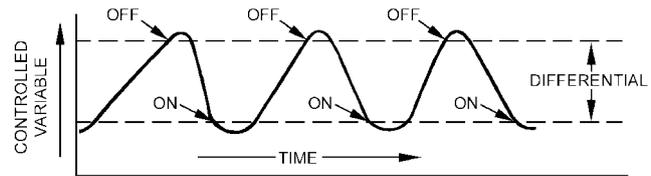

Fig. 4 Two-Position Control

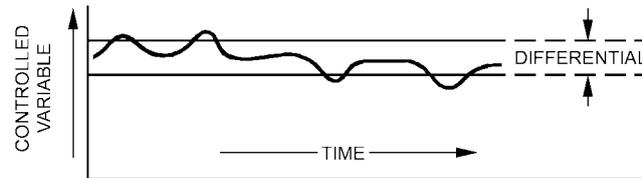

Fig. 5 Floating Control Showing Variations in Controlled Variable as Load Changes

## TYPES OF CONTROL ACTION

Closed loop controls are commonly classified by the type of corrective action the controller is programmed to take when it senses a deviation of the controlled variable from the set point. Both hardware and software controllers can be classified according to the following most common types of control action.

### Two-Position Action

The control device shown in Figure 4 can be positioned only to a maximum or minimum state (e.g., on or off). Because two-position control is simple and inexpensive, it is used extensively for both industrial and commercial control. A typical home thermostat that starts and stops a furnace is an example of two-position action.

**Controller differential**, as it applies to two-position control action, is the difference between a setting at which the controller operates to one position and a setting at which it operates to the other. Thermostat ratings usually refer to the differential (in degrees) that becomes apparent by raising and lowering the dial setting. This differential is known as the **manual differential** of the thermostat. When the same thermostat is applied to an operating system, the total change in temperature that occurs between a “turn-on” state and a “turn-off” state is usually different from the mechanical differential. The **operating differential** may be greater due to thermostat lag or hysteresis or to heating or cooling anticipators built into the thermostat.

**Anticipation Applied to Two-Position Action.** This common variation of strictly two-position action is often used on room thermostats to reduce the operating differential. In heating thermostats, a heater element in the thermostat is energized during “on” periods, thus shortening the on-time because the heater warms the thermostat. This is known as **heat anticipation**. The same anticipation action can be obtained in cooling thermostats by energizing a heater thermostat at “off” periods. In both cases, the percentage of on-time is varied in proportion to the load, while the total cycle time remains relatively constant.

**Timed Two-Position Action.** This action occurs when a heating or cooling element is turned on for a time interval proportional to the deviation from set point. For example, an element may be turned on for two minutes and off for one minute when the deviation from set point is 1 K. This is similar to incremental action applied to floating control, except the time interval is usually shorter for incremental action.

**Floating Action**

In floating action, the controller can perform only two operations—moving the controlled device toward either its open or closed position, usually at a constant rate (Figure 5). Generally, a neutral zone between the two positions allows the controlled device to stop at any position when the controlled variable is within the differential of the controller. When the controlled variable falls outside the differential of the controller, the controller moves the controlled device in the proper direction. In order to function properly, the sensing element must react faster than the actuator drive time. If not, the control functions the same as a two-position control.

**Incremental Action.** This action is a variation of floating control. Incremental action varies the pulse action to open or close an actuator depending on how close the controlled variable is to the set point. As the controlled variable comes close to the set point, the pulses become shorter. This action allows closer control using floating motor actuators.

**Modulating Control**

With modulating control, the output of the controller can vary infinitely over the range of the controller. The following terms are used to describe this type of control:

- **Throttling range** is the amount of change in the controlled variable required to cause the controller to move the controlled device from one extreme to the other. It can be adjusted to meet job requirements. Throttling range is inversely proportional to proportional gain.
- **Control point** is the actual value of the controlled variable at which the instrument is controlling. It varies within the throttling range of the controller and changes with changing load on the system and other variables.
- **Offset**, or error signal, is the difference between the set point and the actual control point under stable conditions. This is sometimes called drift, deviation, droop, or steady-state error.

The following are the three typical modulating control modes:

**Proportional Action.** In proportional action, the controlled device is positioned proportionally in response to changes in the controlled variable (Figure 6). A proportional controller can be described mathematically by

$$V_p = K_p e + V_o \tag{1}$$

where

- $V_p$  = output of controller
- $K_p$  = proportional gain (inversely proportional to throttling range)
- $e$  = error signal or offset
- $V_o$  = offset adjustment parameter

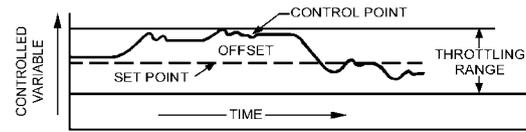

The output of the controller is proportional to the difference between the sensed value, the controlled variable, and its set point. The controlled device is normally adjusted to be in the middle of its control range at set point by using an offset adjustment. This control is similar to that shown in Figure 1.

**Proportional plus Integral (PI) Action.** This type of control improves on simple proportional control by adding another component to the control action that eliminates the offset typical of proportional control (Figure 7). **Reset action** may be described by

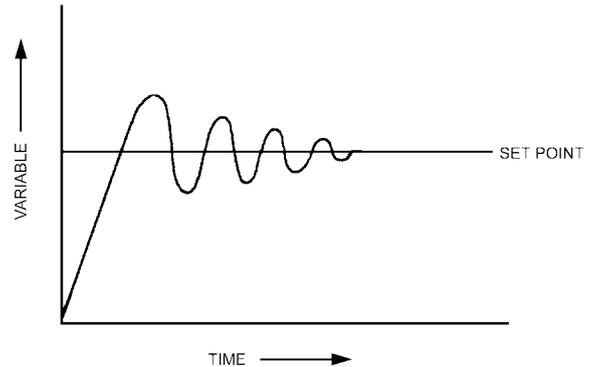

$$V_p = K_p e + K_i \int e d\theta + V_o \tag{2}$$

where

- $K_i$  = integral gain
- $\theta$  = time

**Fig. 6 Proportional Control Showing Variations in Controlled Variable as Load Changes**

**Fig. 7 Proportional plus Integral (PI) Control**

The second term in Equation (2) implies that the longer error  $e$  exists, the more the controller output will change in attempting to eliminate the error. Proper selection of proportional and integral gain constants increases stability, and eliminates offset, giving greater control accuracy. PI control can also improve energy efficiency in applications such as VAV fan control, chiller control, and hot and cold deck control of the air handler.

**Proportional-Integral-Derivative (PID) Action.** This type of control is PI control with a derivative term added to the controller. It varies with the value of the derivative of the error. The equation for PID control is

$$V_p = K_p e + K_i \int e d\theta + K_a \frac{de}{d\theta} + V_o \tag{3}$$

where

- $K_a$  = derivative gain of controller
- $de/d\theta$  = time derivative of error

Adding the derivative term gives some anticipatory action to the controller, which results in a faster response and greater stability. However, the derivative term also makes the controller more sensitive to noisy signals and harder to tune than a PI controller. Most HVAC control loops perform satisfactorily with PI control alone. **Adaptive control**, or self tuning, is a form of digital PID control, where the gain factors ( $K_p$ ,  $K_i$ , and  $K_a$ ) are continuously or periodically modified automatically to compensate for the control loop offset.

**Fuzzy Logic**

Fuzzy logic control offers an alternative to traditional control algorithms. A fuzzy logic controller uses a series of “if-then” rules that emulates the way a human operator might control the process. Examples of fuzzy logic might include

1. IF the room temperature is high AND the rate of change is decreasing, THEN increase cooling a little.
2. IF the room temperature is high AND the rate of change is increasing, THEN increase cooling a lot.

The designer of a fuzzy logic controller must first define the rules and then define such terms as *high*, *increasing*, *decreasing*, *a lot*, and *a little*. The room temperature, for instance, might be mapped into a series of functions that include *very low*, *low*, *OK*, *high*, and *very high*. The “fuzzy” element is introduced when the functions overlap and the room temperature is, for example, 70% high and 30% OK. In this case, multiple rules are combined to determine the appropriate control action.

### CLASSIFICATION BY ENERGY SOURCE

Control components may be classified according to the primary source of energy as follows:

- **Pneumatic components** use compressed air, usually at a pressure of 100 to 140 kPa (gage), as an energy source. The air is generally supplied to the controller, which regulates the pressure supplied to the controlled device.
  - **Electric components** use electrical energy, either low- or line-voltage, as the energy source. The controller regulates electrical energy supplied to the controlled device. Controlled devices in this category include relays; electromechanical, electromagnetic, and hydraulic actuators; and solid-state regulating devices. Components that include signal conditioning, modulation, and amplification in their operation are classified as **electronic**.
- A **digital controller** receives electronic signals from the sensors, converts the electronic signals to numbers, and performs mathematical operations on these numbers inside a microprocessor. The output from the digital controller takes the form of a number, which is then converted to an electronic signal to operate the actuator. The digital controller must sample its data because the microprocessor requires time for other operations than reading data. If the sampling interval for the digital controller is properly chosen to avoid second- and third-order harmonics, there will be no significant degradation in control performance due to sampling.
- **Self-powered components** apply the power of the measured system to induce the necessary corrective action. The measuring system derives its energy from the process under control, without any auxiliary source of energy. Temperature changes at the sensor result in pressure or volume changes of the enclosed media that are transmitted directly to the operating device of the valve or damper. A component using a thermopile in a pilot flame to generate electrical energy is also self-powered.

This method of classification can be extended to individual control loops and to complete control systems. For example, the room temperature control for a particular room that includes a pneumatic room thermostat and a pneumatically actuated reheat coil would be referred to as a pneumatic control loop. Many control systems use a combination of controls and are called **hybrid** systems.

### COMPUTERS FOR AUTOMATIC CONTROL

Computers can perform the control described in this chapter. Chapter 38 of the 1999 *ASHRAE Handbook—Applications* covers computer components and some of the ways computers are being used in the HVAC control industry.

### CONTROL COMPONENTS

This section groups components by their function in a complete control system. The section on Controlled Devices considers the controlled device or final control element, examples of which are relays, valves, and dampers. Actuators, which are used to drive the valve or damper assembly, are also covered.

The section on Sensors considers the sensing element that measures changes in the controlled variable. Some of the sensor types included are temperature, humidity, flow, and pressure. While many

other sensors are available, these represent the majority of those found in HVAC control systems.

The section on Controllers reviews various controllers. Controllers are classified according to energy source; pneumatic, electric/electronic, and digital. They are also classified according to the control action they cause to maintain the desired condition (set point)—two-position, floating, proportional, proportional plus integral (PI), or proportional plus integral plus derivative (PID). Thermostats (devices that combine a temperature sensor and controller in a single unit) are also described as well.

Fundamental control systems can be constructed using only the components described in the first three subsections. In practice, however, a fourth group is sometimes necessary. The section on Auxiliary Control Devices covers transducers, switches, power supplies, and air compressors.

### CONTROLLED DEVICES

A controlled device regulates the flow of steam, water, electricity, or air in an HVAC system. Water and steam flow regulators are known as **valves**, and airflow control devices are called **dampers**; both devices perform essentially the same function and must be properly sized and selected for the particular application. The control link to the valve or damper is called an **actuator** or **operator**. This device uses electricity, compressed air, or hydraulic fluid to power the motion of the valve stem or damper linkage through its operating range.

#### Valves

An automatic valve is designed to control the flow of steam, water, gas, or other fluids. It can be considered a variable orifice positioned by an electric or pneumatic actuator in response to impulses or signals from the controller. It may be equipped with a throttling plug or V-port specially designed to provide a desired flow characteristic.

Renewable composition disks are common. They are made of materials best suited to the media handled by the valve, the operating temperature, and the pressure. For high pressure or for superheated steam, metal disks are often used. Internal parts, such as the seat ring, throttling plug, or V-port skirt, disk holder, and stem, are sometimes made of stainless steel or other hard and corrosion-resistant metal for use in severe service.

Various types of automatic valves include the following:

A **single-seated valve** (Figure 8A) is designed for tight shutoff. Appropriate disk materials for various pressures and media are used.

A **double-seated or balanced valve** (Figure 8B) is designed so that the media pressure acting against the valve disk is essentially balanced, reducing the actuator force required. It is widely used where fluid pressure is too high to permit a single-seated valve to close. It cannot be used where a tight shutoff is required.

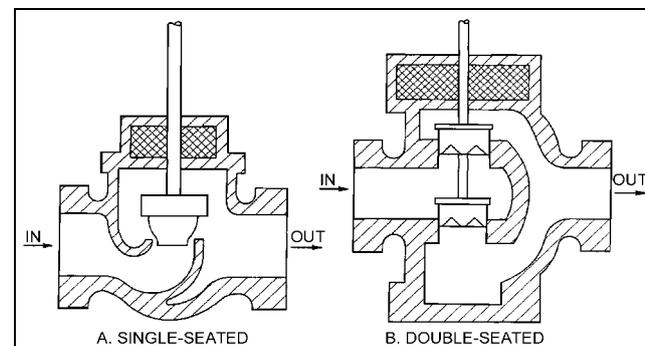

Fig. 8 Typical Single- and Double-Seated Two-Way Valves

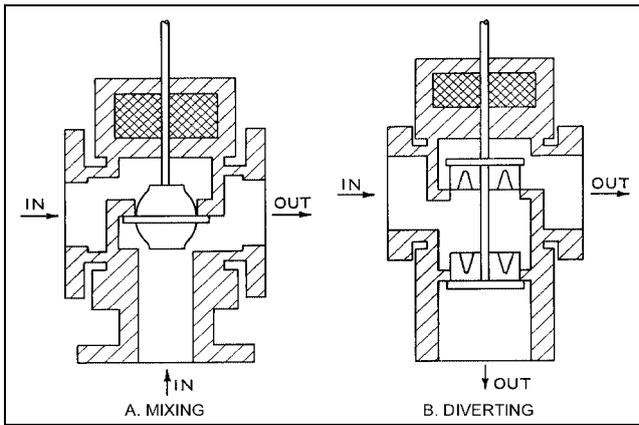

Fig. 9 Typical Three-Way Mixing and Diverting Valves

A **three-way mixing valve** (Figure 9A) has two inlet connections and one outlet connection and a double-faced disk operating between two seats. It is used to mix two fluids entering through the inlet connections and leaving through the common outlet, according to the position of the valve stem and disk.

A **three-way diverting valve** (Figure 9B) has one inlet connection and two outlet connections and two separate disks and seats. It is used to divert the flow to either of the outlets or to proportion the flow to both outlets.

A **butterfly valve** consists of a heavy ring enclosing a disk that rotates on an axis at or near its center and is similar to a round single-blade damper. In principle, the disk seats against a ring machined within the body or a resilient liner in the body. Two butterfly valves can be used together to act like a three-way valve for mixing or diverting.

**Flow Characteristics.** The performance of a valve is expressed in terms of its flow characteristics as it operates through its stroke, based on a constant pressure drop. Three common characteristics are shown in Figure 10 and are defined as follows:

- **Quick opening.** Maximum flow is approached rapidly as the device begins to open.
- **Linear.** Opening and flow are related in direct proportion.
- **Equal percentage.** Each equal increment of opening increases the flow by an equal percentage over the previous value.

Because the pressure drop across a valve seldom remains constant as its opening changes, actual performance usually deviates from the published characteristic curve. The magnitude of the deviation is determined by the overall design. For example, in a system arranged so that control valves or dampers can shut off all flow, the pressure drop across a controlled device increases from a minimum at design conditions to the total pressure drop at no flow. Figure 11 shows the extent of the resulting deviations for a valve or damper designed with a linear characteristic, when selection is based on various percentages of total system pressure drop. To allow for adequate control by valve or damper, the design pressure drop should be a reasonably large percentage of the total system pressure drop, or the system should be designed and controlled so that the pressure drop remains relatively constant.

**Selection and Sizing.** Higher pressure drops for controlled devices are obtained by using smaller sizes with a possible increase in size of other equipment in the system. Because sizing techniques are different for steam, water, and air, each is discussed separately.

**Steam Valves.** Steam-to-water and steam-to-air heat exchangers are typically controlled through regulation of steam flow using a two-way throttling valve. One-pipe steam systems require a line-size, two-position valve for proper condensate drainage and steam

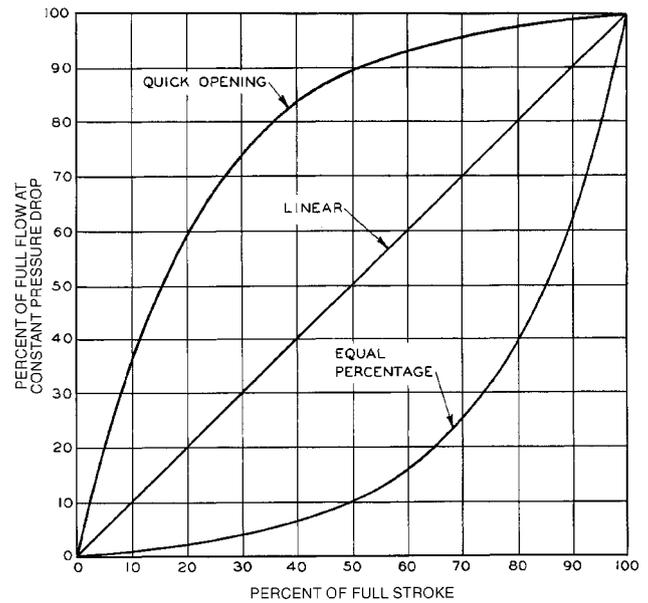

Fig. 10 Typical Flow Characteristics of Valves

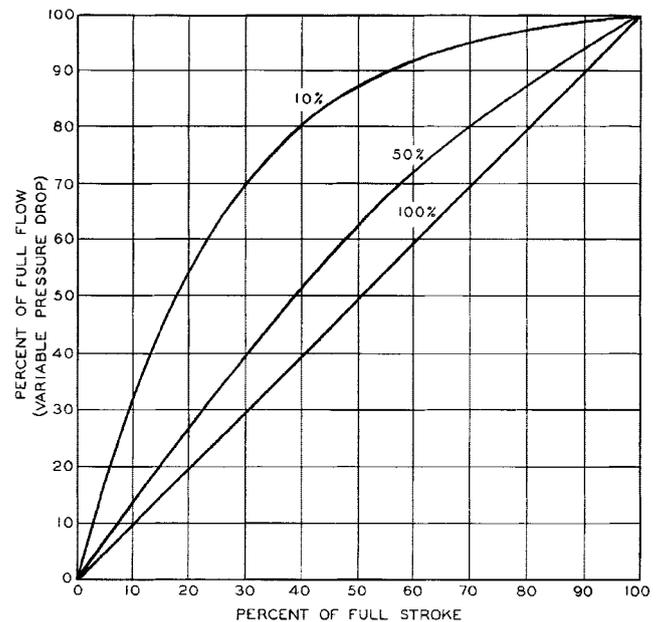

Fig. 11 Typical Performance Curves for Linear Devices at Various Percentages of Total System Pressure Drop

flow, while two-pipe steam systems can be controlled by two-position or modulating (throttling) valves.

**Water Valves.** Valves for water service may be two- or three-way and two-position or proportional. Proportional valves are used most often, but two-position valves are not unusual and are sometimes essential. While it is possible to design a water system in which the pressure differential from supply to return is kept constant, it is seldom done. It is safer to assume that the pressure drop across the valve increases as it modulates from fully open to fully closed. Figure 12 shows the effect in a simple system with one pump, one two-way control valve, and a heat exchanger. The system curve represents the pressure loss in the piping and heat

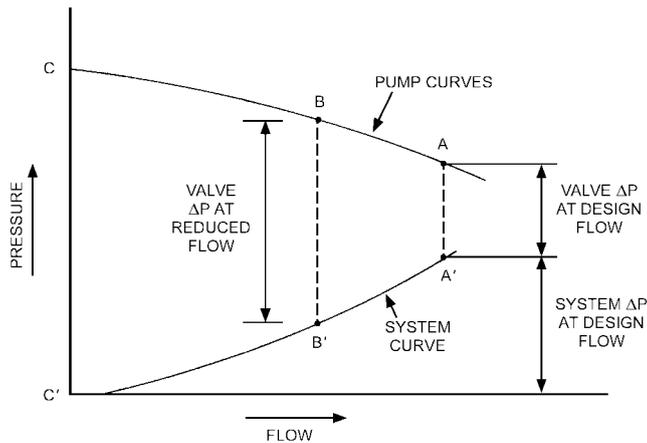

Fig. 12 Pump and System Curves with Valve Control

exchanger at various flow rates. The pump curve is the typical curve for a centrifugal pump. At design flow rates, the valve is selected for a specific pressure drop  $A - A'$ . At part load, the valve must partially close to provide a higher pressure drop  $B - B'$ . The ratio between the design pressure drop  $A - A'$  and the zero Flow pressure drop  $C - C'$  influences the control capability of the valve.

**Equal percentage valves** provide better control at part load, particularly in hot water coils where the heat output of the coil is not linearly related to flow. As flow is reduced, a greater amount of heat is transferred from each unit of water, counteracting the reduction in flow. Equal percentage valves are used in an attempt to linearize the heat transfer from the coil with respect to the control signal.

Two-way control valves should be sized to provide from 20 to 60% of the total system pressure drop. The valve operator should be sized to close the valve against the full pump head pressure to ensure complete shut off during no-flow condition.

For additional information on control valve sizing and selection, see Chapters 12 and 42 of the 2000 *ASHRAE Handbook—Systems and Equipment*.

**Actuators.** Valve actuators include the following general types:

- A **pneumatic valve actuator** consists of a spring-opposed, flexible diaphragm or bellows attached to the valve stem. An increase in air pressure above the minimum point of the spring range compresses the spring and simultaneously moves the valve stem. Springs of various pressure ranges can sequence the operation of two or more devices, if properly selected or adjusted. For example, a chilled water valve actuator may modulate the valve from fully closed to fully open over a spring range of 20 to 60 kPa, while a sequenced steam valve may actuate from 60 to 90 kPa.

Two-position pneumatic control is accomplished using a two-position pneumatic relay to apply either full air pressure or no pressure to the valve actuator. Pneumatic valves and valves with spring-return electric actuators can be classified as normally open or normally closed.

A **normally open valve** assumes an open position, providing full flow, when all actuating force is removed.

A **normally closed valve** assumes a closed position, stopping flow, when all actuating force is removed.

- **Springless pneumatic valve actuators**, which use two opposed diaphragms or two sides of a single diaphragm, are generally limited to special applications involving large valves or high fluid pressure.
- An **electric-hydraulic valve actuator** is similar to a pneumatic one, except that it uses an incompressible fluid circulated by an internal electric pump.

- A **solenoid** consists of a magnetic coil operating a movable plunger. Most are for two-position operation, but modulating solenoid valves are available with a pressure equalization bellows or piston to achieve modulation. Solenoid valves are generally limited to relatively small sizes (up to 100 mm).
- An **electric motor** actuates the valve stem through a gear train and linkage. Electric motor actuators are classified in the following three types:

**Unidirectional**—for two-position operation. The valve opens during one half-revolution of the output shaft and closes during the other half-revolution. Once started, it continues until the half-revolution is completed, regardless of subsequent action by the controller. Limit switches in the actuator stop the motor at the end of each stroke. If the controller has been satisfied during this interval, the actuator continues to the other position.

**Spring-return**—for two-position operation. Electric energy drives the valve to one position and a spring returns the valve to its normal position.

**Reversible**—for floating and proportional operation. The motor can run in either direction and can stop in any position. It is sometimes equipped with a return spring. In proportional control applications, a feedback potentiometer for rebalancing the control circuit is also driven by the motor.

## Dampers

**Types and Characteristics.** Automatic dampers are used in air-conditioning and ventilation to control airflow. They may be used (1) for modulating control to maintain a controlled variable such as mixed air temperature or supply air duct static pressure; or (2) for two-position control to initiate operation such as opening minimum outside air dampers when a fan is started.

**Multiblade dampers** are available in two arrangements—parallel blade and opposed blade (Figure 13). They are used to control flow through large openings typical of those in air handlers. **Parallel-blade dampers** are adequate for two-position control and can be used for modulating control when the pressure drop remains relatively constant (i.e., outdoor air and return air dampers on air-handling unit mixing boxes). However, **opposed-blade dampers** are

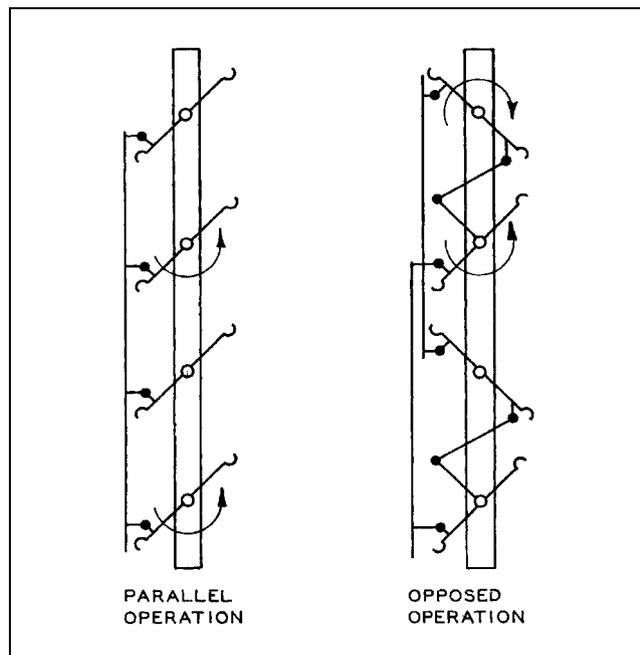

Fig. 13 Typical Multiblade Dampers

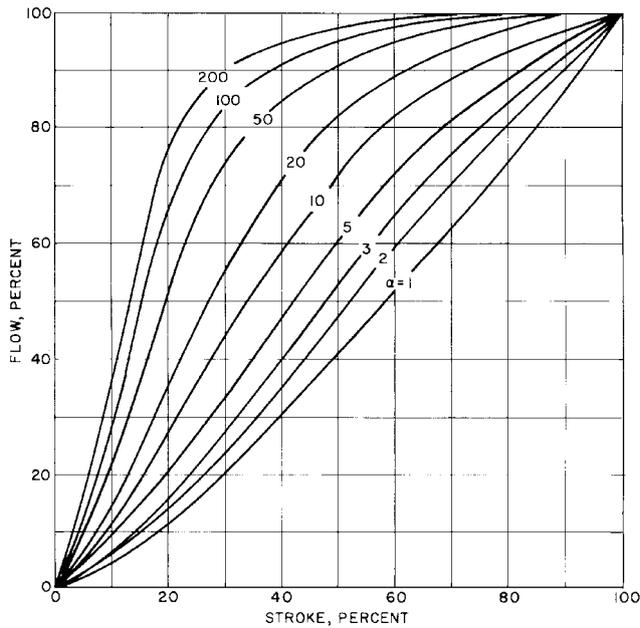

Fig. 14 Characteristic Curves of Installed Parallel-Blade Dampers

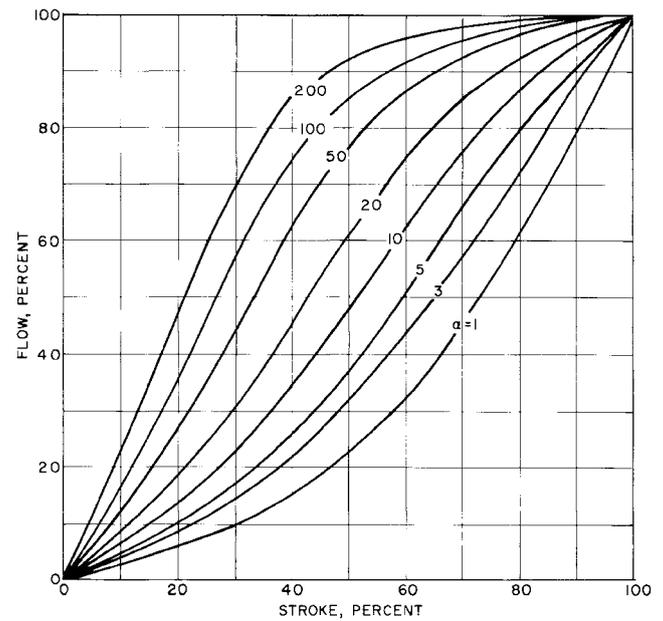

Fig. 15 Characteristic Curves of Installed Opposed-Blade Dampers

preferable for throttling control because they normally provide better control when the ratio of the pressure drop between closed and fully open is large (Figures 14 and 15). In these figures,  $\alpha$  is the ratio of the system pressure drop to the drop across the damper at maximum (fully open) flow. **Single-blade dampers** are typically used for flow control at the zone.

Damper leakage is a concern, particularly where tight shutoff is necessary to reduce energy consumption significantly. Also, outdoor air dampers in cold climates must close tightly to prevent coils and pipes from freezing. Low-leakage dampers cost more and require larger actuators because of the friction of the seals in the closed position; therefore, they should be used only as necessary.

**Actuators.** Either electricity or compressed air is used to actuate dampers.

- **Pneumatic damper actuators** are similar to pneumatic valve actuators, except that they have a longer stroke or the stroke is increased by a multiplying lever. Increasing the air pressure produces a linear motion of the shaft, which, through a linkage, moves the crank arm to open or close the dampers.
- **Electric damper actuators** can be unidirectional, spring-return, or reversible. A **reversible** actuator, which has two sets of motor windings, is frequently used for accurate control in modulating damper applications. Energizing one set of windings turns the actuator output shaft clockwise; energizing the other turns the shaft counter-clockwise.

When neither set of windings is energized, the shaft remains in its last position. The simplest form of control for this actuator is a floating point controller, which causes a contact closure to drive the motor clockwise or counter-clockwise. This type of actuator is available with a wide range of options for rotational shaft travel (expressed in degrees of rotation) and timing (expressed in the number of seconds to move through the rotational range). In addition, a variety of standard electronics signals from electronic controllers, such as 4–20 mA (dc) or 0–10 V (dc), can be used to control this type of modulating actuator.

A two-position **spring-return** actuator moves in one direction when power is applied to its internal windings; when no power is present, the actuator returns (via spring force) to its

normal position. Depending on how the actuator is connected to the dampers, this action opens or closes the dampers. A modulating actuator may also have spring-return action.

**Actuator Mounting.** Damper actuators are mounted in different ways, depending on the size, and accessibility of the damper, and the power required to move the damper. The most common method of mounting electric actuators is directly over the damper shaft with no external linkage. Actuators can also be mounted in the airflow on the damper frame and be linked directly to a damper blade; or they can be mounted outside the duct and connected to a crank arm attached to a shaft extension of one of the blades. On large dampers, two or more actuators may be needed. In this case, they are usually mounted at separate points on the damper. An alternative is to install the damper in two or more sections, each section being controlled by a single damper actuator; however, proper flow control is easier with a single modulating damper. Positive positioners may be required for proper sequencing. A small damper with a two-position spring-return actuator may be used for minimum outside flow, with a large damper being independently controlled for economy cycle cooling.

### Positive Positioners

A pneumatic actuator may not respond quickly or accurately enough to small changes in control pressure due to friction in the actuator or load, or to changing load conditions such as wind acting on a damper blade. Where accurate positioning of a modulating damper or valve in response to load is required, positive positioners should be used. A positive positioner provides up to full supply control air pressure to the actuator for any change in position required by the controller (Figure 16). An increase in branch pressure from the controller (A) moves the relay lever (B), which opens the supply valve (C). This allows supply air to flow into the relay chamber and the actuator cylinder, moving the pistons. A linkage and spring (D) transmit the piston movement to the other end of lever (B), and when the force due to movement balances the control force, the supply valve closes, leaving the actuator in the new position. A decrease in control pressure allows the exhaust valve (E) to open until a new balance is obtained.

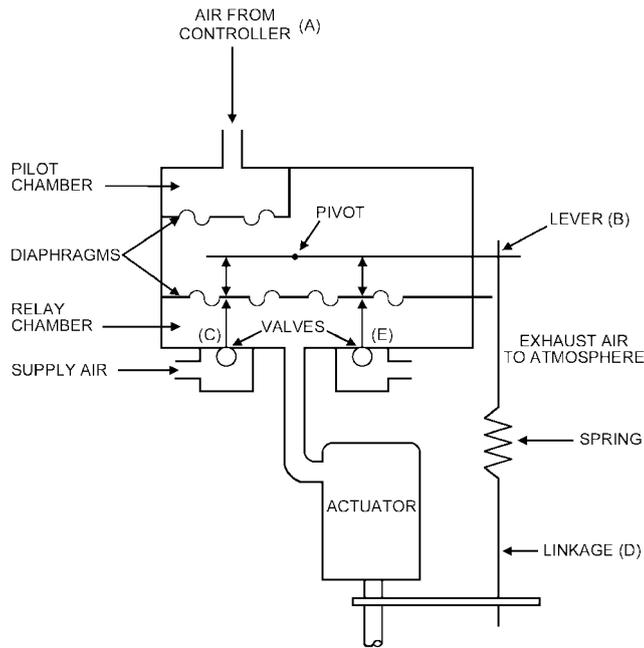

Fig. 16 Pilot Positioner (Positive Positioner)

A positive positioner provides finite and repeatable positioning change and permits adjustment of the control range (spring range of the actuator) to provide a proper sequencing control of two or more controlled devices.

## SENSORS

A sensor is a device that responds to a change in the controlled variable. The response, which is a change in some physical or electrical property of the primary sensing element, is available for translation or amplification by mechanical or electrical signal. This signal is sent to the controller.

Chapter 45 of the 1999 *ASHRAE Handbook—Applications* and manufacturer's catalogs and tutorials include information on specific applications. In selecting a sensor for a specific application, the following should be considered:

- **Operating range of controlled variable.** The sensor must be capable of providing an adequate change in its output signal over the expected input range.
- **Compatibility of controller input.** Electronic and digital controllers accept various ranges and types of electronic signals. The specific controller to be used must be considered in the selection of an electronic sensor; if this is not known, an industry standard signal, such as 4–20 mA (dc) or 0–10 V (dc), should be used.
- **Accuracy and repeatability.** For some control applications, the controlled variable must be maintained within a narrow band around a desired set point. Both the accuracy and the sensitivity of the sensor selected must reflect this requirement. However, even an accurate sensor can not maintain the set point if (1) the controller is unable to resolve the input signal, (2) the controlled device can not be positioned accurately, (3) the controlled device exhibits excessive hysteresis, or (4) disturbances drive its system faster than the controls can regulate it.
- **System response time (or process dynamics).** Associated with a sensor/transducer arrangement is a response curve, which describes the response of the sensor output to change in the controlled variable. If the time constant of the process being

controlled is short, and stable accurate control is important, the sensor selected must have a fast response time.

- **Control agent properties and characteristics.** The control agent is the medium to which the sensor is exposed, or with which it comes in contact, for measuring a controlled variable such as temperature or pressure. If the agent corrodes the sensor or otherwise degrades its performance, a different sensor should be selected, or the sensor must be isolated or protected from direct contact with the control agent.
- **Ambient environment characteristics.** Even when the sensor's components are isolated from direct contact with the control agent, the ambient environment must be considered. The temperature and humidity range of the ambient environment must not reduce the accuracy of the sensor. Likewise, the presence of certain gases, chemicals, and electromagnetic interference (EMI) can cause component degradation. In such cases, a special sensor or transducer housing can be used to protect the element, while ensuring a true indication of the controlled variable.

## Temperature Sensors

Temperature-sensing elements fall into three general categories: (1) those that use a change in relative dimension due to differences in thermal expansion, (2) those that use a change in state of a vapor or liquid, and (3) those that use a change in some electrical property. Within each category, there are a variety of sensing elements to measure room, duct, water, and surface temperatures. Temperature-sensing technologies commonly used in HVAC applications are as follows:

- A **bimetal element** is composed of two thin strips of dissimilar metals fused together. Because the two metals have different coefficients of thermal expansion, the element bends and changes position as the temperature varies. Depending on the space available and the movement required, it may be straight, U-shaped, or wound into a spiral. This element is commonly used in room, insertion, and immersion thermostats.
- A **rod-and-tube element** consists of a high-expansion metal tube containing a low-expansion rod. One end of the rod is attached to the rear of the tube. The tube changes length with changes in temperature, causing the free end of the rod to move. This element is commonly used in certain insertion and immersion thermostats.
- A **sealed bellows element** is either vapor-, gas-, or liquid-filled. Temperature changes vary the pressure and volume of the gas or liquid, resulting in a change in force or a movement.
- A **remote bulb element** is a bulb or capsule that is connected to a sealed bellows or diaphragm by a capillary tube; the entire system is filled with vapor, gas, or liquid. Temperature changes at the bulb cause volume or pressure changes that are conveyed to the bellows or diaphragm through the capillary tube. The remote bulb element is useful where the temperature measuring point is remote from the desired thermostat location.
- A **thermistor** is a semiconductor that changes electrical resistance with temperature. It has a negative temperature coefficient (i.e., the resistance decreases as the temperature increases). Its characteristic curve of temperature versus resistance is nonlinear over a wide range. Several techniques are used to convert its response to a linear change over a particular temperature range. With digital control, one technique is to store a computer "look-up table" that maps the temperature corresponding to the measured resistance. The table breaks the curve into small segments, and each segment is assumed to be linear over its range. Thermistors are used because of their relatively low cost and the large change in resistance possible for a small change in temperature.
- A **resistance temperature device (RTD)** is another sensor that changes resistance with temperature. Most metallic materials increase in resistance with increasing temperature. Over limited ranges, this variation is linear for certain metals such as platinum,

copper, tungsten, and nickel/iron alloys. Platinum, for example, is linear within  $\pm 0.3\%$  from  $-20$  to  $150^\circ\text{C}$ . The RTD sensing element is available in several forms for surface or immersion mounting. Flat grid windings are used for measurements of surface temperatures. For direct measurement of fluid temperatures, the windings are encased in a stainless steel bulb to protect them from corrosion.

### Humidity Sensors

Humidity sensors, or **hygrometers**, are used to measure relative humidity, dew point, or absolute humidity of ambient or moving air. Two types that detect relative humidity are mechanical hygrometers and electronic hygrometers.

A **mechanical hygrometer** operates on the principle that a hygroscopic material, usually a moisture-sensitive nylon or bulk polymer material, retains moisture and expands when exposed to water vapor. The change in size or form is detected by a mechanical linkage and converted to a pneumatic or electronic signal. Mechanical sensors using hair, wood, paper, or cotton do not match the performance of moisture-sensitive nylon or bulk polymer sensors and are not widely used.

**Electronic hygrometers** can use either resistance or capacitance sensing elements. The resistance element is a conductive grid coated with a hygroscopic (water-absorbent) substance. The conductivity of the grid varies with the water retained; thus, the resistance varies according to the relative humidity. The conductive element is arranged in an alternating current excited Wheatstone bridge and responds rapidly to humidity changes.

The capacitance element is a stretched membrane of nonconductive film. It is coated on both sides with metal electrodes and mounted in a perforated plastic capsule. The response of the sensor's capacity to rising relative humidity is nonlinear. The signal is linearized and temperature is compensated in the amplifier circuit to provide an output signal as the relative humidity changes from 0 to 100%.

The **chilled mirror humidity sensor** determines dew point rather than relative humidity. Air flows across a small mirror in the sensor. A thermoelectric cooler lowers the surface temperature of the mirror. The mirror surface condenses until it reaches the dew point of the air. The condensation from the surface reduces the amount of light reflected from the mirror compared to a reference light level.

**Dispersive infrared (DIR) technology** can be used to sense absolute humidity or dew point. It is similar to technology used to sense carbon dioxide or other gases. **Infrared water vapor sensors** are optical sensors that detect the amount of water vapor in air based on the infrared light absorption characteristics of water molecules. Light absorption is proportional to the number of molecules present. The output of an **infrared hygrometer** is typically a value of absolute humidity or dew point. They can operate in diffusion or flow-through sample mode. This type of humidity sensor is unique in that the sensing element (a light detector and an infrared filter) is behind a transparent window that is never exposed directly to the sample environment. As a result, this sensor has excellent long-term stability and life and fast response time, is not subject to saturation, and operates equally well in very high or low humidity. Previously used solely for high-end applications, infrared hygrometers are now commonly used in HVAC applications because they cost about the same as mid-range accuracy (1 to 3%) humidity sensors.

### Pressure Transmitters and Transducers

A pneumatic pressure transmitter converts a change in absolute, gage, or differential pressure to a mechanical motion using a bellows, diaphragm, or Bourdon tube mechanism. When corrected through appropriate links, this mechanical motion produces a change in the air pressure to a controller. In some instances, the

sensing and control functions are combined in a single component, a **pressure controller**.

An electronic pressure transducer may use the mechanical actuation of a diaphragm or Bourdon tube to operate a potentiometer or differential transformer. Another type of transducer uses a strain gage bonded to a diaphragm. The strain gage detects the displacement resulting from the force applied to the diaphragm. Electronic circuits provide temperature compensation and amplification to produce a standard output signal.

### Flow Rate Sensors

Orifice plate, pitot tube, venturi, turbine, magnetic flow, vortex shedding, and Doppler effect meters are used to sense fluid flow. In general, the pressure differential devices (orifice plates, venturi and pitot tubes) are less expensive and simpler to use but have limited range; thus, their accuracy depends on how they are applied and where in a system they are located.

More sophisticated flow devices, such as turbine, magnetic, and vortex shedding meters, usually have better range and are more accurate over a wide range. If an existing piping system is being considered for retrofit with a flow device, the expense of shutting down the system and cutting into a pipe must be considered. In this case, a noninvasive meter, such as a Doppler effect meter, can be cost-effective.

### Indoor Air Quality Sensors

Indoor air quality control can be divided into two categories—ventilation control and contamination protection. Ventilation control measures levels of carbon dioxide or other contaminants in a space and controls the amount of outdoor air introduced into the occupied space. Demand control of ventilation helps maintain proper ventilation rates at all levels of occupancy. Typical control set point levels for carbon dioxide are 800 to 1000 ppm (1400 to 1800  $\text{mg}/\text{m}^3$ ). ASHRAE *Standard 62* provides further information on ventilation for acceptable indoor air quality.

Contamination protection sensors monitor levels of hazardous or toxic substances and issue warning signals and/or initiate corrective actions through the building automation system (BAS). Sensors are available for many different gases. The carbon monoxide (CO) sensor is one of the most common. The CO sensor is used to control and alarm CO levels in parking garages. Oxygen depletion sensors are used to measure, alarm, and initiate ventilation purging in enclosed spaces that house refrigeration equipment to prevent suffocation of occupants upon a refrigeration leak. The application of these sensors determines the type selected, the substances monitored, and the action taken.

### Lighting Level Sensors

Analog lighting level transmitters packaged in various configurations allow control of ambient lighting levels using building automation strategies for energy conservation. Some examples include ceiling-mounted indoor light sensors used to measure room lighting levels; outdoor ambient lighting sensors used to control parking, general exterior, security, and sign lighting; and interior skylight sensors used to monitor and control light levels in skylight wells and other atrium spaces.

### Power Sensing and Transmission

Passive electronic devices that sense the magnetic field around a conductor carrying current allow low-cost instrumentation of power circuits. A wire in the sensor forms an inductive coupling that powers the internal function and senses the level of the power signal. These devices can provide an analog output signal to monitor current flow or operate a switch at a user-set level to turn on an alarm or other device.

## CONTROLLERS

A controller compares the sensor's signal with a desired set point and regulates an output signal to a controlled device. Digital controllers perform the control function using a microprocessor and control algorithm. The sensor and controller can be combined in a single instrument, such as a room thermostat, or they may be two separate devices.

### Pneumatic Receiver-Controllers

Pneumatic receiver-controllers are normally combined with pneumatic elements that use a force or position reaction to the sensed variable to obtain a variable output air pressure. The control mode is usually proportional, but other modes such as proportional-plus-integral can be used. These controllers are generally classified as nonrelay, relay direct, or reverse-acting.

The nonrelay pneumatic controller uses low-volume output. A relay-type pneumatic controller actuates a relay device that amplifies the air volume available for control. The relay provides quicker response to a variable change.

Direct-acting controllers increase the output signal as the controlled variable increases. Reverse-acting controllers increase the output signal as the controlled variable decreases. A reverse-acting thermostat increases output pressure when the temperature drops.

### Electric/Electronic Controllers

For two-position control, the controller output may be a simple electrical contact that starts a burner or pump, or one that actuates a spring-return valve or damper actuator. Single-pole, double-throw (SPDT) switching circuits are used to control a three-wire unidirectional motor actuator. SPDT circuits are also used for heating and cooling applications. Both single-pole, single-throw (SPST) and SPDT circuits can be modified for timed two-position action.

Output for floating control is a SPDT switching circuit with a neutral zone where neither contact is made. This control is used with reversible motors; it has slow response and a wide throttling range.

Pulse modulation control is an improvement over floating control. It provides closer control by varying the duration of the contact closure. As the actual condition moves closer to the set point, the pulse duration shortens for closer control. As the actual condition moves farther from the set point, the pulse duration lengthens.

Proportional control gives continuous or incremental changes in output signal to position an electrical actuator or controlled device.

### Digital Controllers

A microprocessor in the digital controller executes control algorithms on one or multiple control loops. This controller is fundamentally different from pneumatic or electronic controllers in that the control algorithm is stored as a set of program instructions in memory (software or firmware). The controller itself calculates the proper control signals digitally rather than using an analog circuit or mechanical change.

A digital controller can be either single-loop or multiloop. Interface hardware allows the digital computer to process signals from various input devices such as electronic temperature, humidity, or pressure sensors described in the section on Sensors. Based on digitized equivalents of the input voltage or current signals, the control software calculates the required state of the output devices, such as valve and damper actuators and fan starters. The output devices are then positioned to the calculated state via interface hardware that converts the digital signal from the computer to an analog voltage or current required to position the actuator or energize a relay. It is common in both new and retrofit applications to use an additional interface device to convert the analog voltage or current into a pneumatic signal, which operates a pneumatic actuator. Such devices are called **electronic-to-pneumatic (E/P) transducers**.

The operator enters parameters such as set points, proportional or integral gains, minimum on and off times, or high and low limits, but the control algorithms stored in the computer's memory make the control decisions. The computer scans the input devices, executes the control algorithms, and then positions the output device(s), in a stepwise scheme. Digital controllers can be classified with regard to the way control algorithms are stored in memory (such as in firmware and software) and their ability to communicate to higher level devices such as terminals and computers.

**Firmware and Software.** Preprogrammed control routines, known as firmware, are typically stored in permanent memory such as electrically erasable programmable read-only memory (EEPROM). The operator can modify parameters such as set points, limits, and minimum off times within the control routines, but the program logic cannot be changed without replacing the memory chips.

User-programmable controllers allow the algorithms to be changed by the user. The programming language provided with the controller can vary from (1) a derivation of a standard language (such as Pascal or BASIC) to (2) a custom language developed by the controller's manufacturer to (3) graphically based programming. Preprogrammed routines for proportional, proportional plus integral, Boolean logic, timers, and so forth, are typically included in the language. Standard energy management routines may also be preprogrammed and may interact with other control loops where appropriate.

Digital controllers can be furnished with both preprogrammed firmware and user-programmed routines. These routines can automatically modify the parameters of the firmware according to user-defined conditions to accomplish the sequence of control designed by the control engineer.

**Operator Interface.** Some digital controllers are designed for dedicated purposes and are adjustable only through manual switches and potentiometers mounted on the controller. This type of controller cannot be networked with other controllers. An example is the programmable room thermostat. A **direct digital controller** can have manual adjustable features, but it more typically is adjusted through a built-in LED or LCD display, a hand-held device, or a terminal or computer. The DDC controller can communicate digitally, which allows remote connection to other controllers and to higher level computing devices and host operating stations.

A **terminal** allows the user to communicate with the controller and, where applicable, modify the program in the controller. Terminals can range from hand-held units with an LCD display and several buttons to a full-size console with a video monitor and keyboard. The terminal can be limited in function to allow only the display of sensor and parameter values or powerful enough to allow changing or reprogramming the control strategies. In some instances, a terminal can communicate remotely with one or more controllers, thus allowing central displays, alarms, and commands. Usually, hand-held terminals are used by technicians for troubleshooting, and full consoles at a fixed location are used to monitor the entire digital control system.

### Thermostats

Thermostats combine sensing and control functions in a single device. Microprocessor-based thermostats have many of the features described in the following paragraphs.

- The **occupied-unoccupied** or **dual-temperature room thermostat** controls at a reduced temperature at night. It may be indexed (changed from occupied to unoccupied) individually or in groups by a manual switch or time switch from a remote point. Some electric units have an individual clock and switch built into the thermostat.
- The **pneumatic day-night thermostat** uses a two-pressure air supply system—the two pressures often being 90 and 120 kPa (gage), or 100 and 140 kPa (gage). Changing the pressure at a

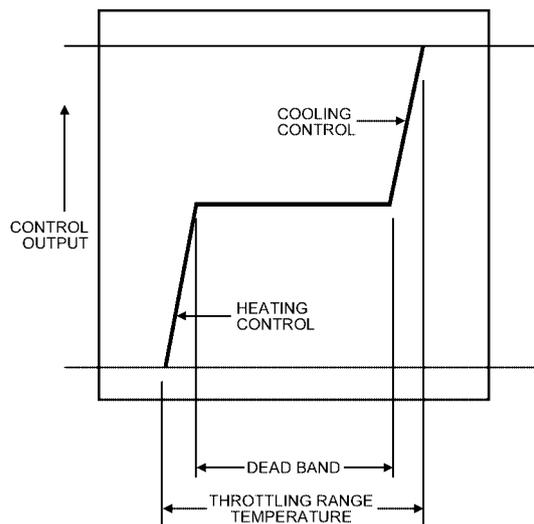

Fig. 17 Dead Band Thermostat

central point from one value to the other actuates switching devices in the thermostat that index it from occupied to unoccupied or vice versa.

- The **heating-cooling or summer-winter thermostat** can have its action reversed and its set point changed by indexing. It is used to actuate controlled devices, such as valves or dampers, that regulate a heating source at one time and a cooling source at another.
- **Multistage thermostats** are arranged to operate two or more successive steps in sequence.
- A **submaster thermostat** has its set point raised or lowered over a predetermined range in accordance with variations in output from a master controller. The master controller can be a thermostat, manual switch, pressure controller, or similar device.
- A **dead band thermostat** has a wide differential over which the thermostat remains neutral, requiring neither heating nor cooling. This differential may be adjustable up to 5 K. The thermostat then controls to maximum or minimum output over a small differential at the end of each dead band (Figure 17).

### AUXILIARY CONTROL DEVICES

Auxiliary control devices for electric systems include

- **Transformers** to provide current at the required voltage.
- **Occupancy sensors** to automatically adjust controlled variables based on occupancy such as lighting, ventilation rate, and temperature.
- **Signal transducers** to change one standard signal into another. The popularity of digital control and other electric-based control systems has generated a variety of transducers. The variables usually transformed include voltage [0–10, 0–5, 2–10 V (dc)], current [4–20 mA], resistance [0–135 Ω], pressure (20–100, 0–140 kPa), phase cut voltage [0–20 V (dc)], pulse-width modulation, and time duration pulse. Signal transducers allow the use of an existing control device in a retrofit application.
- **Electric relays** to control electric heaters or to start and stop burners, compressors, fans, pumps, or other apparatus for which the electrical load is too large to be handled directly by the controller. Other uses include time-delay and circuit-interlocking safety applications.
- **Potentiometers** for manual positioning of proportional control devices, for remote set point adjustment of electronic controllers, and for feedback.

- **Manual switches**, either two-position or multiple-position with single or multiple poles.
- **Auxiliary switches** on valve and damper actuators for selecting a sequence of operation.

Auxiliary control devices for pneumatic systems include

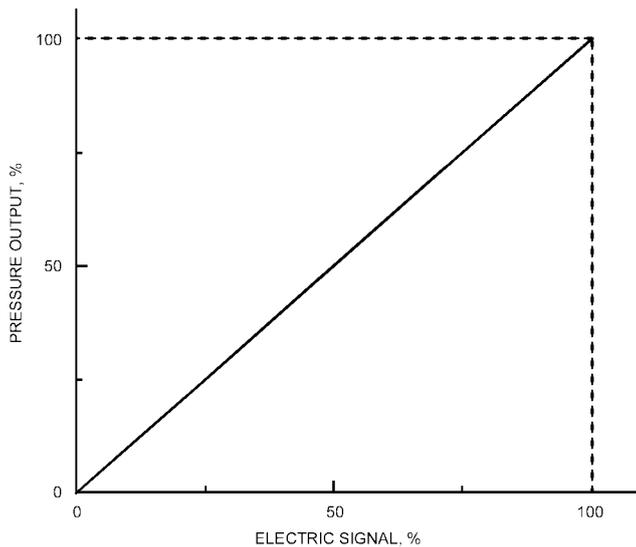

- **Air compressors** and accessories, including dryers and filters, to provide a source of clean, dry air at the required pressure.
- **Electropneumatic relays**, electrically actuated air valves for operating pneumatic equipment according to variations in electrical input to the relay.
- **Pneumatic-electric switches**, which are actuated by the pressure from a controller to permit a controller actuating a proportional device to also actuate one or more two-position devices.
- **Pneumatic transducers**, which are used to reverse the action of a proportional controller, select the higher or lower of two or more pressures, average two or more pressures, respond to the difference between two pressures, add or subtract pressures, and amplify or retard pressure changes.
- **Positive positioning relays** to ensure accurate positioning of a valve or damper actuator in response to changes in pressure from a controller.
- **Switching relays**, which are pneumatically operated air valves used to divert air from one circuit to another or to open and close air circuits.
- **Pneumatic switches**, which are manually operated devices used to divert air from one circuit to another or to open and close air circuits. They can be two-position or multiple-position.
- **Gradual switches**, which are proportional devices used to manually vary air pressure in a circuit.

Auxiliary control devices common to both electric and pneumatic systems include the following:

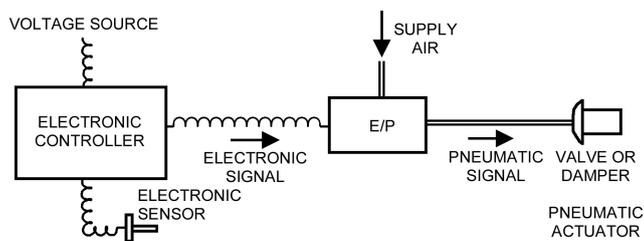

- **Step controllers** to operate several switches in sequence by means of a proportional electric or pneumatic actuator. They are commonly used to control several steps of refrigeration capacity. They may be arranged to prevent simultaneous starting of compressors and to alternate the sequence to equalize wear. These controllers may also be used for sequenced operation of electric heating elements and other equipment.
- **Power controllers** to control electric power input to resistance heating elements. The final controlled device may be a variable autotransformer, a saturable-core reactor, or a solid-state power controller. They are available with various ratings for single- or three-phase heater loads and are usually arranged to regulate power input to the heater in response to the demands of the proportional electronic or pneumatic controllers. However, solid-state controllers may also be used in two-position control modes.
- **Clocks or timers** to turn apparatus on and off at predetermined times, to switch control systems from day to night operation, and to regulate other time sequence functions.
- **Transducers**, which consist of combinations of electric or pneumatic control devices, may be required. For these applications, transducers are used to convert electric signals to pneumatic output or vice versa. Transducers may convert proportional input to either proportional or two-position output.

The electronic-to-pneumatic (E/P) transducer is used in many applications. It converts a proportional electronic output signal into a proportional pneumatic signal (as illustrated in Figure 18) and can be used to combine electronic and pneumatic control components to form a control loop, as illustrated in Figure 19. Electronic components are used for sensing and signal conditioning, while pneumatic components are used for actuation. The electronic controller can be either analog or digital.

The E/P transducer presents a special option for retrofit applications. An existing HVAC system with pneumatic controls can be re-

**Fig. 18** Response of Electronic-to-Pneumatic (E/P) Transducer

**Fig. 19** Electronic and Pneumatic Control Components Combined with Electronic-to-Pneumatic (E/P) Transducer

retrofit with electronic sensors and controllers while retaining the existing pneumatic actuators (Figure 20).

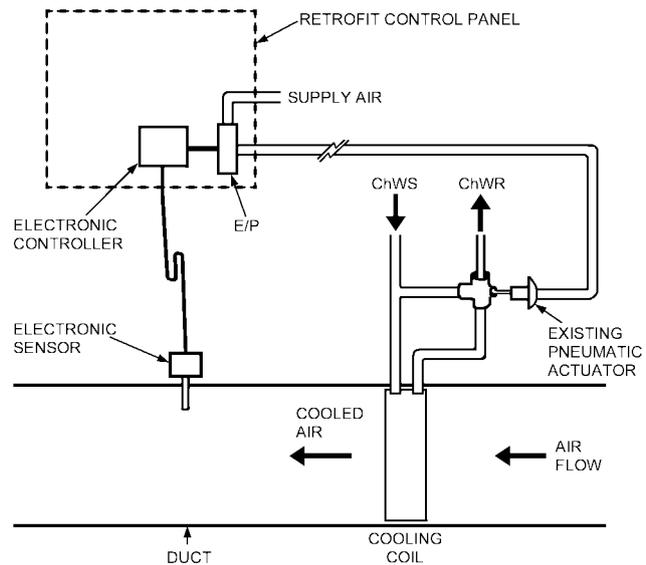

## COMMUNICATION NETWORKS FOR BUILDING AUTOMATION SYSTEMS

A **building automation system (BAS)** is a centralized control and/or monitoring system for many or all building systems (e.g., HVAC, electrical, life safety, security). A BAS may link together information from control systems actuated by different technologies.

One important characteristic of direct digital control (DDC) is the ability to share information. Information is transferred (1) between controllers to coordinate their action, (2) between controllers and building operator interfaces to monitor and command systems, and (3) between controllers and other computers for off-line calculation. This information is typically shared over communication networks. DDC systems nearly always involve at least one network and commonly involve more than one. A **network** is a set of connections between controllers, routers, bridges, and computers that enables them to exchange digital information.

### COMMUNICATION PROTOCOLS

A **protocol** is a set of rules that define the communication behavior of each element in a communication network. The word may

**Fig. 20** Retrofit of Existing Pneumatic Control with Electronic Sensors and Controllers

describe the communication at one layer of the network [e.g., **Internet protocol (IP)**, which defines the network layer in the Internet suite of protocols], or it may refer to the entire communication process. In discussions of BASs, most communication needs are described in terms of the entire process, but it is sometimes necessary to discuss the protocols at a particular layer.

There is great interest in open protocols for BASs to facilitate communication among devices from different suppliers. Although there is no commonly accepted definition of "openness," the Institute of Electrical and Electronics Engineers defines three classes of protocols (*IEEE Standard 802*):

- **Standard protocol.** Published and controlled by a standards body. Examples include BACnet by ASHRAE, LonTalk by Electronic Industries Alliance, and TCP/IP by Internet Engineering Task Force.
- **Public protocol.** Published but controlled by a private organization.
- **Private protocol.** Unpublished; use and specification controlled by a private organization. Examples include the proprietary communications used by many building automation devices.

Multivendor communication is possible with any of these three classes, but the challenges vary. Specifying a common protocol does not ensure that the end user's requirement for interoperability is met. The engineer may select an open protocol and specify the interaction between devices. This limits the bidders, but assures the engineer of certain communication characteristics. On the other hand, the engineer can specify the required interoperation and put the burden on the suppliers to select combinations of products that meet the need. This is likely to result in a wider range of options, but they may be more difficult to compare.

### THE OSI NETWORK MODEL

*ISO Standard 7498-1* presents a seven-layer model of information exchange called the **Open Systems Interconnection (OSI) Reference Model** (Figure 21). Most descriptions of computer networks, especially open networks, are based on this reference model. The layers can be thought of as steps in the translation of a message from something with meaning at the application layer, to something measurable at the physical layer, and back to meaningful information at the application layer.

7 Application Layer	Window between applications and network.
6 Presentation Layer	Coordinates representation of information between different applications.
5 Session Layer	Synchronizes and structures exchange of data messages between specific users.
4 Transport Layer	Converts data messages into packets for transmission, and converts received packets into messages. Responsible for data message error recognition and recovery, and ensures reliable delivery of messages.
3 Network Layer	Addressing and routing packets independent of media and topology.
2 Data Link Layer	Responsible for point-to-point reliability. Media access. Representation of bits and bytes as physical signals. Organizes bits into data packets.
1 Physical Layer	Electrical characteristics of devices and conductors.

Fig. 21 OSI Reference Model

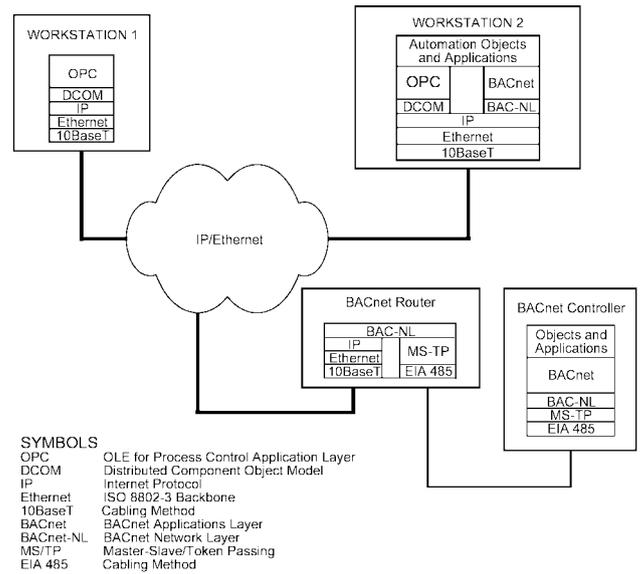

Fig. 23 Network Layers in BAS Devices

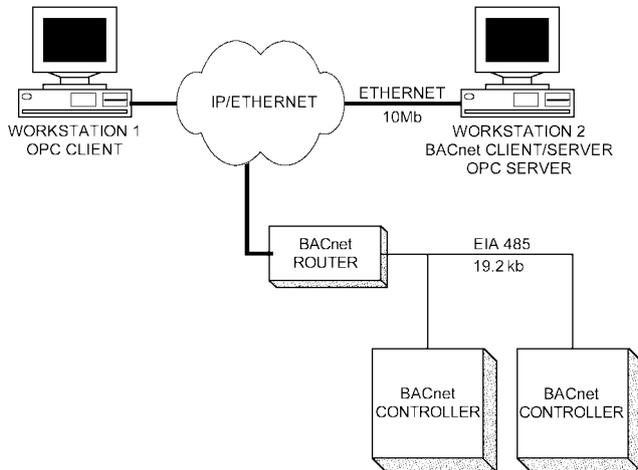

Fig. 22 Portion of a BAS Network

The layered approach to network design is valuable because it allows developers to take advantage of existing standards such as IP at the network layer or Electronic Industries Association (EIA) Standard 485, a signaling standard, at the physical layer without becoming tied to one technology.

The full seven-layer model does not apply to every network, but it is still used to describe the aspects that do fit. When describing DDC networks that use the same technology throughout the system, the seven-layer model is relatively unimportant. For systems that employ various technologies at different points in the network, the model helps describe where and how the pieces are bound together.

The portion of network shown in Figure 22 illustrates how the OSI Reference Model describes communications. The system includes a number of controllers on a BACnet network and several operator workstations connected by an ISO 8802-3 backbone or local area network (LAN), in this case an Ethernet. A BACnet router links the BACnet controllers to the Ethernet.

Figure 23 shows the network layers in each device that make communication possible. Workstation 2 and the BACnet controller both show communication stacks with BACnet at the application layer; however, these devices do not communicate directly because they use different protocols at the lower layers. If the stacks are dif-

ferent at any layer, a device that bridges the gap is required. The BACnet router shows two stacks. One matches the physical, data link, and network layers of the BACnet controllers; the other matches the bottom three layers of the BACnet stack on Workstation 2. The BACnet network layer is the common layer that delivers BACnet messages from one end of the router to the other. When a message reaches the router, it travels up through the stack. The router reformats it and sends the same message out through the other stack to the other network. This makes it possible for application data to pass between the controller and BACnet devices on the Ethernet. Bushby (1998) described this process more fully.

Both workstations contain an OPC stack. **OPC** (OLE for process control) is a standard for communicating automation data between computers or processes; it is based on distributed component object model (DCOM) technology. DCOM is a software development standard that facilitates interchangeability of software components.

The workstations communicate with each other over the Ethernet with OPC messages. Workstation 2 and the BACnet router communicate with each other over the Ethernet using BACnet messages. Although they are on the same network, Workstation 1 and the BACnet router do not communicate directly with each other because their protocol stacks do not match at the upper layers. If BACnet data is required at Workstation 1, it must pass through the OPC server on Workstation 2.

### NETWORK STRUCTURE

Often, a single DDC system applies several different network technologies at different points in the system. For example, a relatively low-speed, inexpensive network with relatively primitive functions may link a group of room controllers to a larger equipment controller. A faster, more sophisticated network links the large controller to its peers and to an operator's workstation. Several workstations communicate over a high-speed, relatively expensive, general-purpose office automation network. Figure 24 illustrates this sort of high-speed **hierarchical** network. Structures like it have been popular in DDC for years. Frequently, the network hierarchy corresponds roughly to a hierarchy related to the control function of the devices. Variations on this hierarchical structure will continue to emerge. The opposite extreme is a completely **flat** network architecture. A flat architecture links all the devices through the same network without altering any other hierarchy that exists among the devices. A flat architecture is more

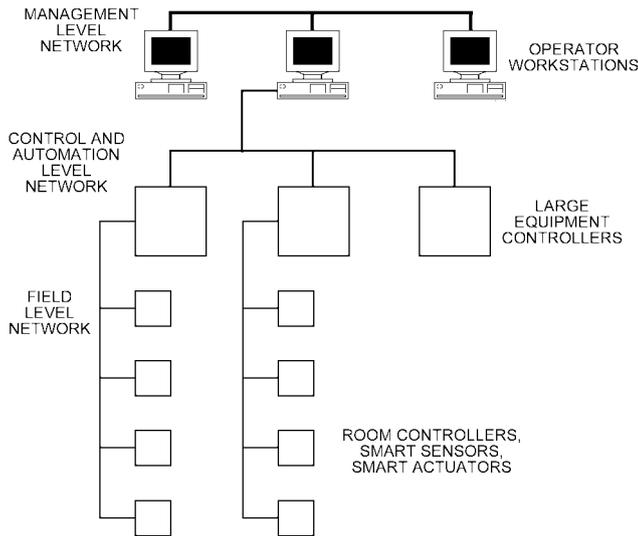

Fig. 24 Hierarchical Network

viable in small systems than in large ones due to the considerations discussed in the following paragraph.

Network structure sometimes affects the cost, operation, and opportunities for expansion of a BAS. The structure can affect the reliability and failure modes of the system. It may be appropriate to separate sections of a network in order to isolate failures. Structure can affect the way devices load the information carrying capacity of the network. It can isolate one busy branch from the rest of the system. It can isolate branches from the high-speed backbone. Structure affects the cost of the system because it determines the mix of low-speed and high-speed devices. Network structure can influence system data security and access control. The relative merits of one structure versus another depend on the communication functions required, the hardware and software available for the task, and cost. For a given job, there is probably more than one suitable structure. Product capabilities change quickly. Engineers who choose to specify network structure must be aware of new technologies to take advantage of the most cost-effective solutions.

### Connections Between Networks and Network Segments

Some BAS networks use other networks to connect segments of the BAS. This occurs

- Within a building, using the information technology network
- Between buildings, using telephone lines
- Between buildings, using the Internet

In each case, the link between BAS segments must be considered part of the BAS network when evaluating function, security, and performance. The link also raises new issues. The connecting segment is likely to be outside the control of the owner of the BAS, which could affect availability of service. It may mean that traffic and bandwidth issues have to be addressed outside the facilities department.

The connection may be **switched** (dial-up) or **dedicated**. In the case of a switched connection, the function of the network depends on which segment may dial the other and the circumstances that trigger the call. Switched connections are most commonly used to handle remote buildings or to serve a remote operator (i.e., one who is on call over the weekend).

### Transmission Media

The transmission medium is the foundation of the network. It is usually, but not always, cable. In cases where physical cable

Table 1 Comparison of Fiber Optic Technology

	Multimode Fiber	Single-Mode Fiber
Light source	LED	Laser
Cable designation (core/cladding diameter)	62.6/125	8.3/125
Transmission distance	2000 m	3000 m
Data rate	>10 gigabit/s and increasing	Even higher
Relative cost	Less per connection, more per data rate	More per connection, less per data rate

connection is not possible or practical, devices may transfer information using wireless technologies, such as radio waves or infrared light. However, this section covers only physical cabling media.

**Twisted-Pair Copper Cable.** A twisted-pair cable consists of multiple twisted pairs (typically 24 AWG) of wire covered by an overall sheath or jacket. Varying the number of twists for each pair relative to the other pairs in the cable can greatly reduce crosstalk (interference between signals on different pairs).

**In shielded twisted pair (STP) cable,** each wire pair, as well as the combined grouping of all pairs, is covered with a layer of shielding to minimize interference-related problems. STP cable performs better than **unshielded twisted pair (UTP) cable** in environments where a high level of immunity and/or a low level of emissions is critical. It also allows less crosstalk than UTP. However, STP requires a more labor-intensive installation, and any break or improper grounding of the shield reduces its overall effectiveness.

Category 5 (defined by TIA/EIA *Standard 568-A*) UTP cable is currently the most common medium. RJ-45 jacks and plugs are specified and have standard pinouts. This cable is rated at up to 1 gigabit per second for 100 m and can be used over much longer distances for lower speed applications (e.g., EIA *Standard 485*).

**Fiber Optic Cable.** Fiber optic cable uses glass or plastic fibers to transfer data in the form of light pulses, which are typically generated by either a laser or an LED. Fiber optic cable systems are classified as either single-mode fiber or multimode fiber systems. Table 1 compares their characteristics.

Light in a fiber optic system experiences less energy loss than electrical signals traveling through copper and no capacitance. This translates into greater transmission distances and dramatically higher data transfer rates. With the rapid advances in this technology, the data transfer rate of a fiber cable imposes no limits on a BAS. Fiber optics also have exceptional noise immunity. However, the necessary conversions between light-based signaling and electricity-based computing make fiber optics more expensive per device, which sometimes offsets the other advantages.

**Structured Cabling.** TIA/EIA *Standard 568-A*, Commercial Building Telecommunications Cabling Standard, permits cable planning and installation to begin before the network engineering is finalized. It supports both voice and data. The standard was written for the telecommunications industry, but cabling is gaining recognition as building infrastructure, and the standard is being applied to BAS networks as well.

TIA/EIA *Standard 568-A* specifies **star topology** (each device individually cabled to a hub) because connectivity is more robust and management is simpler than for busses and rings. If the wires in a leg are shorted, only that leg fails, making fault isolation easier; with a bus, all drops would fail.

The basic structure specified is a **backbone**, which typically runs from floor to floor within a building and possibly between buildings. The **horizontal cabling** runs between the distribution frames on each floor and the information outlets in the work areas. The maximum length of horizontal cabling recommended is 100 m.

## SPECIFYING BAS NETWORKS

Specifying a DDC system includes specifying a network. The many network technologies available deliver many performance levels at many different prices. A rational selection requires an assessment of the requirements (i.e., what information will pass between devices and at what rates). In some cases, the new equipment is required to interface with existing devices, which may limit networking options.

### Specification Method

As with other aspects of an HVAC system, an engineer must choose a method of specification. The Construction Specification Institute lists four methods. The following list relates those methods to BAS networks.

- **Descriptive.** Calls out the exact properties of the products. Properties could include communication protocols and data transfer rates.
- **Performance.** Tells what result is required and the criteria by which performance will be verified. Allows bidders to propose products to meet the need.
- **Reference standard.** Requires products to conform to an established standard. Does not oblige contractor to meet end user's needs not addressed in the standard.
- **Proprietary.** Calls out brand names. May be necessary in expansion of existing systems.

To write a descriptive network specification, the designer must know the details of network technology. To succeed with any specification, the designer must articulate the end user's needs. Typically, a performance-based specification results in the best value for the customer (Ehrlich and Pittel 1999).

### Communication Tasks

Determining network performance requirements means identifying and quantifying the communication functions required. Ehrlich and Pittel (1999) identified five basic communication tasks. To establish network requirements, the specifier must elaborate on each basic task. They are listed here along with some of the questions an engineer can use to identify the client's needs.

**Data Exchange.** What data passes between which devices? What control and optimization data passes between controllers? What update rates are required? What data does an operator need to reach? How much delay is acceptable in retrieving values? What update rates are required on "live" data displays? Within one system, the answers may vary according to the use of the data. Which set points and control parameters do operators need to adjust over the network?

**Alarms and Events.** Where do alarms originate? Where are they logged and displayed? How much delay is acceptable? Where are they acknowledged? What information must be delivered along with the alarm? (Depending on the design of the system, alarm messages may be passed over the network along with the alarms.) Where are alarm summary reports required? How and where do operators need to adjust alarm limits, etc?

**Schedules.** For the HVAC equipment that runs on schedules, where can the schedules be read? Where can they be modified?

**Trends.** Where does trend data originate? Where is it stored? How much will be transmitted? Where is it displayed and processed? Which user interfaces can set and modify trend collection parameters?

**Network Management.** What network diagnostic and maintenance functions are required at which user interfaces? Data access and security functions may be handled as network management functions.

Bushby et al. (1999) refer to the same five communication tasks as **interoperability areas** and list many more specific considerations in each area.

## APPROACHES TO INTEROPERABILITY

In the surge toward interoperability, many approaches have been proposed and applied, each with varying degrees of success under various circumstances. The field changes quickly as product lines emerge and standards develop and gain acceptance. The building automation world continues to evaluate the options project by project.

Typically, an interoperable system uses one of two approaches: standard protocols or special-purpose gateways. With a standard, the supplier is responsible for compliance with the standard; the system specifier or integrator is responsible for interoperation. With a gateway, the supplier takes responsibility for interoperation. The majority of integrated building automation systems currently depend on gateways, especially where the job requires interoperation with existing equipment. Bushby (1998) addressed this issue and some of the limitations associated with gateways. To date, interoperability by any method requires solid field engineering and capable system integration; the issues extend well beyond the selection of a communication protocol.

### Standard Protocols

Several standard protocols have been applied successfully in building automation systems. Their different characteristics make some more suited to particular tasks than others. The European Committee for Standardization (CEN) discusses characteristics of protocols appropriate for different building functions (CEN 1999). Table 2 lists some of the applicable standard protocols.

**Table 2 Some Standard Communication Protocols Applicable to BAS**

Protocol	Definition
BACnet	ASHRAE <i>Standard</i> 135
LonTalk	EIA <i>Standard</i> 709.1
PROFIBUS FMS	EN 50170:1996 Volume 2
EIB	ENV 13154-2 Annex C
EIBnet	ENV 18321-2

### Gateways and Interfaces

Rather than conforming to a published standard, a supplier can design a specific device to exchange data with another specific device. This typically requires cooperation between two manufacturers. It can be simpler and more cost-effective than for both manufacturers to conform to an agreed-upon standard. Sometimes the device is developed for one particular installation; other times it is an off-the-shelf product. In either case, the communication tasks must be carefully specified to ensure that the gateway performs as needed.

Choosing a system that supports a variety of gateways may be a way to maintain a flexible position as products and standards continue to develop.

## COMMISSIONING

A successful control system requires a proper start-up and testing, not merely the adjustment of a few parameters (set points and throttling ranges) and a few quick checks. With the services of an experienced control professional, the typical DDC system can be used effectively in the commissioning process to test and document the performance of the HVAC system. In general, the increased use of VAV systems and digital controls has increased the importance of and need for commissioning.

Design and construction specifications should include specific commissioning procedures. In addition, commissioning should be coordinated with testing, adjusting, and balancing (TAB) because each affects the other. The TAB procedure begins by checking each control device to ensure that it is installed and connected according to approved drawings. Each electrical and pneumatic connection is verified, and all interlocks to fan and pump motors and primary heating and cooling equipment are checked. *ASHRAE Guideline 1* explains how commissioning starts with project conception and continues for the life of the building.

### TUNING

The systematic tuning of controllers improves the performance of all controls and is particularly important for digital control. First, the controlled process should be controlled manually between various set points to evaluate the following questions:

- Is the process noisy (rapid fluctuations in controlled variable)?
- Is there appreciable hysteresis (backlash) in the actuator?
- How easy (or difficult) is it to maintain and change set point?
- In which operating region is the process most sensitive (highest gain)?

If the process cannot be controlled manually, the reason should be identified and corrected before the controller is tuned.

Tuning selects control parameters that determine the steady-state and transient characteristics of the control system. HVAC processes are nonlinear, and characteristics change on a seasonal basis. Controllers tuned under one operating condition may become unstable as conditions change. A well-tuned controller (1) minimizes the steady-state error for set point, (2) responds quickly to disturbances, and (3) remains stable under all operating conditions. Tuning proportional controllers is a compromise between minimizing steady-state error and maintaining margins of stability. Proportional plus integral (PI) control minimizes this compromise because the integral action reduces steady-state error, while the proportional term determines the controller's response to disturbances.

### Tuning Proportional, PI, and PID Controllers

Popular methods of determining proportional, PI, and PID controller tuning parameters include closed- and open-loop process identification methods and trial-and-error methods. Two of the most widely used techniques for tuning these controllers are ultimate oscillation and first order plus dead time. There are many optimization calculations for these two techniques, but the most widely used is the Ziegler-Nichols, which is given here.

**Ultimate Oscillation (Closed-Loop) Method.** The closed-loop method increases the gain of the controller in proportional-only mode until the equipment continuously cycles after a set point change (Figure 25, where  $K_p = 40$ ). Proportional and integral terms are then computed from the cycle's period of oscillation and the  $K_p$  value that caused cycling. The ultimate oscillation method is as follows:

1. Adjust control parameters so that all are essentially off. This corresponds to a proportion band (gain) at its maximum (minimum), the reset (repeats per minute) to maximum (minimum), and derivative to its minimum.
2. Adjust the manual output of the controller to give a measurement as close to midscale as possible.
3. Put the controller in automatic.
4. Slowly and gradually increase the proportional constant effect (this corresponds to reducing the proportional band or increasing the proportional gain) until the observed oscillations neither grow nor diminish in amplitude. If the response saturates at either extreme, start over at Step 2 to obtain a stable response. If no oscillations are observed, change the set point and try again.

5. Record the proportional band as  $PB_u$  and the period of the oscillations as  $T_u$ .
6. Use the recorded proportional band and oscillation period to calculate controller settings as follows:

Proportional only:

$$PB = 1.8(PB_u) \quad \text{percent} \quad (4)$$

Proportional plus integral (PI):

$$PB = 2.22(PB_u) \quad \text{percent} \quad (5)$$

$$T_i = 0.83T_u \quad \text{minute per repeat} \quad (6)$$

Proportional plus integral plus derivative (PID):

$$PB = 1.67(PB_u) \quad \text{percent} \quad (7)$$

$$T_i = 0.50T_u \quad \text{minute per repeat} \quad (8)$$

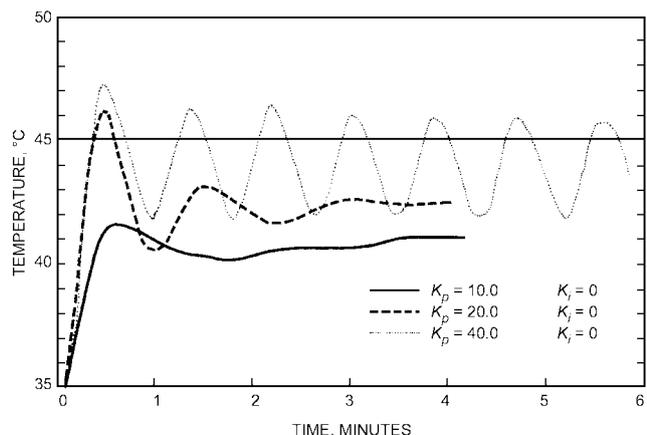

$$T_d = 0.125T_u \quad \text{minute} \quad (9)$$

**First-Order-plus-Dead-Time (Open-Loop) Method.** The open-loop method introduces a step change in input into the opened control loop. A graphical technique is used to estimate the process transfer function parameters. Proportional and integral terms are calculated from the estimated process parameters using a series of equations.

The value of the process variable must be recorded over time, and the dead time and time constant must be determined from it. This can be accomplished graphically as seen in Figure 26. The first-order-plus-dead-time method is as follows:

1. Adjust the controller manual output to give a midscale measurement.
2. Arrange for the recording of the process variable over time.
3. Move the manual output of the controller by 10% as rapidly as possible to approximate a step change.
4. Record the value of the process variable over time until it reaches a new steady state value.
5. Determine the dead time and time constant.
6. Use the dead time (TD) and time constant (TC) values to calculate PID values as follows:

$$a_{in} = \frac{\% \text{ change in controlled variable}}{\% \text{ change in control signal}} \quad (10)$$

**Fig. 25** Response of Discharge Air Temperature to Step Change in Set Points at Various Proportional Constants with No Integral Action

Proportional only:

$$PB = \text{Gain}/(\text{TC}/\text{TD}) \quad (11)$$

Proportional plus integral (PI):

$$PB = 0.9(\text{Gain})/(\text{TC}/\text{TD}) \quad (12)$$

$$T_i = 3.33(\text{TD}) \quad (13)$$

Proportional-integral-derivative (PID):

$$PB = 1.2(\text{Gain})/(\text{TC}/\text{TD}) \quad (14)$$

$$T_i = 2(\text{TD}) \quad (15)$$

$$T_d = 0.5(\text{TD}) \quad (16)$$

**Trial and Error Method.** This method involves adjusting the gain of the proportion-only controller until the desired response to a set point is observed. Conservative tuning dictates that this response should have a small initial overshoot and quickly damp to steady-state conditions. Set point changes should be made in the range where controller saturation, or output limit, is avoided. The integral term is then increased until changes in set point produce the same dynamic response as the controller under proportional control, but with the response now centered about the set point (Figure 27).

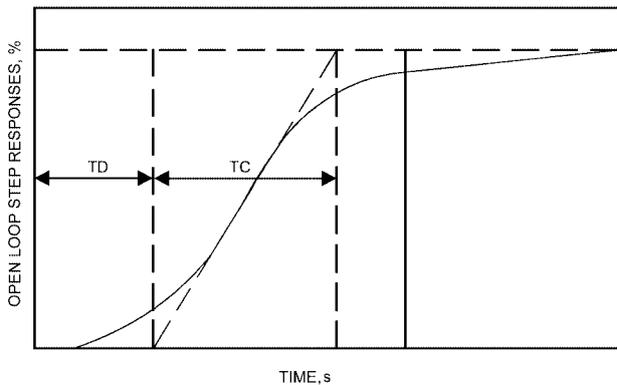

Fig. 26 Open Loop Step Response Versus Time

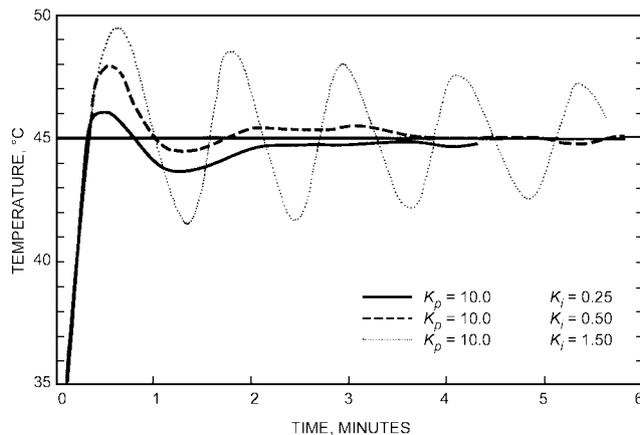

Fig. 27 Response of Discharge Air Temperature to Step Change in Set Points at Various Integral Constants with Fixed Proportional Constant

### Tuning Digital Controllers

In tuning digital controllers, additional parameters may need to be specified. The digital controller sampling interval is critical because it can introduce harmonic distortion if not selected properly. This sampling interval is usually set at the factory and may not be adjustable. A controller sampling interval of about one-half the time constant of the controlled process usually provides adequate control. Many digital control algorithms include an error dead band to eliminate unnecessary control actions when the process is near set point. Hysteresis compensation is possible with digital controllers, but it must be carefully applied because overcompensation can cause continuous cycling of the control loop.

**A**IRFLOW around buildings affects worker safety, process and building equipment operation, weather and pollution protection at inlets, and the ability to control environmental factors of temperature, humidity, air motion, and contaminants. Wind causes variable surface pressures on buildings that change intake and exhaust system flow rates, natural ventilation, infiltration and exfiltration, and interior pressures. The mean flow patterns and turbulence of wind passing over a building can cause recirculation of exhaust gases to air intakes. This chapter contains information for evaluating flow patterns, estimating wind pressures, and identifying problems caused by the effects of wind on intakes, exhausts, and equipment. Related information can be found in Chapters 12, 14, 26, and 27 of this volume; in Chapters 28, 29, 43, and 51 of the 1999 *ASHRAE Handbook—Applications*; and in Chapters 25, 30, and 36 of the 2000 *ASHRAE Handbook—Systems and Equipment*.

## FLOW PATTERNS

Buildings having even moderately complex shapes, such as L- or U-shaped structures formed by two or three rectangular blocks, can generate flow patterns too complex to generalize for design. To determine flow conditions influenced by surrounding buildings or topography, wind tunnel or water channel tests of scale models or tests of existing buildings are required. However, if a building is oriented perpendicular to the wind, it can be considered as consisting of several independent rectangular blocks. Only isolated rectangular block buildings are discussed here. Saunders and Melbourne (1979), Hosker (1984, 1985), Walker et al. (1996), and English and Fricke (1997) review the effects of nearby buildings.

The **mean speed of wind**  $U_H$  approaching a building increases with height  $H$  above the ground (Figure 1). Both the upwind velocity profile shape and its turbulence intensity strongly influence flow patterns and surface pressures (Melbourne 1979). A **stagnation zone** exists on the upwind wall. The flow separates at the sharp edges to generate **recirculating flow zones** that cover the downwind surfaces of the building (roof, sides, and leeward walls) and extend for some distance into the **wake**. If the building has sufficient length  $L$  in the windward direction, the flow will reattach to the building (Figure 2) and may generate two distinct regions of separated recirculating flow—on the building and in its wake.

Surface flow patterns on the upwind wall are largely influenced by **approach wind characteristics**. Higher wind speed at roof level causes a larger **stagnation pressure** on the upper part of the wall than near the ground, which leads to downwash on the lower one-half to two-thirds of the building (Figure 1). On the upper one-quarter to one-third of the building, the surface flow is directed upward over the roof. For a building whose height  $H$  is three or more times the width  $W$  of the upwind face, an **intermediate zone** can exist between the **upwash** and **downwash** regions, where the **surface**

**streamlines** pass horizontally around the building. The downwash on the lower surface of the upwind face separates from the building before it reaches ground level and moves upwind to form a **vortex** that can generate high velocities close to the ground. This **ground level upwind vortex** is carried around the sides of the building in a U shape (Figure 1) and is responsible for the suspension of dust and debris that can contaminate air intakes close to ground level.

For wind perpendicular to a building wall, the height  $H$  and width  $W$  of the upwind building face determine the flow patterns shown in Figure 2. According to Wilson (1979), the **scaling length**  $R$  is

$$R = B_s^{0.67} B_L^{0.33} \quad (1)$$

where

$B_s$  = smaller of upwind building face dimensions  $H$  and  $W$

$B_L$  = larger of upwind building face dimensions  $H$  and  $W$

When  $B_L$  is larger than  $8B_s$ , use  $B_L = 8B_s$  in Equation (1). For buildings with varying roof levels or with wings separated by at least a distance  $B_s$ , only the height and width of the building face below the portion of the roof in question should be used to calculate  $R$ .

**Streamline patterns** are independent of wind speed and depend mainly on building shape and upwind conditions. Because of the three-dimensional flow around a building, the shape and size of the **recirculation airflow** is not constant over the surface. The airflow reattaches closer to the upwind building face along the edges of the building than it does near the middle of the roof and sidewalls (Figure 2). The height  $H_c$  of the **recirculation region** (Figures 1 and 3) also decreases near roof edges.

The wind above the roof recirculation region is affected by the presence of the building. The flow accelerates as the **streamlines** curve upward over the roof and decelerates as they curve downward over the wake on the downwind side of the building. The distance above roof level where a building influences the flow is approximately  $1.5R$  (Figure 1). The roof pitch begins to affect flow when it exceeds about  $15^\circ$  (1:4). When roof pitch reaches  $20^\circ$  (1:3), the flow remains attached to the upwind pitched roof and produces a recirculation region downwind of the roof ridge that is larger than that for a flat roof.

The downwind wall of a building exhibits a region of low average velocity and high turbulence. Velocities near the downwind wall are typically one-quarter of those at the corresponding upwind wall location. Figures 1 through 3 show that an upward flow exists over most of the downwind walls. A flow recirculation region extends for an approximate distance  $L_r = 1.0R$  downwind.

If the angle of the approach wind is not perpendicular to the upwind face, complex flow patterns result. Strong vortices develop from the upwind edges of a roof, causing a strong downwash into the building wake above the roof. High speeds in these vortices cause large negative pressures near roof corners that can be a hazard to roof-mounted equipment during high winds. When the angle

The preparation of this chapter is assigned to TC 2.5, Air Flow Around Buildings.

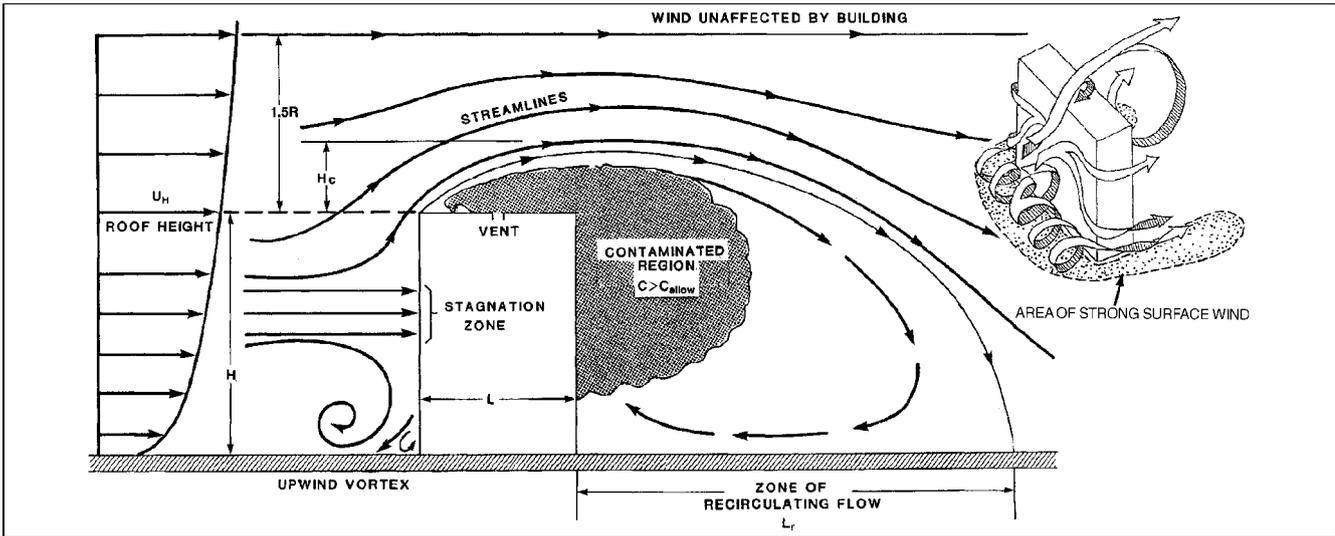

Fig. 1 Flow Patterns Around Rectangular Building

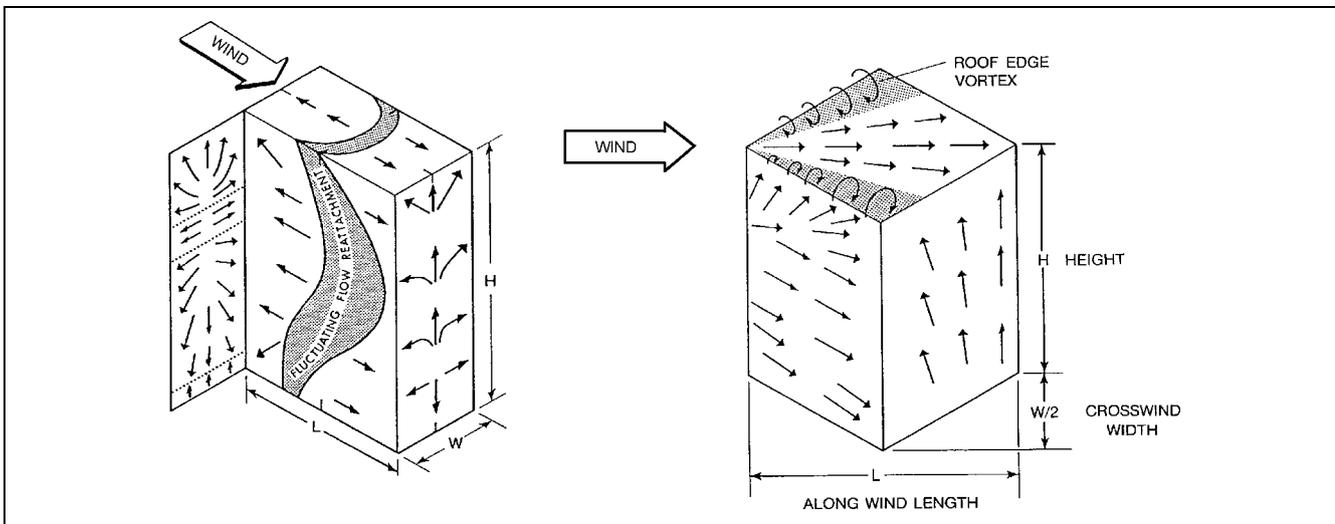

Fig. 2 Surface Flow Patterns and Building Dimensions

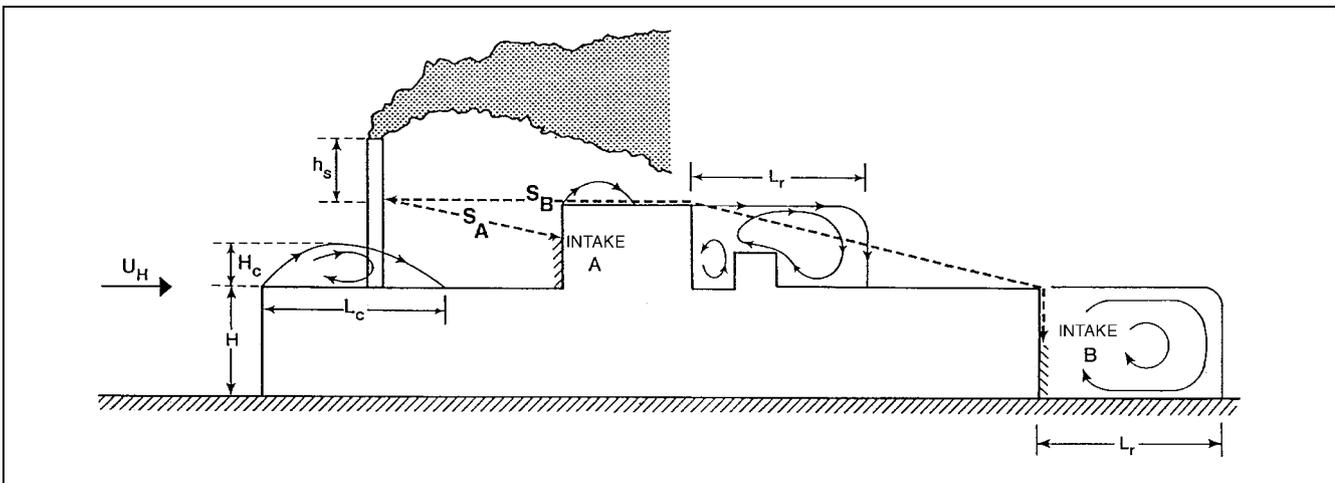

Fig. 3 Flow Recirculation Regions and Exhaust-to-Intake Stretched-String Distances  
(Wilson 1982)

between the wind direction and the upwind face of the building is less than about  $70^\circ$ , the downwash-upwash patterns on the upwind face of the building are less pronounced, as is the ground level vortex shown in Figure 1. For an approach flow angle of  $45^\circ$ , streamlines remain close to the horizontal in their passage around the sides of the building (Figure 2), except near roof level where the flow is sucked upward into the roof edge vortices (Cochran 1992).

### WIND PRESSURE ON BUILDINGS

In addition to the flow patterns described previously, the **turbulence** or **gustiness** of the approaching wind and the unsteady character of the separated flows cause surface pressures to fluctuate. The pressures discussed here are **time-averaged values**, with an averaging period of about 600 s. **Instantaneous pressures** may vary significantly above and below these averages, and **peak pressures** two or three times the mean values are possible. Although peak pressures are important with regard to structural loads, mean values are more appropriate for computing infiltration and ventilation rates. The time-averaged surface pressures are proportional to the wind velocity pressure  $p_v$  given by **Bernoulli's equation**:

$$p_v = \frac{\rho_a U_H^2}{2} \quad (2)$$

where

$$U_H = \text{approach wind speed at upwind wall height } H$$

$$\rho_a = \text{ambient (outdoor) air density}$$

The difference  $p_s$  between the pressure on the building surface and the local **outdoor atmospheric pressure** at the same level in an undisturbed wind approaching the building is

$$p_s = C_p p_v \quad (3)$$

where  $C_p$  is the local wind pressure coefficient for the building surface.

The local wind speed  $U_H$  at the top of the wall that is required for Equation (2) is estimated by applying terrain and height corrections to the hourly wind speed  $U_{met}$  from a nearby meteorological station.

**Table 1 Atmospheric Boundary Layer Parameters**

Terrain Category	Description	Exponent $a$	Layer Thickness $\delta$ , m
1	Large city centers, in which at least 50% of buildings are higher than 21 m, over a distance of at least 2000 m or 10 times the height of the structure upwind, whichever is greater	0.33	460
2	Urban and suburban areas, wooded areas, or other terrain with numerous closely spaced obstructions having the size of single-family dwellings or larger, over a distance of at least 2000 m or 10 times the height of the structure upwind, whichever is greater	0.22	370
3	Open terrain with scattered obstructions having heights generally less than 10 m, including flat open country typical of meteorological station surroundings	0.14	270
4	Flat, unobstructed areas exposed to wind flowing over water for at least 1.6 km, over a distance of 500 m or 10 times the height of the structure inland, whichever is greater	0.10	210

$U_{met}$  is generally measured in flat, open terrain. The anemometer that records  $U_{met}$  is located at a height  $H_{met}$ , usually 10 m above ground level. The hourly average wind speed  $U_H$  at wall height  $H$  in the undisturbed wind approaching a building in its local terrain (Figures 1 and 3) can be calculated from  $U_{met}$  as follows:

$$U_H = U_{met} \left( \frac{\delta_{met}}{H_{met}} \right)^{a_{met}} \left( \frac{H}{\delta} \right)^a \quad (4)$$

The wind boundary layer thickness  $\delta$  and exponent  $a$  for the local building terrain and  $a_{met}$  and  $\delta_{met}$  for the meteorological station are determined from Table 1. Typical values for meteorological stations located in flat, open terrain (Category 3 in Table 1) are  $a_{met} = 0.14$  and  $\delta_{met} = 270$  m. The values and terrain categories in Table 1 are consistent with those adopted in other engineering applications, for example ASCE *Standard 7*. Equation (4) gives the wind speed at height  $H$  above the average height of local obstacles, such as buildings and vegetation, weighted by the plan-area. At heights at or below this average obstacle height (e.g., at roof height in densely built-up suburbs), the speed depends on the geometrical arrangement of the buildings, and Equation (4) is less reliable.

An alternative mathematical description of the **atmospheric boundary layer**, which uses a logarithmic function, is given by Deaves and Harris (1978). While this model is more complicated than the power law used in Equation (4), it more closely models the real physics of the atmosphere and has been adopted by several foreign codes (e.g., SSA *Standard AS-1170* from Australia).

### Local Wind Pressure Coefficients

Values of the mean local wind pressure coefficient  $C_p$  used in Equation (3) depend on building shape, wind direction, and the influence of nearby buildings, vegetation, and terrain features. Accurate determination of  $C_p$  can be obtained only from wind tunnel model tests of the specific site and building. Ventilation rate calculations for single, unshielded rectangular buildings can be reasonably estimated using existing wind tunnel data. Many wind load codes (e.g., ASCE 7-98, AS-1170) give mean pressure coefficients for common building shapes.

Figure 4 shows pressure coefficients for walls of a tall rectangular cross section building (high-rise) sited in urban terrain (Davenport and Hui 1982). Figure 5 shows pressure coefficients for walls of a low-rise building (Holmes 1986). Generally, high-rise buildings are those where the height  $H$  is more than three times the crosswind width  $W$ . For  $H > 3W$ , use Figure 4, and for  $H < 3W$ , use Figure 5. At a wind angle  $\theta = 0^\circ$  (e.g., wind perpendicular to the face in question), the pressure coefficients are positive, and their magnitudes decrease near the sides and the top as the flow velocities increase.

As can be seen in Figure 4,  $C_p$  generally increases with height, which reflects the increasing velocity pressure in the approach flow as wind speed increases with height. As the wind direction moves off normal ( $\theta = 0^\circ$ ), the region of maximum pressure occurs closer to the upwind edge (B in Figure 4) of the building. At a wind angle of  $\theta = 45^\circ$ , the pressures become negative at the downwind edge (A in Figure 4) of the front face. At some angle  $\theta$  between  $60^\circ$  and  $75^\circ$ , the pressures become negative over the whole front face. For  $\theta = 90^\circ$ , maximum suction (negative) pressure occurs near the upwind edge (B in Figure 4) of the building side and then recovers towards  $C_p = 0$  towards the downwind edge (A in Figure 4). The degree of this recovery depends on the length of the side in relation to the width  $W$  of the structure. For wind angles larger than  $\theta = 100^\circ$ , the side is completely within the separated flow of the wake and the spatial variations in pressure over the face are not as great. The average pressure on a face is positive for wind angles from  $\theta = 0^\circ$  to almost  $60^\circ$  and negative (suction) for  $\theta = 60^\circ$  to  $180^\circ$ .

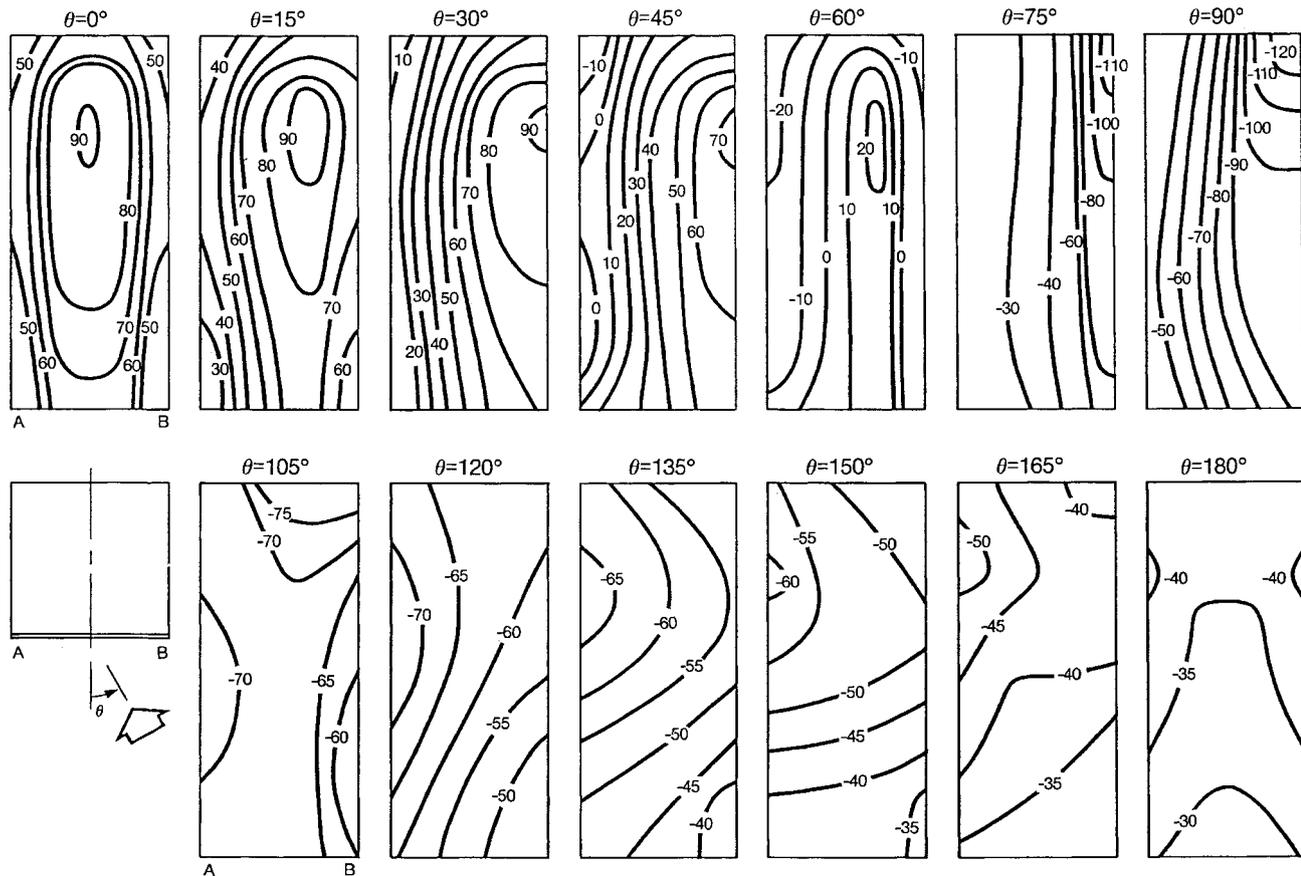

Fig. 4 Local Pressure Coefficients ( $C_p \times 100$ ) for Tall Building with Varying Wind Direction (Davenport and Hui 1982)

A similar pattern of behavior in the wall pressure coefficients for a low-rise building is shown in Figure 5. Here, the recovery from the strong suction with distance from the upwind edge is more rapid.

### Surface Averaged Wall Pressures

Surface averaged pressure coefficients may be used in determining ventilation and/or infiltration rates, as discussed in Chapter 26. Figure 6 shows the surface pressure coefficient  $C_s$  averaged over a complete wall of a low-rise building (Swami and Chandra 1987). The figure also includes the values calculated from the pressure distributions shown in Figure 5. Similar results for a tall building are shown in Figure 7 (Akins et al. 1979).

The wind-induced indoor-outdoor pressure difference is found using the coefficient  $C_{p(in-out)}$ , which is defined as

$$C_{p(in-out)} = C_p - C_{in} \quad (5)$$

where  $C_{in}$  is the internal wind-induced pressure coefficient. For uniformly distributed air leakage sites in all the walls,  $C_{in}$  is about  $-0.2$ .

### Roof Pressures

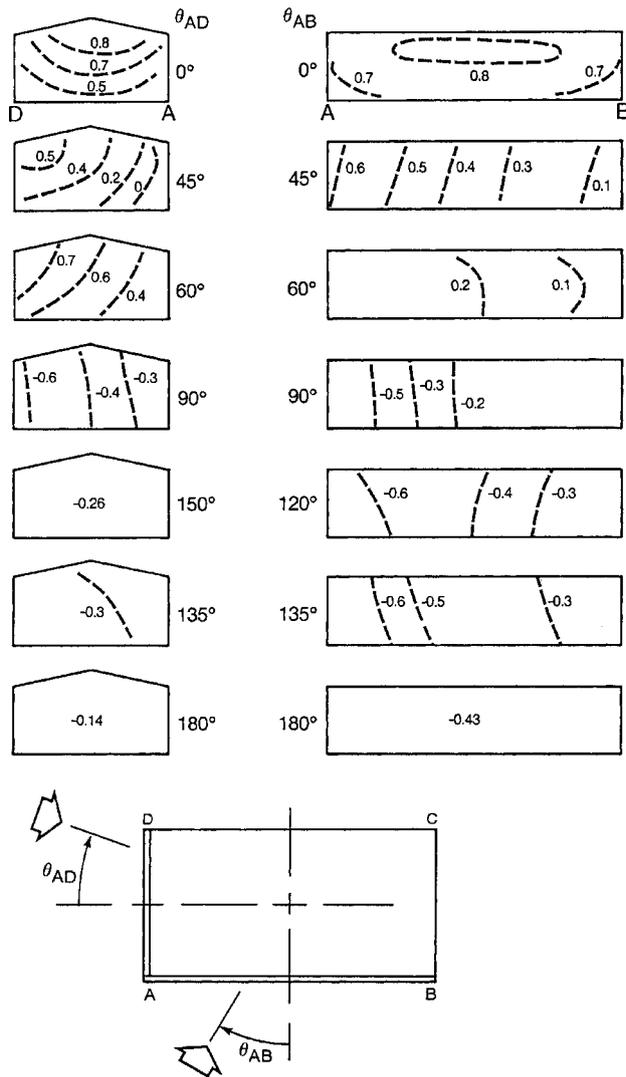

Surface pressures on the roof of a low-rise building depend strongly on roof slope. Figure 8 shows typical distributions for a wind direction normal to a side of the building. For very low slopes, the pressures are negative over the whole roof surface. The magnitude is greatest within the separated flow zone near the leading edge and recovers toward the free stream pressure downwind of the edge. For steeper slopes, the pressures are weakly positive

on the windward slope and negative within the separated flow over the leeward slope. With a wind angle of about  $45^\circ$ , the vortices originating at the leading corner of a roof with a low slope can induce very large localized negative pressures (Figure 2). A similar vortex forms on the downwind side of a leading ridge end on a steep roof. A discussion of roof corner vortices and how to disrupt their influence may be found in Cochran and Cermak (1992) and Cochran and English (1997), respectively. Figure 9 shows the average pressure coefficient over the roof of a tall building (Akins et al. 1979).

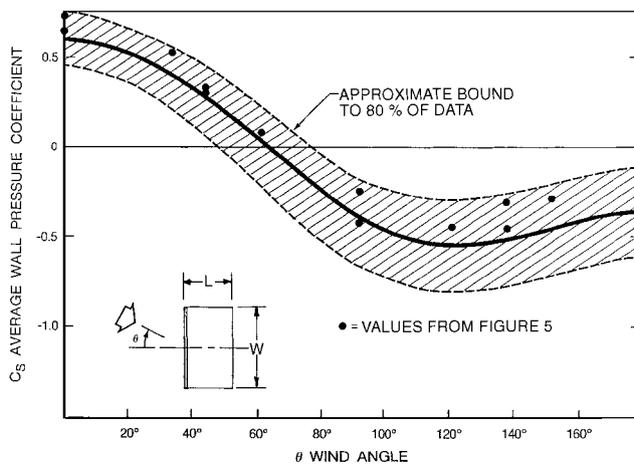

The section on Combining Driving Forces in Chapter 26 discusses the effect of stack pressure and mechanical systems on infiltration and ventilation in a building.

### Interference and Shielding Effects on Pressures

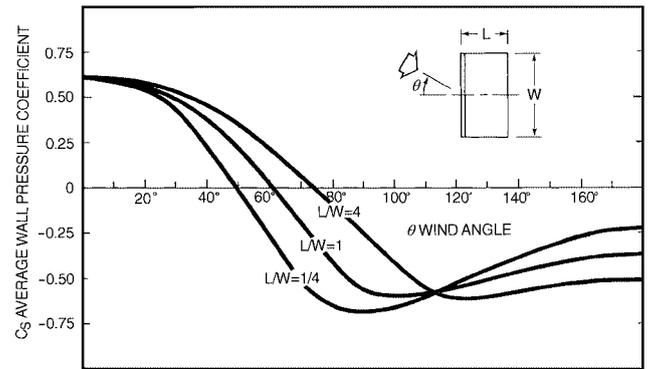

Nearby structures strongly influence surface pressures on both high- and low-rise buildings. These effects are very strong for spacing-to-height ratios less than five, where the distributions of pressure shown in Figures 4 through 9 do not apply. Although the effect of shielding is for low-rise buildings still significant at larger spacing, it is largely accounted for by the reduction in  $p_v$  with increased terrain roughness. Saunders and Melbourne (1979), Sherman and Grimsrud (1980), Bailey and Kwok (1985), and Walker et al. (1996) discuss interference. English and Fricke (1997) discuss shielding through use of an interference index, while Walker et al. (1996) present a wind shadow model for predicting shelter factors. Chapter 26 gives shielding classes for air infiltration and ventilation applications.

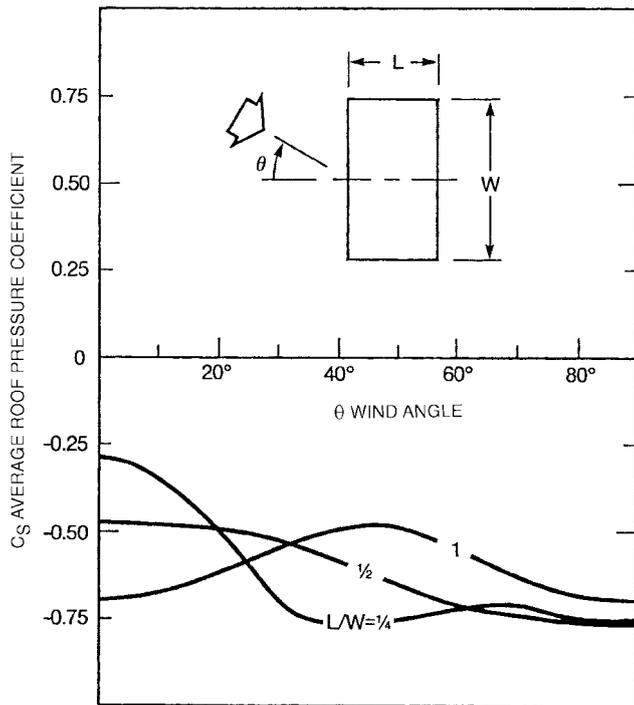

**Fig. 8** Local Roof Pressure Coefficients for Roof of Low-Rise Buildings (Holmes 1986)

**Sources of Wind Data**

In order to design for the effects of airflow around buildings, wind speed and direction frequency data should be obtained. The simplest forms of wind data are tables or charts of climatic normals, which give hourly average wind speeds, prevailing wind directions, and peak gust wind speeds for each month of the year. This information can be found in sources such as *The Weather Almanac* (Bair 1992) and the *Climatic Atlas of the United States* (DOC 1968). Climatic design information, including wind speed at various frequencies of occurrence, is included in Chapter 27. A current source, which contains information on wind speed and direction frequencies, is the *International Station Meteorological Climatic Summary* available in CD-ROM format from the National Climatic Data Center (NCDC) in Asheville, North Carolina. Where more detailed information is required, digital records of hourly winds and other meteorological parameters are available (on magnetic tape or CD-ROM) from the NCDC for stations throughout the world. Most countries also have weather services that provide data. For example, in Canada, the Atmospheric Environment Service in Downsview, Ontario, provides hourly meteorological data and summaries.

When an hourly wind speed  $U_{met}$  at a specified probability level (e.g., the wind speed that is exceeded 1% of the time) is desired, but only the average annual wind speed  $U_{annual}$  is available for a given meteorological station,  $U_{met}$  may be estimated from Table 2. The

**Fig. 9 Surface Averaged Roof Pressure Coefficients for Tall Buildings**  
(Akins et al. 1979)

**Table 2 Typical Relationship of Hourly Wind Speed  $U_{met}$  to Annual Average Wind Speed  $U_{annual}$**

Percentage of Hourly Values That Exceed $U_{met}$	Wind Speed Ratio $U_{met}/U_{annual}$
90%	$0.2 \pm 0.1$
75%	$0.5 \pm 0.1$
50%	$0.8 \pm 0.1$
25%	$1.2 \pm 0.15$
10%	$1.6 \pm 0.2$
5%	$1.9 \pm 0.3$
1%	$2.5 \pm 0.4$

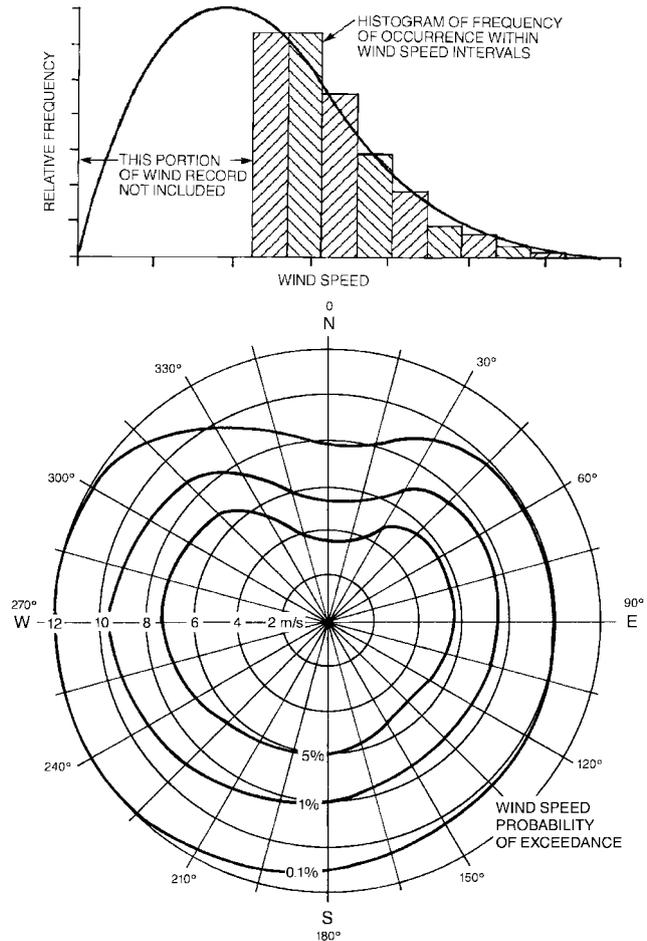

ratios  $U_{met}/U_{annual}$  are based on long-term data from 24 weather stations widely distributed over North America. At these stations,  $U_{met}$  ranges from 3.1 to 6.3 m/s. The uncertainty ranges listed in Table 2 are one standard deviation of the wind speed ratios. The following example demonstrates the use of Table 2.

**Example 1.** The wind speed  $U_{met}$  that is exceeded 1% of the time (88 hours per year) is needed for a building pressure or exhaust dilution calculation. If  $U_{annual} = 4$  m/s, find  $U_{met}$ .

**Solution:** From Table 2, the wind speed  $U_{met}$  exceeded 1% of the time is  $2.5 \pm 0.4$  times  $U_{annual}$ . For  $U_{annual} = 4$  m/s,  $U_{met}$  is 10 m/s with an uncertainty range of 8 to 12 m/s at one standard deviation.

Using a single prevailing wind direction for design can cause serious errors. For any set of wind direction frequencies, one direction always has a somewhat higher frequency of occurrence. Thus, it is often called the prevailing wind, even though winds from other directions may be almost as frequent.

When using long-term meteorological records, check the anemometer location history as the instrument may have been relocated and its height varied. This can affect its directional exposure and the recorded wind speeds. Equation (4) can be used to correct wind data

**Fig. 10 Frequency Distribution of Wind Speed and Direction**

collected at different mounting heights. Poor anemometer exposure due to obstructions or mounting on top of a building cannot be easily corrected, and the records for that period should be deleted.

If an estimate of the probability of an extreme wind speed outside the range of the recorded values at a site is required, the observations may be fit to an appropriate probability distribution (e.g., a Weibull distribution) and the particular probabilities calculated from the resulting function (see Figure 10). This process is usually repeated for each of 16 wind directions (e.g., 22.5° intervals).

Where estimates at extremely low probability (high wind speed) are required, curve fitting at the tail of the probability distribution is very important and may require special statistical techniques applicable to extreme values (see Chapter 27). Building codes for wind loading on structures contain information on estimating extreme wind conditions. For ventilation applications, extreme winds are usually not required, and the 99 percentile limit can be accurately estimated from airport data averaged over less than 10 years.

**Estimating Wind at Sites Remote from Recording Stations**

Many building sites are located far from the nearest long-term wind recording site, which is usually an airport meteorological station. To estimate wind conditions at such sites, the terrain surrounding both the anemometer site and the building site should be checked. In the simplest case of flat or slightly undulating terrain with few obstructions extending for large distances around and between the anemometer site and building site, recorded wind data

can be assumed to be representative of that at the building site. Wind direction occurrence frequency at a building site should be inferred from airport data only if the two locations are on the same terrain, with no terrain features that could alter wind direction between them.

In cases where the only significant difference between the anemometer site terrain and the building site terrain is surface roughness, the mean wind speed can be adjusted using Equation (4) and Table 1, to yield approximate wind velocities at the building site. Wind direction frequencies at the site are assumed to be the same as at the recording station.

In using Equation (4), cases may be encountered where, for a given wind direction, the terrain upwind of either the building site or the recording site does not fall into just one of the categories in Table 1. The terrain immediately upwind of the site may fall into one category, while that somewhat further upwind falls into a different category. For example, at a downtown airport the terrain may be flat and open (Category 3) immediately around the recording instrument, but urban or suburban (Category 2) a relatively short distance away. This difference in terrains also occurs when a building site or recording site is in an urban area near open water or at the edge of town. In these cases, the suggested approach is to use the terrain category that is most representative of the average condition within approximately 1.6 km upwind of the site (Deaves 1981). If the average condition is somewhere between two categories described in Table 1, the values of  $a$  and  $\delta$  can be interpolated from those given in the table.

A rough guideline is that only wind speeds  $U_H$  of 4 m/s or greater at the building site can be estimated reliably using Equation (4) and Table 2 for building and meteorological stations in different terrain categories.

In addition to changes in **surface roughness**, several other factors are important in causing the wind speed and direction at a building site to differ from values recorded at a nearby meteorological station. Wind speeds for buildings on hillcrests or in valleys where the wind is accelerated or channeled can be 1.5 times higher than meteorological station data. Wind speeds for buildings sheltered in the lee of hills and escarpments can be reduced to 0.5 times the values at nearby flat meteorological station terrain.

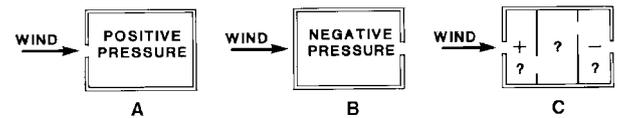

**Solar heating** of valley slopes can cause light winds of 1 to 4 m/s to occur as warm air flows upslope. At night, radiant cooling of the ground can produce similar speeds as cold air drains downslope. In general, rolling terrain experiences a smaller fraction of low speeds than nearly flat terrain.

When the wind is calm or light in the rural area surrounding a city, urban air tends to rise in a buoyant plume over the city center. This rising air, heated by man-made sources and higher solar absorption in the city, is replaced by air pushed toward the city center from the edges. In this way, the **urban heat island** can produce light wind speeds and direction frequencies significantly different than those at a rural meteorological station.

In more **complex terrain**, both wind speed and direction may be significantly different from those at the distant recording site. In these cases, building site wind conditions should not be estimated from airport data. Options are either to establish an on-site wind recording station or to commission a detailed wind tunnel correlation study between the building site and long-term meteorological station wind observations.

## WIND EFFECTS ON SYSTEM OPERATION

With few exceptions, building intakes and exhausts cannot be located or oriented such that a prevailing wind ensures ventilation and air-conditioning system operation. Wind can assist or hinder inlet and exhaust fans, depending on their positions on the building, but even in locations with a predominant wind direction, the ventilating system must perform adequately for all other directions. To

### Pressures in Building Resulting from Wind:

- With upstream opening only, pressure is positive.
- With downstream opening only, pressure is negative.
- Pressures are as shown if openings are equal in shape and area. With unequal openings, pressures can be either negative or positive in each space, depending on relative areas of openings.

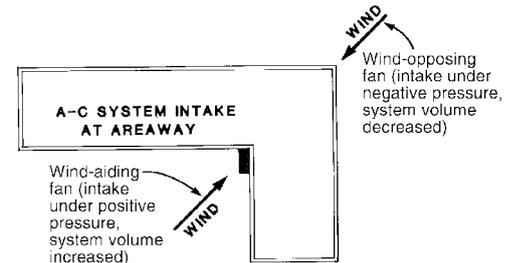

Fig. 11 Sensitivity of System Volume to Locations of Building Openings, Intakes, and Exhausts

avoid variability in system flow rates, use Figures 4, 5, and 8 as a guide to placing inlets and exhausts in locations where the surface pressure coefficients do not vary greatly with the wind direction.

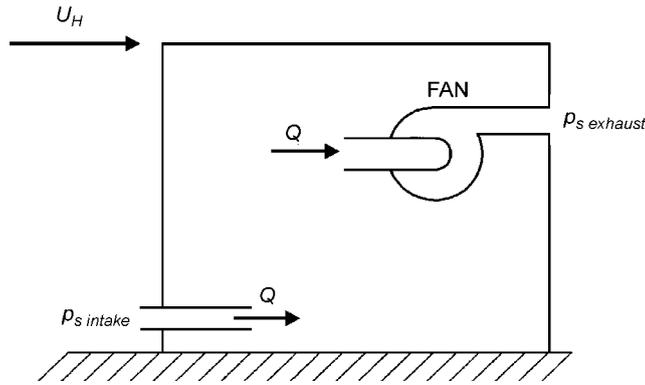

**Cooling towers** and similar equipment should be oriented to take advantage of prevailing wind directions, based on careful study of the meteorological data and flow patterns on the building for the area and time of year involved.

A building with only upwind openings is under a positive pressure (Figure 11). Building pressures are negative when there are only downwind openings. A building with internal partitions and openings is under various pressures depending on the relative sizes of the openings and the wind direction. With larger openings on the windward face, the building interior tends to remain under positive pressure; the reverse is also true (see Figures 4 through 9, and Chapter 26).

**Airflow through a wall opening** results from differential pressures, which may exceed 125 Pa during high winds. Supply and exhaust systems, openings, dampers, louvers, doors, and windows make the building flow conditions too complex for direct calculation. Iterative calculations are required because of the nonlinear dependence of volume flow rate on the differential pressure across an opening. Several **multizone airflow models** are available for these iterative calculations (Walton 1997, Feustel and Dieris 1992). The opening and closing of doors and windows by building occupants add further complications. In determining  $C_{p(in-out)}$  from Equation (5), the wind direction is more important than the position of an opening on a wall, as shown in Figures 4 and 5. Please see Chapter 26 for more detailed information regarding wind effects on building ventilation, including natural and mechanical systems.

## Natural and Mechanical Ventilation

With **natural ventilation**, wind may augment, impede, or sometimes reverse the airflow through a building. For large roof areas (Figure 2), the wind can reattach to the roof downwind of the leading edge. Thus, any natural ventilation openings could see either a positive or negative pressure, dependent on wind speed and wind direction. Positive pressure existing where negative pressures were expected could lead to a reversal of expected natural ventilation. These reversals can be avoided by using stacks, continuous roof ventilators, or other exhaust devices in which the flow is augmented by the wind.

**Fig. 12 Intake and Exhaust Pressures on Exhaust Fan in Single Zone Building**

**Mechanical ventilation** is also affected by wind conditions. A low-pressure wall exhaust fan (12 to 25 Pa) can suffer drastic reduction in capacity. Flow can be reversed by wind pressures on windward walls, or its rate can be increased substantially when subjected to negative pressures on the lee and other sides. Clarke (1967), when measuring medium-pressure air-conditioning systems (250 to 370 Pa), found flow rate changes of 25% for wind blowing into intakes on an L-shaped building compared to wind blowing away from intakes. Such changes in flow rate can cause noise at the supply outlets and drafts in the space served.

For mechanical systems, the wind can be thought of as an additional pressure source in series with a system fan, either assisting or opposing it (Houlihan 1965). Where system stability is essential, the supply and exhaust systems must be designed for high pressures (about 750 to 1000 Pa) or must use devices to actively minimize unacceptable variations in flow rate. To conserve energy, the system pressure selected should be consistent with system needs.

Quantitative estimates of the effect of wind on a mechanical ventilation system can be made by using the pressure coefficients in Figures 4 through 9 to calculate the wind pressure on air intakes and exhausts. A simple worst-case estimate is to assume a system with 100% makeup air supplied by a single intake and exhausted from a single outlet. The building is treated as a single zone, with an exhaust-only fan as shown in Figure 12. This will overestimate the effect of wind on system volume flow.

Combining Equations (2) and (3), the wind pressures at the air intake and exhaust locations are

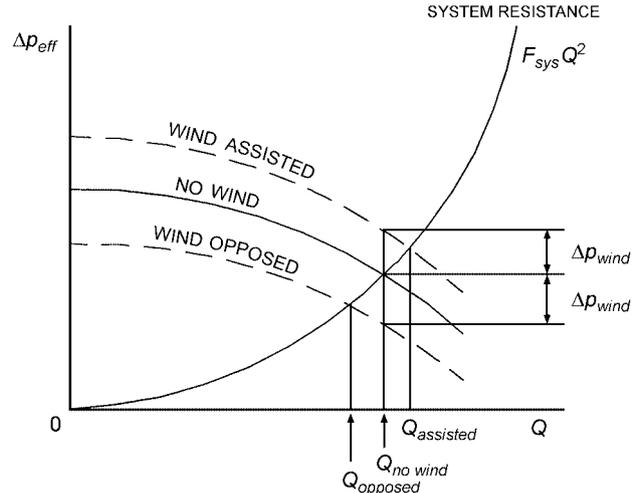

$$P_{s \text{ intake}} = C_{p \text{ intake}} \frac{\rho_a U_h^2}{2} \quad (6)$$

$$P_{s \text{ exhaust}} = C_{p \text{ exhaust}} \frac{\rho_a U_h^2}{2} \quad (7)$$

For the single zone building shown in Figure 12, a worst-case estimate of wind effect neglects any flow resistance in the intake grill and duct, making the interior building pressure  $p_{\text{interior}}$  equal to the outdoor wind pressure on the intake,  $p_{\text{interior}} = P_{s \text{ intake}}$ . Then, with all the system flow resistance assigned to the exhaust duct in Figure 12, and a pressure rise  $\Delta p_{\text{fan}}$  across the fan, the pressure drop from outdoor intake to outdoor exhaust yields

$$(P_{s \text{ intake}} - P_{s \text{ exhaust}}) + \Delta p_{\text{fan}} = F_{\text{sys}} \frac{\rho Q^2}{A_L^2} \quad (8)$$

where  $F_{\text{sys}}$  is the system flow resistance,  $A_L$  is the flow leakage area, and  $Q$  is the system volume flow rate. This result shows that for the

**Fig. 13 Effect of Wind-Assisted and Wind-Opposed Flow**

worst case estimate, the wind induced pressure difference simply adds to or subtracts from the fan pressure rise. With the inlet and exhaust pressures from Equations (6) and (7), the effective fan pressure rise  $\Delta p_{\text{fan eff}}$  is

$$\Delta p_{\text{fan eff}} = \Delta p_{\text{fan}} + \Delta p_{\text{wind}} \quad (9)$$

where 
$$\Delta p_{\text{wind}} = (C_{p \text{ intake}} - C_{p \text{ exhaust}}) \frac{\rho_a U_h^2}{2} \quad (10)$$

The fan will be wind-assisted when  $C_{p \text{ intake}} > C_{p \text{ exhaust}}$  and wind-opposed when the wind direction changes causing  $C_{p \text{ intake}} < C_{p \text{ exhaust}}$ . The effect of wind-assisted and wind-opposed pressure differences is illustrated in Figure 13.

**Example 2.** Make a worst-case estimate for the effect of wind on the supply fan for a low-rise building with a height  $H = 15$  m located in a city suburb. Use the hourly average wind speed that will be exceeded only 1% of the time and assume an annual hourly average speed of  $U_{\text{annual}} = 4$  m/s measured on a meteorological tower at height  $H_{\text{met}} = 10$  m at a nearby airport. Outdoor air density is  $\rho_a = 1.2$  kg/m<sup>3</sup>.

**Solution:** From Table 2 the wind speed that is exceeded only 1% of the hours each year will be a factor of  $2.5 \pm 0.4$  higher than the annual average of 4 m/s, so the 1% maximum speed at the airport meteorological station is

$$U_{\text{met}} = 2.5 \times 4 = 10 \text{ m/s}$$

From Table 1, the airport meteorological station is in terrain category 3, with a boundary layer thickness  $\delta_{\text{met}} = 270$  m and a velocity profile exponent  $a = 0.14$ . The suburban location of the building places it in terrain category 2 in Table 2, with  $\delta = 370$  m and  $a = 0.22$ . Using Equation (4) to determine the wind speed  $U_H$  at roof level  $H = 15$  m in the flow approaching the building,

$$U_H = 10 \left( \frac{270}{10} \right)^{0.14} \left( \frac{15}{370} \right)^{0.22} = 7.8 \text{ m/s}$$

A worst-case estimate of wind effect must assume intake and exhaust locations on the building that produce the largest difference ( $C_{p \text{ intake}} - C_{p \text{ exhaust}}$ ) in Equations (9) and (10). From Figure 5, the largest difference occurs for the intake on the upwind wall AB and the exhaust on the downwind wall CD, with a wind angle  $\theta_{\text{AB}} = 0^\circ$ . For this worst case,  $C_{p \text{ intake}} = +0.8$  on the upwind wall and  $C_{p \text{ exhaust}} = -0.43$  on the downwind wall. Using these coefficients in Equations (9) and (10) to evaluate the effective fan pressure  $\Delta p_{\text{fan eff}}$ ,

$$\begin{aligned}\Delta p_{fan\ eff} &= \Delta p_{fan} + [0.8 - (-0.43)] \frac{1.2(7.8)^2}{2} \\ &= \Delta p_{fan} + 44.9\ \text{Pa}\end{aligned}$$

This wind-assisted hourly averaged pressure is exceeded only 1% of the time (88 hours per year). When the wind direction reverses, the outlet will be on the upwind wall and the inlet on the downwind wall, producing wind-opposed flow, changing the sign from +44.9 Pa to -44.9 Pa. The importance of these pressures depends on their size relative to the fan pressure rise  $\Delta p_{fan}$ , as shown in Figure 13.

### Building Pressure Balance

Proper **building pressure balance** avoids flow conditions that make doors hard to open, cause drafts, and prevent the confinement of contaminants to specific areas. Although the supply and exhaust systems in an area may be in nominal balance, wind can upset this balance, not only because of the changes in fan capacity but also by superimposing infiltrated or exfiltrated air or both on the area. These effects can make it impossible to control environmental conditions. Where building balance and minimum infiltration are important, consider the following:

- Design HVAC system with pressure adequate to minimize wind effects
- Include controls to regulate flow rate or pressure or both
- Separate supply and exhaust systems to serve each building area requiring control or balance
- Effect of doors (possibly self-closing) or double-door air locks to noncontrolled adjacent areas, particularly outside doors
- Sealing of windows and other leakage sources and closing natural ventilation openings.

System volume and pressure control is described in Chapter 45 of the 1999 *ASHRAE Handbook—Applications*. This control is not possible without adequate system pressure for both the supply and exhaust systems to overcome wind effects. Such a control system may require fan inlet or discharge dampers, fan speed or pitch control, or both.

### Fume Hood Operation

Wind effects can interfere with safe fume hood operation. Supply volume variations can cause both disturbances at hood faces and a lack of adequate fume hood makeup air. Volume surges, due to fluctuating wind pressures acting on the exhaust system, can cause momentary inadequate hood exhaust. If highly toxic contaminants are involved, surging is unacceptable. The system should be designed to eliminate this condition. On low-pressure exhaust systems, it is impossible to test the hoods under wind-induced, surging conditions. These systems should be tested during calm conditions for safe flow into the hood faces; they should be rechecked by smoke tests during high wind conditions. For more information, see Chapter 13 of the 1999 *ASHRAE Handbook—Applications*.

### Minimizing Wind Effect on System Volume

Wind effect can be reduced by careful selection of inlet and exhaust locations. Because wall surfaces are subject to a wide variety of positive and negative pressures, wall openings should be avoided when possible. When they are required, wall openings should be away from corners formed by building wings (Figure 11). Mechanical ventilation systems should operate at a pressure high enough to minimize wind effect. **Low-pressure systems** and **propeller exhaust fans** should not be used with wall openings unless their ventilation rates are small or they are used in noncritical services such as storage areas.

Although roof air intakes in flow recirculation zones best minimize wind effect on system flow rates, current and future air quality

in these zones must be considered. These locations should be avoided if a source of contamination exists or may be added in the future. The best area is near the middle of the roof because the negative pressure there is small and least affected by changes in wind direction (Figure 8). Avoid the edges of the roof and walls, where large pressure fluctuations occur. Either vertical or horizontal (mushroom) openings can be used. On roofs having large areas, where the intake may be outside the roof recirculation zone, mushroom or 180° gooseneck designs minimize impact pressure from wind flow. The 135° gooseneck that is frequently used or vertical louvered openings are undesirable for this purpose or for rain protection.

Heated air or contaminants should be exhausted vertically through stacks, above the roof recirculation zone. Horizontal, louvered (45° down), and 135° gooseneck discharges are undesirable, even for heat removal systems, because of their sensitivity to wind effects. A 180° gooseneck for systems handling hot air may be undesirable because of air impingement on tar and felt roofs. Vertically discharging stacks located in a recirculation region (except near a wall) have the advantage of being subjected only to negative pressure created by wind flow over the tip of the stack. See Chapter 43 of the 1999 *ASHRAE Handbook—Applications* for information regarding stack design.

## BUILDING INTERNAL PRESSURE AND FLOW CONTROL

In air-conditioning and ventilation systems for a building containing airborne contaminants, the correct internal airflow is toward the contaminated areas. Airflow direction is maintained by controlling pressure differentials between spaces. In a laboratory building, for example, peripheral rooms such as offices and conference rooms are maintained at a positive pressure, and laboratories at a negative pressure, both with reference to corridor pressure. Pressure differentials between spaces are normally obtained by balancing the air-conditioning and ventilation supply system airflows in the spaces in conjunction with the exhaust systems in the laboratories, with differential pressure instrumentation to control the airflow. Chapter 45 of the 1999 *ASHRAE Handbook—Applications* has further information on controls.

Airflow in corridors is sometimes controlled by an outdoor reference probe that senses static pressure at doorways and air intakes. The differential pressure measured between the corridor and the outside may then signal a controller to increase or decrease airflow to the corridor. Unfortunately, it is difficult to locate an external probe where it will sense the proper external static pressure. High wind velocity and resulting pressure changes around entrances can cause great variations in pressure. Care must be taken to ensure that the probe is unaffected by wind pressure.

The pressure differential for a room adjacent to a corridor can be controlled using the corridor pressure as the reference. Outdoor pressure cannot control pressure differentials within rooms, even during periods of relatively constant wind velocity (wind-induced pressure). A single pressure sensor can measure the outside pressure at one point only and may not be representative of pressures elsewhere.

## SCALE MODEL SIMULATION AND TESTING

For many routine design applications, the flow patterns and wind pressures can be estimated using the data and equations presented in the previous sections. Exhaust dilution for simple building geometries located in homogeneous terrain environments (e.g., no larger buildings or terrain features nearby) can be estimated using the data and equations presented in the previous sections and in Chapter 43 of the 1999 *ASHRAE Handbook—Applications*. However, in critical applications, such as where health and safety are of concern, **physical modeling** or **full-scale field evaluations** may be required

to obtain more accurate estimates. Measurements on small-scale models in wind tunnels or water channels can provide information for design prior to construction. These measurements can also be used as an economical method of performance evaluation for existing facilities. Full-scale testing is not generally useful in the initial design phase because of the time and expense required to obtain meaningful information. On the other hand, full-scale testing is useful for verifying data derived from physical modeling and for planning remedial changes to improve existing facilities.

Detailed accounts of physical modeling, field measurements and applications, and engineering problems resulting from atmospheric flow around buildings are available in the proceedings of conferences on wind engineering (see the section on Bibliography).

The wind tunnel is the main tool used to assess and understand the airflow around buildings. Water channels or tanks can also be used. However, the water methods are more difficult to implement and give only qualitative results for some cases. Models of buildings, complexes, and the local surrounding topography are constructed and tested in a simulated turbulent atmospheric boundary layer. The airflow, wind pressures, snow loads, structural response, or pollutant concentrations can then be measured directly by properly scaling the wind, building geometry, and exhaust flow characteristics. Weil et al. (1981), Petersen (1987a), and Dagleish (1975) found generally good agreement between the results of wind tunnel simulations and corresponding full-scale data. Cochran (1992) and Cochran and Cermak (1992) have found good agreement between the model- and full-scale measurements of low-rise architectural aerodynamics and cladding pressures, respectively.

### Similarity Requirements

Physical modeling is most appropriate for applications involving small-scale atmospheric motions, such as recirculation of exhaust downwind of a laboratory, wind loads on structures, wind speeds around building clusters, snow loads on roofs, and airflow over hills or other terrain features. Winds associated with tornadoes, thunderstorms, and large-scale atmospheric motion cannot currently be simulated accurately.

Snyder (1981) gives guidelines for fluid modeling of atmospheric diffusion. This report contains explicit directions and should be used whenever designing wind tunnel studies to assess concentration levels due to air pollutants. ASCE *Standard 7* and ASCE *Manual of Practice 67* (ASCE 1999) also provide guidance when wind tunnels are used for evaluating wind effects on structures.

A complete and exact simulation of the airflow over buildings and the resulting concentration or pressure distributions cannot be achieved in a physical model. However, this is not a serious limitation. Cermak (1971, 1975, 1976a,b), Snyder (1981), and Petersen (1987a,b) found that an accurate simulation of the transport and dispersion of laboratory exhaust can be achieved if the following criteria are met in the model and full scale:

1. Match exhaust velocity to wind speed ratios,  $V_e/U_H$ .
2. Match exhaust to ambient air density ratios,  $\rho_e/\rho_a$ .
3. Match exhaust Froude numbers.  $Fr^2 = \rho_a V_e^2 / [(\rho_e - \rho_a)gd]$ , where  $d$  is the effective exhaust stack diameter.
4. Ensure fully turbulent stack gas flow by ensuring stack flow Reynolds number ( $Re_s = V_e d/\nu$ ) is greater than 2000 (where  $\nu$  is the kinematic viscosity of ambient (outdoor) air), or by placing an obstruction inside the stack to enhance turbulence.
5. Ensure fully turbulent wind flow.
6. Scale all dimensions and roughness by a common factor.
7. Match atmospheric stability by the bulk Richardson number (Cermak 1975). For most applications related to airflow around buildings, neutral stratification is assumed, and no Richardson number matching is required.
8. Match mean velocity and turbulence distributions in the wind.

9. Ensure building wind Reynolds number ( $Re_b = U_H R/\nu$ ) is greater than 11 000 for sharp-edged structures, or greater than 90 000 for round-edged structures.
10. Ensure less than 5% blockage of wind tunnel cross section.

For wind speeds, flow patterns, or pressure distributions around buildings, only Conditions 5 through 10 are necessary. Usually, each wind tunnel study requires a detailed assessment to determine the appropriate parameters to match in the model and full scale.

In wind tunnel simulations of exhaust gas recirculation, the buoyancy of the exhaust gas (Condition 3) is often not modeled. This allows using a high wind tunnel speed or a smaller model to achieve high enough Reynolds numbers (Conditions 4, 5, and 9). Neglecting buoyancy is justified if the density of building exhaust air is within 10% of the ambient (outdoor) air. Also, critical minimum dilution  $D_{crit}$  occurs at wind speeds high enough to produce a well-mixed, neutrally stable atmosphere, allowing stability matching (Condition 7) to be neglected (see Chapter 43 of the 1999 *ASHRAE Handbook—Applications* for discussion of  $D_{crit}$ ). Omission of Conditions 3 and 7 simplifies the test procedure considerably, reducing both testing time and cost.

Buoyancy should be properly simulated for high-temperature exhausts such as boilers and diesel generators. Equality of model and prototype Froude numbers (Condition 3) requires tunnel speeds of less than 0.5 m/s for testing. However, greater tunnel speeds may be needed to meet the minimum building Reynolds number requirement (Condition 4).

### Wind Simulation Facilities

Boundary layer wind tunnels are required for conducting most wind studies. The wind tunnel test section should be long enough so that a deep boundary layer that slowly changes with downwind distance can be established upwind of the model building.

Other important wind tunnel characteristics include the width and height of the test section, range of wind speeds, roof adjustability, and temperature control. Larger models can be used in tunnels that are wider and taller, which, in turn, give better measurement resolution. Model blockage effects can be minimized by an adjustable roof height. Temperature control of the tunnel surface and airflow is required when atmospheric conditions other than neutral stability are to be simulated. Boundary layer characteristics appropriate for the site are established by using roughness elements on the tunnel floor that produce mean velocity and turbulence intensity profiles characteristic of the full scale.

Water can also be used for the modeling fluid if an appropriate flow facility is available. Flow facilities may be in the form of a tunnel, tank, or open channel. Water tanks with a free surface ranging in size up to that of a wind tunnel test section have been used by towing a model (upside down) through the nonflowing fluid. Stable stratification can be obtained by adding a salt solution. This technique (towed model in a tank) does not permit development of a boundary layer and therefore yields only approximate, qualitative information on flow around buildings. Water channels can be designed to develop thick turbulent boundary layers similar to those developed in the wind tunnel. One advantage of such a flow system is ease of flow visualization, but this is offset by a greater difficulty in developing the correct turbulence structure and the measurement of flow variables and concentrations.

### Designing Model Test Programs

The first step in planning a test program is selection of the model length scale. Choice of this scale depends on cross-sectional dimensions of the test section, dimensions of the buildings to be included in the model, and/or topographic features and thickness of the simulated atmospheric boundary layer. Typical geometric scales range from about 120:1 to 1000:1.

Because a large model size is desirable to meet minimum Reynolds number and Froude number requirements, a wide test section is advantageous. In general, the model at any section should be small compared to the test section area so that blockage is less than 5% (Melbourne 1982).

The test program must include specifications of the meteorological variables to be considered. These include wind direction, wind speed, and thermal stability. Data taken at the nearest meteorological station should be reviewed to obtain a realistic assessment of wind climate for a particular site. Ordinarily, local winds around a building, pressures, and/or concentrations are measured for 16 wind directions (e.g., 22.5° intervals). This is easily accomplished by mounting the building model and its nearby surroundings on a turntable. More than 16 wind directions are required for highly toxic exhausts or for finding peak fluctuating pressures on a building. If only local wind information and pressures are of interest, testing at one wind speed with neutral stability is sufficient.

### SYMBOLS

- $A_L$  = flow leakage area, Equation (8), m<sup>2</sup>  
 $a$  = exponent in power law wind speed profile for local building terrain, Equation (4) and Table 1, dimensionless  
 $a_{met}$  = exponent  $a$  for the meteorological station, Equation (4) and Table 1, dimensionless  
 $B_L$  = larger of the two upwind building face dimensions  $H$  and  $W$ , Equation (1), m  
 $B_s$  = smaller of the two upwind building face dimensions  $H$  and  $W$ , Equation (1), m  
 $C_{p\ in}$  = internal wind-induced pressure coefficient, Equation (5), dimensionless  
 $C_p$  = local wind pressure coefficient for building surface, Equation (3), dimensionless  
 $C_{p\ (in-out)}$  = difference between outdoor and indoor pressure coefficients, Equation (5), dimensionless  
 $C_s$  = surface-averaged pressure coefficient, Figure 6, dimensionless  
 $d$  = effective stack diameter, m  
 $D_{crit}$  = critical dilution factor at roof level for uncapped vertical exhaust at critical wind speed (see Chapter 43 of the 1999 *ASHRAE Handbook—Applications*), dimensionless  
 $Fr$  = Froude number, dimensionless  
 $F_{sys}$  = system flow resistance, Equation (8), dimensionless  
 $g$  = acceleration of gravity, 9.8 m/s<sup>2</sup>  
 $H$  = wall height above ground on upwind building face, Equation (4) and Figure 1, m  
 $H_c$  = maximum height above roof level of upwind roof edge flow recirculation zone, Figures 1 and 3, m  
 $H_{met}$  = height of anemometer at meteorological station, Equation (4), m  
 $L$  = length of building in wind direction, Figures 1 and 2, m  
 $L_c$  = length of upwind roof edge recirculation zone, Figure 3, m  
 $L_r$  = length of flow recirculation zone behind rooftop obstacle or building, Figures 1 and 3, m  
 $p_s$  = wind pressure difference between exterior building surface and local ambient (outdoor) atmospheric pressure at the same elevation in an undisturbed approach wind, Equation (3), Pa  
 $p_v$  = wind velocity pressure at roof level, Equation (2), Pa  
 $Q$  = volumetric flow rate, Equation (8), m<sup>3</sup>/s  
 $R$  = scaling length for roof flow patterns, Equation (1), m  
 $Re_b$  = building Reynolds number, dimensionless  
 $Re_s$  = stack flow Reynolds number, dimensionless  
 $U_{annual}$  = annual average of hourly wind speeds  $U_{met}$ , Table 2, m/s  
 $U_H$  = mean wind speed at height  $H$  of upwind wall in undisturbed flow approaching building, Equation (2) and Figures 1, 2 and 3, m/s  
 $U_{met}$  = meteorological station hourly wind speed, measured at height  $H_{met}$  above ground in smooth terrain, Equation (4) and Table 2, m/s  
 $V_e$  = exhaust face velocity, m/s  
 $W$  = width of upwind building face, Figure 2, m  
 $\delta$  = fully developed atmospheric boundary layer thickness, Equation (4) and Table 1, m  
 $\delta_{met}$  = atmospheric boundary layer thickness at meteorological station, Equation (4) and Table 1, m  
 $\Delta p_{fan}$  = pressure rise across fan, Equation (8), Pa

$\Delta p_{fan\ eff}$  = effective pressure rise across fan, Equation (9), Pa

$\Delta p_{wind}$  = wind-induced pressure, Equations (9) and (10), Pa

$\nu$  = kinematic viscosity of ambient (outdoor) air, m<sup>2</sup>/s

$\rho_a$  = ambient (outdoor) air density, Equation (2), kg/m<sup>3</sup>

$\rho_e$  = density of exhaust gas mixture, kg/m<sup>3</sup>

$\theta$  = angle between perpendicular line from upwind building face and wind direction, Figures 4 through 7, degrees

**B**UILDINGS and facilities of various types may be heated, ventilated, air conditioned, and refrigerated—using systems and equipment designed for that purpose and using the site energy forms commonly available—without concern for the original **energy resources** from whence those energy forms came. Since the energy used in buildings and facilities comprises a significant amount of the total energy used for all purposes, and since the use of this energy has an impact on energy resources, ASHRAE recognizes the “effect of its technology on the environment and natural resources to protect the welfare of posterity” (ASHRAE 1990).

Many governmental agencies regulate energy conservation legislation for obtaining building permits (Conover 1984). The application of specific values to building energy use situations has a considerable effect on the selection of HVAC&R systems and equipment and how they are applied.

## CHARACTERISTICS OF ENERGY AND ENERGY RESOURCE FORMS

The HVAC&R industry deals with energy forms as they occur on or arrive at a building site. Generally, these forms are fossil fuels (natural gas, oil, and coal) and electricity. Solar energy and wind energy are also available at most sites, as is low-level geothermal energy (**energy source** for heat pumps). Direct-use (high-temperature) geothermal energy is available at some. These are the prime forms of energy used to power or heat the improvements on a site.

### Forms of On-Site Energy

Fossil fuels and electricity are commodities that are usually metered or measured for payment by the facility owner or operator. On the other hand, solar or wind, each of which might be considered a dispersed energy form in its natural state (i.e., requiring neither central processing nor a distribution network) costs nothing for the commodity itself, but does incur cost for the means to make use of it. High-temperature geothermal energy, which is not universally available, may or may not be a sold commodity, depending on the particular locale and local regulations. Chapter 31 of the 1999 *ASHRAE Handbook—Applications* has more information on geothermal energy.

Some prime on-site energy forms require further processing or conversion into other forms more directly suited for the particular systems and equipment needed in a building or facility. For instance, natural gas or oil is burned in a boiler to produce steam or hot water, a form of thermal energy which is then distributed to various use points (such as heating coils in air-handling systems,

unit heaters, convectors, fin-tube elements, steam-powered cooling units, humidifiers, and kitchen equipment) throughout the building. Although electricity is not converted in form on-site, it is nevertheless used in a variety of ways, including lighting, running motors for fans and pumps, powering electronic equipment and office machinery, and space heating. While the methods and efficiencies with which these processes take place fall within the scope of the HVAC&R designer, the process by which a prime energy source arrives at a given facility site is not under direct control of the professional. On-site energy choices, if available, may be controlled by the designer based in part on the present and future availability of the associated resource commodities.

The basic energy source for heating may be natural gas, oil, coal, or electricity. Cooling may be produced by electricity, thermal energy, or natural gas. If electricity is generated on-site, the generator may be turned by an engine using natural gas or oil, or by a turbine using steam or gas directly.

The term **energy source** refers to on-site energy in the form in which it arrives at or occurs on a site (e.g., electricity, gas, oil, or coal). **Energy resource** refers to the raw energy, which (1) is extracted from the earth (wellhead or mine-mouth), (2) is used in the generation of the energy source delivered to a building site (coal used to generate electricity), or (3) occurs naturally and is available at a site (solar, wind, or geothermal energy).

### Nonrenewable and Renewable Energy Resources

From the standpoint of energy conservation, energy resources may be classified in two broad categories: (1) nonrenewable (or discontinuous) resources, which have definite, although sometimes unknown, limitations; and (2) renewable (or continuous) resources, which can generally be freely used without depletion or have the potential to renew in a reasonable period. Resources used most in industrialized countries, both now and in the past, are nonrenewable (Gleeson 1951).

#### Nonrenewable resources of energy include

- Coal
- Crude oil
- Natural gas
- Uranium-235 (atomic energy)

#### Renewable resources of energy include

- Hydropower
- Solar
- Wind
- Earth heat (geothermal)
- Biomass (wood, wood wastes, and municipal solid waste)
- Tidal power

The preparation of this chapter is assigned to TC 1.10, Energy Resources.

- Ocean thermal
- Atmosphere or large body of water (as used by the heat pump)
- Crops (for alcohol production)

### Characteristics of Fossil Fuels and Electricity

Most on-site energy for buildings in developed countries involves electricity and fossil fuels as the prime on-site energy sources. Both fossil fuels and electricity can be described in terms of their energy content (joules). This implies that the two energy forms are comparable and that an equivalence can be established. In reality, however, fossil fuels and electricity are only comparable in energy terms when they are used to generate heat. Fossil fuels, for example, cannot directly drive motors or energize light bulbs. Conversely, electricity gives off heat as a byproduct regardless of whether it is used for running a motor or lighting a light bulb, and regardless of whether that heat is needed. Thus, electricity and fossil fuels have different characteristics, uses, and capabilities aside from any differences relating to their derivation.

Beyond the building site, further differences between these energy forms may be observed, such as methods of extraction, transformation, transportation, and delivery, and the characteristics of the resource itself. Natural gas arrives at the site in virtually the same form in which it was extracted from the earth. Oil is processed (distilled) before arriving at the site; having been extracted as crude oil, it arrives at a given site as, for example, No. 2 oil or diesel fuel. Electricity is created (converted) from a different energy form, often a fossil fuel, which itself may first be converted to a thermal form. The total electricity conversion, or generation, process includes energy losses governed largely by the laws of thermodynamics.

Fuel cells, which are used only on a small scale, convert a fossil fuel to electricity by chemical means.

Fossil fuels undergo a conversion process by combustion (oxidation) and heat transfer to thermal energy in the form of steam or hot water. The conversion equipment used is a boiler or a furnace in lieu of a generator, and conversion usually occurs on a project site rather than off-site. (District heating is an exception.) Inefficiencies of the fossil fuel conversion occur on-site, while the inefficiencies of most electricity generation occur off-site, before the electricity arrives at the building site. (Cogeneration is an exception.)

## SUSTAINABILITY

As the world has increased in population and developed technologically, the consequences of uncontrolled growth are being recognized: pollution, toxic waste creation, waste disposal, global climate change, ozone depletion, deforestation, and resource depletion. Continuation of current trends without implementation of mitigation strategies will adversely impact the ability of the earth's ecosystem to regenerate and remain viable for future generations.

The built environment contributes significantly to these effects, accounting for one-sixth of the world's fresh water use, one-quarter of its wood harvest, and two-fifths of its material and energy flows. Other impacts include air quality, transportation patterns, and watersheds. The resources required to serve this sector are considerable—and many of them are diminishing (Gottfried 1996).

The building industry's recognition of the impacts of its activities is changing the way it approaches the design, construction, operation, maintenance, reuse, and demolition of what it creates—namely, toward addressing the environmental and long-term economic consequences of its actions. While this **sustainable design ethic**—or **sustainability**—covers things beyond the purview of the heating, ventilating, air-conditioning (HVAC) industry alone, design for the efficient use of energy resources would certainly be a key element of any sustainable design, and it is certainly very much under the control of the HVAC designer.

The following section of this chapter provides guidance in achieving a sustainable design.

## DESIGNING FOR EFFECTIVE ENERGY RESOURCE UTILIZATION

The preponderance of energy used in buildings is from nonrenewable energy resources, the cost of which historically has not included considerations of replenishment or environmental impact. As a result, energy use resulting from many building system designs has been based primarily upon economic considerations, which unfortunately are biased to encourage more rather than less use.

As these resources become less readily available and practitioners look toward the use of more exotic and replenishable sources, the need to operate buildings effectively using less energy becomes paramount. Extensive study since the mid-1970s has revealed that significant reductions in building energy use can be achieved by the application of some fundamental principles.

### THE ENERGY ETHIC: RESOURCE CONSERVATION DESIGN PRINCIPLES

The basic approach to achieving an energy-efficient design is reducing loads (power), improving transport systems, and providing efficient components and “intelligent” controls. Design concepts applicable to successful energy-efficient design include understanding the relationship between *energy* and *power*, maintaining *simplicity*, using *self-imposed budgets*, and applying *energy-smart design practices*.

#### Energy and Power

From the standpoint of economics, more energy-efficient systems need not be more expensive than less efficient systems; quite the opposite is true. This observation results from the simple relationship between energy and power in which power is simply the time rate of energy use (or, conversely, energy is power times time). Power, in turn, describes the size of something. For example, power terms such as watt or kilowatt might be used in expressing the size of a motor, chiller, boiler, or transformer. Of course, the smaller something is, the less it costs; then, other things being equal, as the unit of a smaller size operates over time, it consumes less energy. Thus, in designing for energy efficiency, the first objective is always to reduce the power required to the bare minimum necessary to provide the desired performance—starting with the building's heating and cooling loads (a power term, in kW) and working through the various systems and subsystems.

#### Simplicity

Complex designs to save energy will seldom function in the manner intended unless the systems are continually managed and operated by technically skilled individuals. Experience in designing energy-efficient systems has shown that achieving energy-efficient performance over a long period of time with a complex system is seldom achievable; further, when these complex systems are operated by minimally skilled individuals, not only are energy efficiencies not achieved but performance suffers as well. The majority of the techniques discussed subsequently can be implemented with a high degree of simplicity.

#### Self-Imposed Budgets

Just as an engineer must work to a cost budget with most designs, self-imposed power budgets can be similarly helpful in achieving an energy-efficient design. Examples of some budgets that designers have set for themselves for office buildings in a typical midwestern or northeastern temperate climate are

Installed lighting (overall)	14 W/m <sup>2</sup>
Space sensible cooling	63 W/m <sup>2</sup>
Space heating load	47 W/m <sup>2</sup>

Fan system pressure	1 kPa
Air circulation rates	5 L/s·m <sup>2</sup>
Electric power (overall)	48 W/m <sup>2</sup>
Thermal power (overall)	95 W/m <sup>2</sup>
Hydronic system pressure	210 kPa
Water chiller (water cooled)	0.17 kW/kW cooling
Chilled water system auxiliaries	0.04 kW/kW cooling
Unitary air-conditioning systems	0.28 kW/kW cooling
Annual electric energy	970 MJ/m <sup>2</sup> ·yr
Annual thermal energy	205 kJ/m <sup>2</sup> ·yr·K·day

Then, as the building and its systems are designed, all decisions become interactive as the result of each subsystem's power or energy performance being continually compared to the "budget."

### THE ENERGY-EFFICIENT DESIGN PROCESS

Energy efficiency should be considered at the beginning of the building design process because energy-efficient features are most easily and effectively incorporated at that time. Active participation of all members of the design team—including owner, architect, engineer, and often the contractor—should be sought early in the design process. Consider building attributes such as building function, form, orientation, window/wall ratio, and HVAC system types early as each has major energy implications.

Address a building's energy requirements in the following sequence:

1. **Minimize the impact of the building's functional requirements** by analyzing how the building relates to its external environment. Advocate changes in building form, aspect ratio, and other attributes that reduce, redistribute, or delay (shift) loads. The load calculation should be interactive so that the impact of those factors can be seen immediately.
2. **Minimize loads** by analyzing the external and internal loads imposed on the building energy-using subsystems, both for peak-load and part-load conditions.
3. **Maximize subsystem efficiency** by analyzing the diversified energy and power requirements of each energy-using subsystem serving the building's functional requirements. Consider static and dynamic efficiencies of energy conversion and energy transport subsystems, and consider opportunities to reclaim, redistribute, and store energy for later use.
4. **Study alternate ways to integrate subsystems** into the building by considering both power and time components of energy use. Identify, evaluate, and design each of these components to control overall design energy consumption. The following should be considered when integrating major building subsystems:
  - Address more than one problem at time when developing design solutions, and make maximum use of building components incorporated for nonenergy reasons (e.g., windows, structural mass).
  - Examine design solutions that consider time (i.e., *when* the energy use takes place) since sufficient energy may already be present from the environment (e.g., solar heat, night cooling) or from internal equipment (e.g., lights, computers) but available at times different from when needed. Thus, active (e.g., heat pumps with water tanks) and passive (e.g., building mass) storage techniques may be considered.
  - Examine design solutions that consider the anticipated use of space. For example, in large but relatively unoccupied spaces, task or zone lighting may be considered. Transporting excess energy (light and heat) from locations of production and availability to locations of need may be considered instead of purchasing additional energy.
  - Never reject waste energy at temperatures usable for space conditioning or other practical purposes without calculating the economic benefit of energy recovery or treatment for reuse.

- Consider or advocate design solutions that provide more comfortable surface temperatures or increase the availability of controlled daylight in buildings where human occupancy is a primary function.
- Use easily understood design solutions as they have a greater probability of use by building operators and occupants.
- Where the functional requirements of a building are known to be likely to change over time, design the installed environmental system to adapt to meet those changes that can be anticipated as well as to provide flexibility in meeting future changes in use, occupancy, or other functions.

### BUILDING ENERGY USE ELEMENTS

#### Envelope

- Control thermal conductivity through the use of insulation (including movable insulation), thermal mass, and/or phase change thermal storage at levels that minimize net heating and cooling loads on a time-integrated (annual) basis.
- Minimize unintentional or uncontrolled thermal bridges, and consider them in energy-related calculations because they can radically alter the conductivity of a building envelope. Examples include wall studs, balconies, ledges, and extensions of building slabs.
- Minimize infiltration so that it approaches zero. (An exception is when infiltration provides the sole means of ventilation such as in small residential units.) This effort will minimize fan energy consumption in pressurized buildings during occupied periods and minimize heat loss (or unwanted heat gain in warm climates) during unoccupied periods. An additional benefit of a tight envelope in warm humid climates is that it improves indoor air quality. Infiltration should be reduced through design details that enhance the fit and integrity of building envelope joints in ways that may be readily achieved during construction. This includes infiltration control by caulking, weatherstripping, vestibule doors, and/or revolving doors—with construction meeting accepted specifications.
- Consider operable windows to allow occupant-controlled ventilation. If this is done, the design of the building's mechanical system must be carefully executed to minimize unnecessary HVAC energy consumption, and building operators and occupants should be cautioned about how operable windows may be improperly used.
- Strive to maintain occupant radiant comfort regardless of whether the building envelope is designed to be a static or dynamic membrane. Opaque surfaces should be designed so that the average inside surface temperatures remain within 3 K of room temperature in the coldest anticipated weather (i.e., winter design conditions) and so that the coldest inside surface will remain within 14 K of room temperature (but always above the indoor dew point). In a building with time-varying internal heat generation, consider thermal mass for controlling radiant comfort. In the perimeter zone, thermal mass is more effective when it is positioned inside the envelope's insulation.
- Effective control of solar radiation is critical to the design of energy-efficient buildings due to the high level of internal heat production already present in most commercial buildings. In some climates, lighting energy consumption savings due to daylighting techniques can be greater than the heating and cooling energy penalties that result from additional glazed surface area required, provided that the building envelope is properly designed for daylighting and that lighting controls are installed and used. (In other climates, such net savings may not be realized.) Daylighting designs are most effective if direct solar beam radiation is not allowed to cause glare in building spaces.
- Design the transparent portions of the building envelope to prevent solar radiant gain above that necessary for effective daylighting

and solar heating. On south-facing facades, the use of low shading coefficients is generally not as effective as external physical shading devices in achieving this balance. Low-emissivity, high-visible-transmittance glazings may be considered for effective control of radiant heat gains and losses. For shading control, designers may consider the judicious use of vegetation to block excess gain year-round or seasonally, depending on the plant species chosen.

### Lighting

Lighting is both a major energy end use in commercial buildings (especially office buildings) and a major contributor to internal loads by increasing cooling loads and decreasing heating loads. Therefore, it is important to produce (or advocate) a design that meets the lighting functional criteria of the space as well as one that minimizes energy use. The *IESNA Lighting Handbook* (IESNA 2000) recommends illuminance levels for visual tasks and surrounding lighted areas. Principles of energy-conserving design within that context are described as follows:

- Energy use is determined by the lighting load (demand power) and its duration of use (time). Minimize the actual demand load rather than just the apparent connected load. Control the load rather than just area switching, if switching may adversely affect the quality of the luminous environment.
- Consider daylighting along with the proper use of controls to reduce costs of electric lighting. Design should be sensitive to window glare, sudden changes in luminances, and general user acceptance of daylighting controls. Window treatment (blinds, drapes, and shades) and glazing should be carefully selected to control direct solar penetration and luminance extremes while still maintaining the view and daylight penetration.
- Design the lighting system so that illumination required for tasks is primarily limited to the location of the task and comes from a direction that minimizes direct glare and veiling reflections on the task. When the design concept is based on nonuniform illuminance, walls should be a light to medium color or otherwise illuminated to provide visual comfort. In densely occupied work spaces, uniform distribution of general lighting may be most appropriate. Where necessary, provide supplementary task illumination. General ambient illumination should not be lower than a third of the luminance required for the task; this will help maintain visually comfortable luminance ratios.
- Use local task lighting to accommodate the need for higher lighting levels due to task visual difficulty, glare, intermittently changing requirements, or individual visual differences (poor or aging eyesight).
- Group similar activities so that high illuminance or special lighting for particular tasks can be localized in certain rooms or areas, and so that less efficient fixtures required for critical glare control do not have to be installed uniformly when they are only required sparsely.
- Use lighting controls throughout so lighting is available when and where it is needed, but not wasted during those times when tasks being performed are less critical or spaces are not fully occupied. Also consider user acceptance of control strategies to maximize energy saving.
- Limit use of lower efficiency lamps (such as incandescent) to those applications where their color, lumens, or distribution characteristics cannot be duplicated by other sources. Due to their lower efficiency, limit the use of extended service incandescent lamps to those applications where fixtures are difficult to reach and/or maintenance costs for replacing lamps would be excessive.
- Continue carrying through the lighting design process as the building's interior design is occurring. Reduced light absorption may be achieved by using lighter finishes, particularly on ceilings, walls, and partitions.

### Other Loads

- Minimize the thermal impact of equipment and appliances on HVAC systems by the use of hoods, radiation shields, or other confining techniques, and by using controls to ensure that such equipment is turned off when not needed. In addition, locate, where practical, major heat-generating equipment where it can balance other heat losses. Computer centers or kitchen areas usually have separate, dedicated HVAC equipment. In addition, consider heat recovery for this equipment.
- Use storage techniques to level or distribute loads that vary on a time or spatial basis to allow operation of a device at maximum (often full-load) efficiency.

### HVAC System Design

- Consider separate HVAC systems to serve areas expected to operate on widely differing operating schedules or design conditions. For instance, systems serving office areas should generally be separate from those serving retail areas.
- Arrange systems so that spaces with relatively constant and weather-independent loads are served with systems separate from those serving perimeter spaces. Areas with special temperature or humidity requirements, such as computer rooms, should be served by systems separate from those serving areas that require comfort heating and cooling only. Alternatively, these areas may be served by supplementary or auxiliary systems.
- Sequence the supply of zone cooling and heating to prevent the simultaneous operation of heating and cooling systems for the same space to the extent possible. Where this is not possible due to ventilation, humidity control, or air circulation requirements, reduce air quantities as much as possible before incorporating reheating, recooling, or mixing hot and cold airstreams. As an example, if reheat is necessary to provide dehumidification and prevent overcooling, *only* the ventilation air need be so treated rather than the entire recirculated air quantity. Finally, reset the supply air temperature up to the extent possible to reduce reheating, recooling, or mixing losses.
- Provide controls to allow operation in an occupied mode and an unoccupied mode. In the occupied mode, controls may provide for a gradually changing control point as system demands change from cooling to heating. In the unoccupied mode, ventilation and exhaust systems should be shut off if possible, and comfort heating and cooling systems should be shut off except to maintain space conditions ready for the next occupancy cycle.
- In geographical areas where diurnal temperature swings and humidity levels permit, consider the judicious coupling of air distribution and building structural mass to allow nighttime cooling to reduce the requirement for daytime mechanical cooling.
- High ventilation rates, where required for special applications, can impose enormous heating and cooling loads on HVAC equipment. In these cases, consider recirculation of filtered and cleaned air to the extent possible rather than 100% outside air. Also, consider preheating outside air with reclaimed heat from other sources.

### HVAC Equipment Selection

- To allow for HVAC equipment operation at the highest efficiencies, match conversion devices to load increments, and sequence the operation of modules. Oversized or large-scale systems should never serve small seasonal loads (e.g., a large heating boiler serving a summer service water-heated load). Include specific low-load units and auxiliaries where prolonged use at minimal capacities is expected.
- Select the most efficient (or highest COP) equipment practical at both design and reduced capacity (part-load) operating conditions.

- In the selection of large power devices such as chillers (including their auxiliary energy burdens), seriously consider life-cycle purchasing techniques.
- Keep fluid temperatures for heating equipment devices as low as practical and for cooling equipment as high as practical, while still meeting loads and minimizing flow quantities.

### Energy Transport Systems

Energy should be transported by the most energy-efficient means possible. The following options are listed in order of efficiency from the lowest energy transport burden (most efficient) to the highest (least efficient):

1. Electric wire or fuel pipe
2. Two-phase fluid pipe (steam or refrigerant)
3. Single-phase liquid/fluid pipe (water, glycol, etc.)
4. Air duct

Select a distribution system that complements other parameters such as control strategies, storage capabilities, conversion efficiency, and utilization efficiency.

The following are specific design techniques that may be applied to thermal energy transport systems:

#### Steam Systems

- Include provisions for seasonal or non-use shutdown.
- Minimize the venting of steam and ingestion of air with the design directed toward full-vapor performance.
- Avoid subcooling, if practical.
- Return condensate to boilers or source devices at the highest possible temperature.

#### Hydronic Systems

- Minimize flow quantity by designing for the maximum practical temperature range ( $\Delta t$ ).
- Vary flow quantity with load where possible.
- Design for the lowest practical pressure rise (or drop).
- Provide OPERATING and IDLE control modes.
- When locating equipment, identify the critical pressure path and size runs for the minimum reasonable pressure drop.

#### Air Systems

- Minimize airflow by careful load analysis and an effective distribution system. If the application allows, the supply air quantity should vary with the sensible load (i.e., VAV systems). Hold the fan pressure requirement to the lowest practical value and avoid using fan pressure as a source for control power.
- Provide NORMAL and IDLE control modes for the fan systems as well as the psychrometric systems.
- Keep duct runs as short as possible, and keep runs on the critical pressure path sized for minimum practical pressure drop.

#### Power Distribution

- Size transformers and generating units as close as possible to the actual anticipated load (i.e., avoid oversizing to minimize fixed thermal losses).
- Consider distribution of electric power at the highest practical voltage and load selection at the maximum power factor consistent with safety.
- Consider tenant submetering in commercial and multifamily buildings as a cost-effective energy conservation measure. (A large portion of energy use in tenant facilities occurs simply because there is no economic incentive to conserve.)

#### Domestic Hot Water Systems

- Choose shower heads that provide and maintain user comfort and energy savings. They should not have removable flow-restricting inserts to meet flow limitation requirements.

- Consider point-of-use water heaters where their use will reduce energy consumption and annual energy cost.
- Consider using storage facilitate heat recovery when the heat to be recovered is out of phase with the demand for hot water or when energy use for water heating can be shifted to take advantage of off-peak rates.

### Controls

- A well-designed digital control system provides information to managers and operators as well as to the data processor that serves as the intelligent controller. Include the energy saving concepts discussed previously throughout the operating sequences and control logic. However, energy conservation should not be sought at the expense of inadequate performance; in a well-designed system, these two parameters are compatible.

### ON-SITE ENERGY/ENERGY RESOURCE RELATIONSHIPS

An HVAC&R designer sooner or later must consider the use of one or more forms of prime energy. Most likely, these would be fossil fuels and electricity, although installations are sometimes designed using a single energy source (e.g., only a fossil fuel or only electricity).

Solar energy normally impinges on the site (and on the facilities to be put there), so it has an impact on the energy consumption of the facility. The designer must account for this impact and may have to decide whether to make active use of solar energy. Other naturally occurring and distributed renewable forms such as wind power and earth heat (if available) might also be considered.

The designer should be aware of the relationship between on-site energy sources and raw energy resources—including how these resources are used and what they are used for. The relationship between energy sources and energy resources involves two parts: (1) quantifying the energy resource units expended and (2) considering the societal impact of the depletion of one energy resource (caused by on-site energy use) with respect to others. The following two sections describe those parts in more specific terms.

#### Quantifiable Relationships

As on-site energy sources are consumed, a corresponding amount of resources are consumed to produce that on-site energy. For instance, for every volume of No. 2 oil consumed by a boiler at a building site, some greater volume of crude oil is extracted from the earth. On leaving the well, the crude oil is transported and processed into its final form, perhaps stored, and then transported to the site where it will be used.

Even though gas requires no significant processing, it is transported, often over long distances, to reach its final destination, which causes some energy loss. Electricity may have as its raw energy resource a fossil fuel, uranium, or an elevated body of water (hydroelectric generating plant).

Data to assist in determining the amount of resource use per delivered on-site energy source unit are available. In the United States, data are available from entities within the U.S. Department of Energy and from the agencies and associations listed at the end of this chapter.

A **resource utilization factor** (RUF) is the ratio of resources consumed to energy delivered (for each form of energy) to a building site. Specific RUFs may be determined for various energy sources normally consumed on-site, including nonrenewable sources such as coal, gas, oil, and electricity, and renewable sources such as solar, geothermal, waste, and wood energy. With electricity, which may derive from several resources depending on the particular fuel mix of the generating stations in the region served, the overall RUF is the weighted combination of individual factors applicable to electricity and a particular energy resource. Grumman (1984) gives specific formulas for calculating RUFs.

While a designer is usually not required to determine the amount of energy resources attributable to a given building or building site for its design or operation, this information may be helpful when assessing the long-range availability of energy for a building or the building's impact on energy resources. Factors or fuel-quantity-to-energy resource ratios or factors are often used, which suggests that energy resources are of concern to the HVAC&R industry.

**Intangible Relationships**

Energy resources should not simply be converted into common energy units [e.g., gigajoule] because the commonality gives a misleading picture of the equivalence of these resources. Other differences and limitations of each of the resources defy easy quantification but are nonetheless real. For instance, electricity that arrives and is used on a site can be generated from coal, oil, natural gas, uranium, or hydropower. The end result is the same: electricity at  $x$  kV,  $y$  Hz. However, is a megajoule of electricity generated by hydropower equal in societal impact to that same megajoule generated by coal, by uranium, by domestic oil, or by imported oil?

Intangible factors such as safety, environmental acceptability, availability, and national interest also are affected in different ways by the consumption of each resource. Heiman (1984) proposes a procedure for weighting the following intangible factors:

**National/Global Considerations**

- Balance of trade
- Environmental impacts
- International policy
- Employment
- Minority employment
- Availability of supply
- Alternative uses
- National defense
- Domestic policy
- Effect on capital markets

**Local Considerations**

- Exterior environmental impact—air
- Exterior environmental impact—solid waste
- Exterior environmental impact—water resources

- Local employment
- Local balance of trade
- Use of distribution infrastructure
- Local energy independence
- Land use
- Exterior safety

**Site Considerations**

- Reliability of supply
- Indoor air quality
- Aesthetics
- Interior safety
- Anticipated changes in energy resource prices

**SUMMARY**

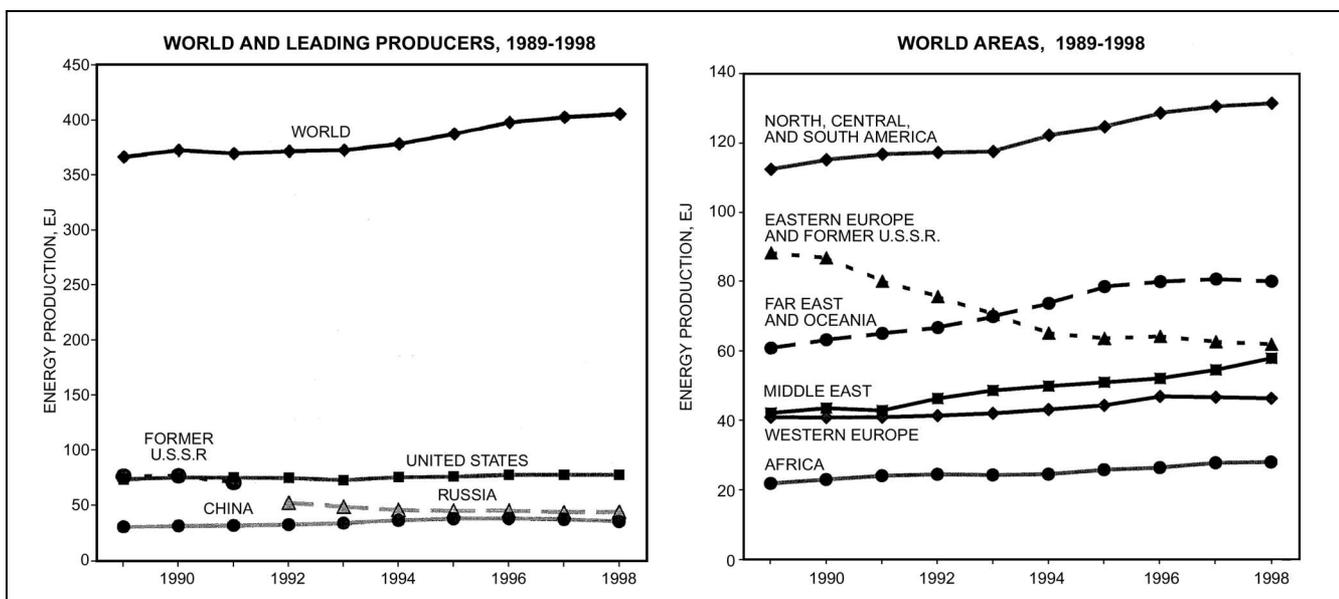

In designing HVAC&R systems, the need to address immediate issues such as economics, performance, and space constraints often prevents designers from fully considering the energy resources affected. Today's energy resources are less certain because of issues such as availability, safety, national interest, environmental concerns, and the world political situation. As a result, the reliability, economics, and continuity of many common energy resources over the potential life of a building being designed are unclear. For this reason, the designer of building energy systems must consider the energy resources on which the long-term operation of the building will depend. If the continued viability of those resources is reason for concern, the design should provide for, account for, or address such an eventuality.

**OVERVIEW OF GLOBAL ENERGY RESOURCES**

**WORLD ENERGY RESOURCES**

**Production**

Energy production trends for the world, by leading producers and world areas, from 1989 to 1998, are shown in Figure 1. World primary energy production, following essentially no increase in the

**Fig. 1 World Primary Energy Production**  
 (Basis: Energy Information Administration/Annual Energy Review 1999)

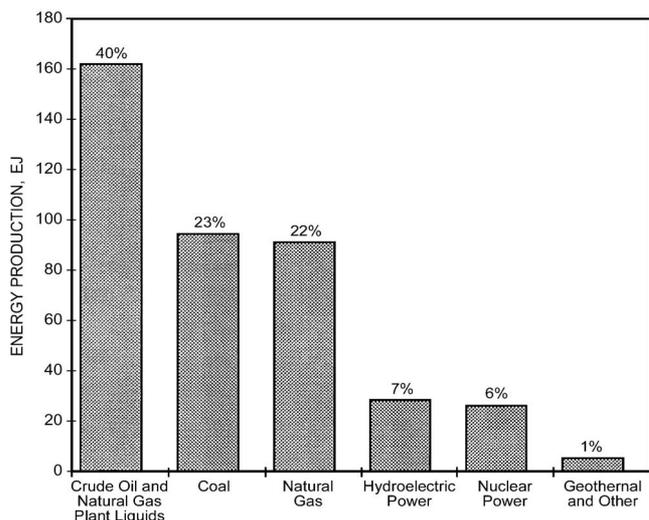

Fig. 2 World Primary Energy Production by Resource: 1998

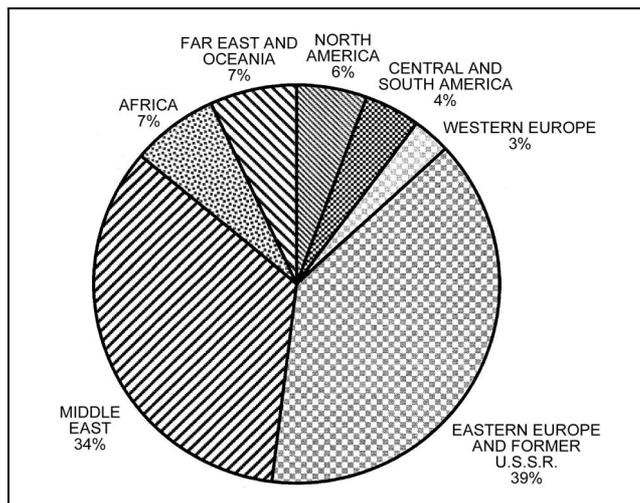

Fig. 4 World Natural Gas Reserves: January 1, 1999 (Basis: Oil and Gas Journal)

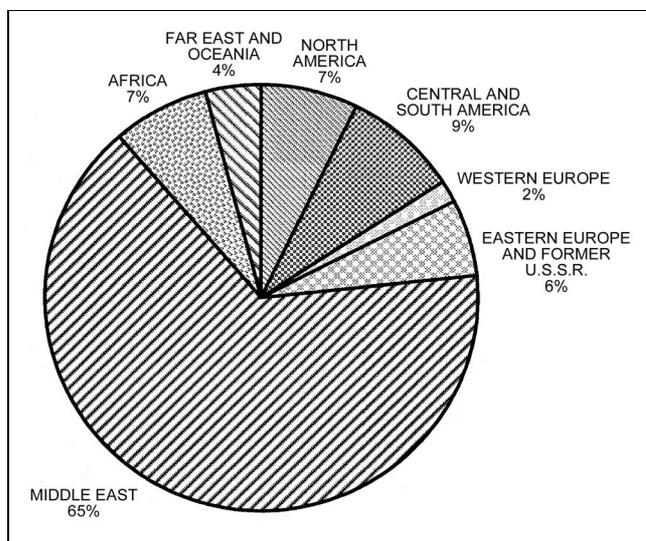

Fig. 3 World Crude Oil Reserves: January 1, 1999 (Basis: Oil and Gas Journal)

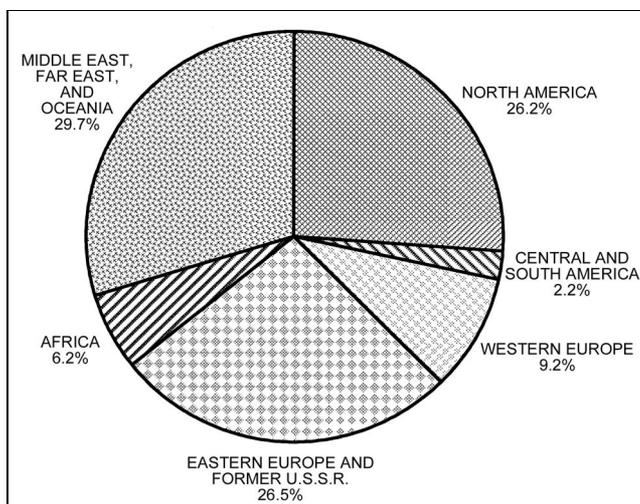

Fig. 5 World Recoverable Coal Reserves: December 31, 1996 and January 1, 1999 (U.S. Only) (Basis: Energy Information Administration)

early 1990s, has risen subsequently at about 1.7% per year. The largest total energy producers in 1998 were the United States (20%), Russia (11%), and China (9%). Saudi Arabia (5%+) was the world's fourth largest producer. Together these producers accounted for almost half of the world's energy. Total world energy production by resource type is shown in Figure 2.

**Crude Oil.** World crude oil production was  $10.7 \times 10^6$  m<sup>3</sup> per day in 1999—up 18% since 1973. The biggest crude oil producers in 1999 were the eight nations comprising the Organization of Petroleum Exporting Countries (OPEC) at 42% (including Saudi Arabia at 12%+), Russia (9%), and the United States (9%). Oil production declined most noticeably since 1992 in Russia (20%) and in the United States (17%). The other primary non-OPEC producers were China, Mexico, Norway, the United Kingdom, and Canada.

**Natural Gas.** World production reached  $2.3 \times 10^{12}$  m<sup>3</sup> in 1998—up 15% from the 1989 level. The biggest producers in 1998 were Russia (25%) and the United States (23%).

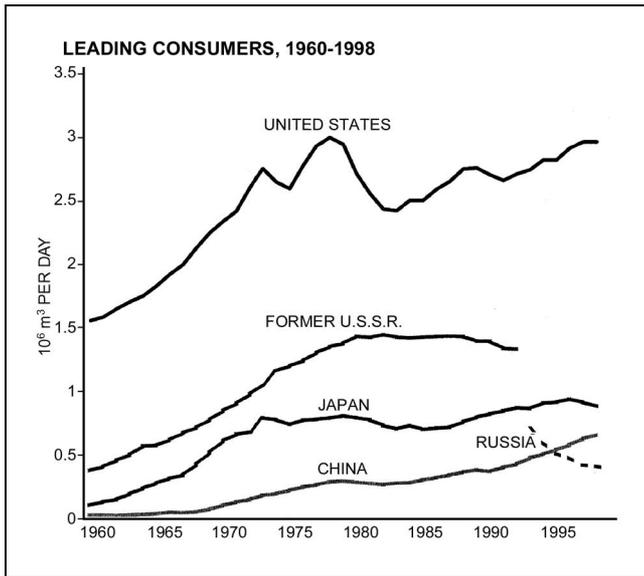

**Coal.** At  $4.5 \times 10^9$  Mg in 1998, coal production was lower by 0.3% than in 1989 and comprised 23% of the world's energy

production. The leading producers of coal were China (27%), the United States (22%), India (7%), Russia (5%+), Germany (5%), and Poland (4%).

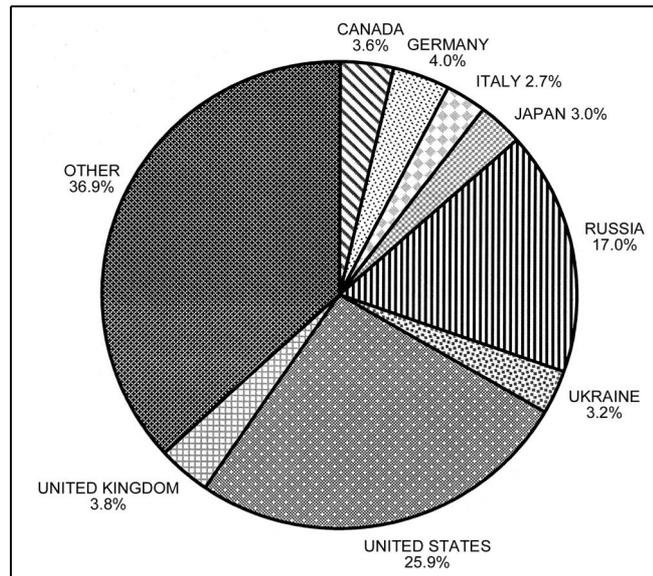

**Reserves**

On January 1, 1999, the estimated world reserves of crude oil and gas were distributed by world region as shown in Figures 3 and 4. Saudi Arabia was estimated to have 39% of the Middle Eastern crude oil reserves. Iraq, the United Arab Emirates, Kuwait, and Iran were each estimated to have more crude oil reserves than any world region outside the Middle East. Outside the Middle East, the biggest reserves were estimated to be in Venezuela, Russia, and Mexico. The country with the largest gas reserves by far was Russia.

World coal reserves as of January 1, 1996, are shown by world area in Figure 5 (note that the U.S. data are as of January 1, 1999). The countries with the most plentiful reserves, as a percent of total, were Russia (16%), the United States (25%), China (12%), and Australia (9%).

**Fig. 6 World Petroleum Consumption: 1960-1998**  
(Basis: Energy Information Administration/Annual Energy Review 1999)

**Fig. 7 World Natural Gas Consumption: 1998**  
(Basis: Energy Information Administration)

**Consumption**

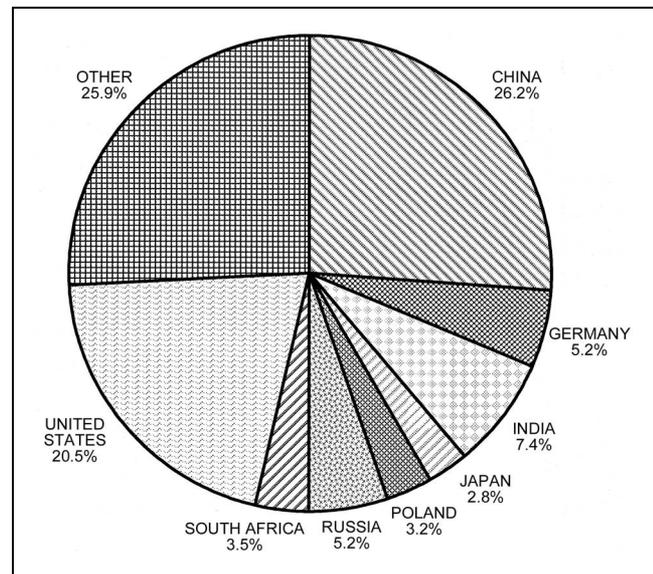

Data on world energy consumption are available only by type of resource rather than by total energy consumed.

**Petroleum.** The consumption trends of the leading consumers from 1960 to 1998 are depicted in Figure 6. In 1998, the United States consumed far more than any other country—26% of world consumption and 40% of the consumption of Organization for Economic Cooperation and Development (OECD) countries. By contrast, Japan, the second largest consumer among OECD countries, consumed just 7.5% of the world total and 12% of that of the OECD countries. Of the non-OECD countries, Russia and China were the biggest consumers (3% and 6%, respectively, of world consumption).

**Natural Gas.** Transport pipelines notwithstanding, this energy resource tends to be consumed close to the site of production; and indeed, in 1998 the two biggest natural gas producers were also the two biggest consumers. Figure 7 depicts natural gas consumption by the leading consumer countries as a percentage of world consumption. Of the major consumers, the United States consumed more than it produced (114%), and the former U.S.S.R. consumed less (67%). Germany and the United Kingdom, the third and fourth largest consumers, produced very little. Canadian consumption was 49% of its production. World consumption of natural gas increased 55% between 1980 and 1998, with the three major gas-consuming states of the former U.S.S.R. (Russia, Ukraine, and Uzbekistan) up 35% and the United States up 7%. After the United States and Russia, no single country consumed more than 5% of the world total.

**Coal.** Here, the three largest producers were also the three largest consumers. Figure 8 depicts the percentage of world consumption by the leading consumers during 1998. Since 1980, world coal consumption has increased 21%, with most of that increase in the early 1980s. Over the same period, consumption by China increased 93%, the United States 48%, India 185%, and Japan 43%. Significant drops occurred in Germany, Poland, and Russia.

**Electricity.** Figure 9 shows the world's electricity generation by energy resource in 1998. Figure 10 shows installed capacity for the same resources at the beginning of 1998. Both net generation and installed capacity were dominated by the United States (26%+ and 25%, respectively). Comparable figures for the next largest are

**Fig. 8 World Coal Consumption: 1998**  
(Basis: Energy Information Administration)

China (8% for both), Japan (7% and 7+%), and Russia (6% and 7%). China, which has grown almost four times in net electric generating capacity since 1980, has surpassed Japan in the last few years.

Electricity generated by hydroelectric means increased in the world by 47% between 1980 and 1998, with the largest increase occurring in Central and South America. The top countries for hydroelectric generation in 1998 were the United States, Canada, and Brazil—collectively accounting for 37% of the world total quantity of electricity generated by that means.

Total world electricity generation from nuclear resources increased 239% between 1980 and 1998, with higher-than-average increases occurring in the Far East/Oceania, Western Europe, and Africa. The top-generating countries in 1998 were the United States (27% of world total), China (8%), and Japan (7%).

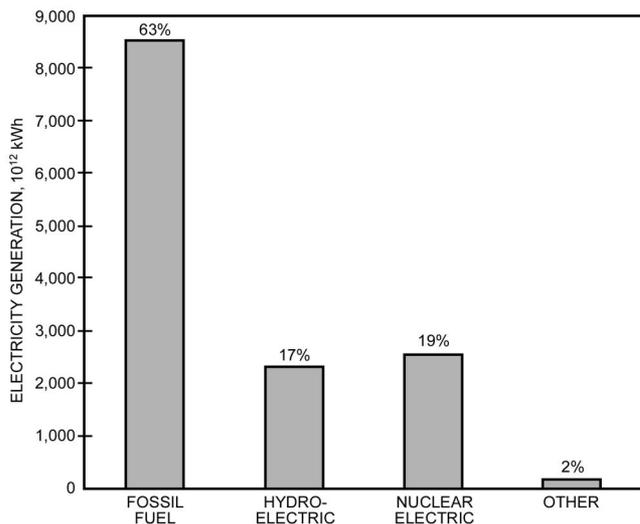

Fig. 9 World Electricity Generation by Resource: 1998

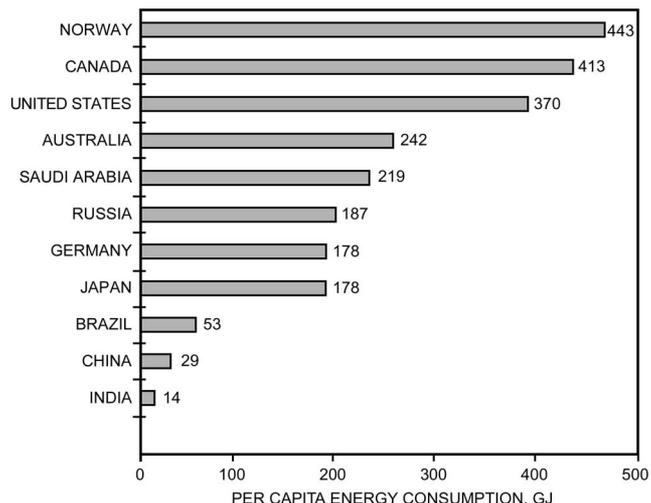

Fig. 11 Per Capita Energy Consumption by Selected Developed Countries in 1998

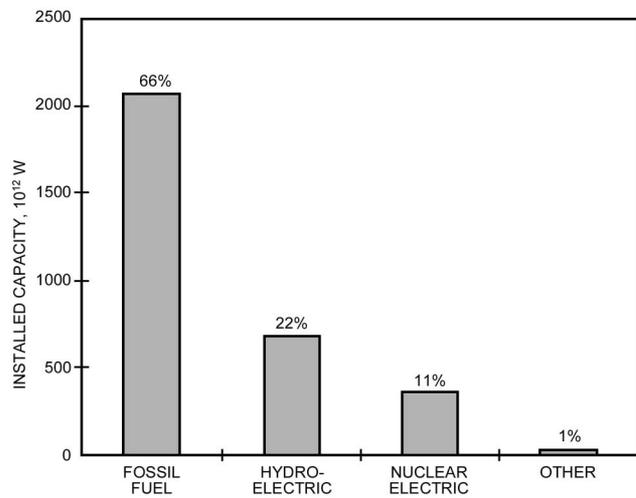

Fig. 10 World Installed Electricity Generation Capacity by Resource: January 1, 1998

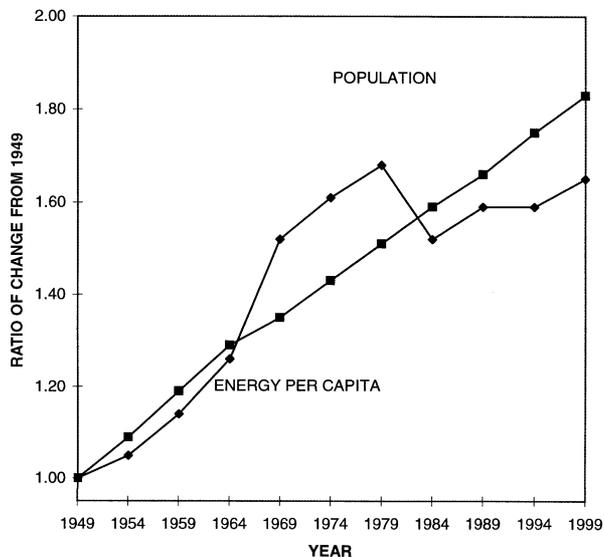

Fig. 12 Per Capita End-Use Energy Consumption Trends in the United States

**Per Capita.** Figure 11 compares the per capita commercial energy consumption of selected developed countries for 1998. As is apparent, the per capita energy consumption in cold-climate countries tends to be highest; also, the level in more developed countries is vastly different from that in less developed countries and differs considerably even among the more developed countries.

**UNITED STATES ENERGY USE**

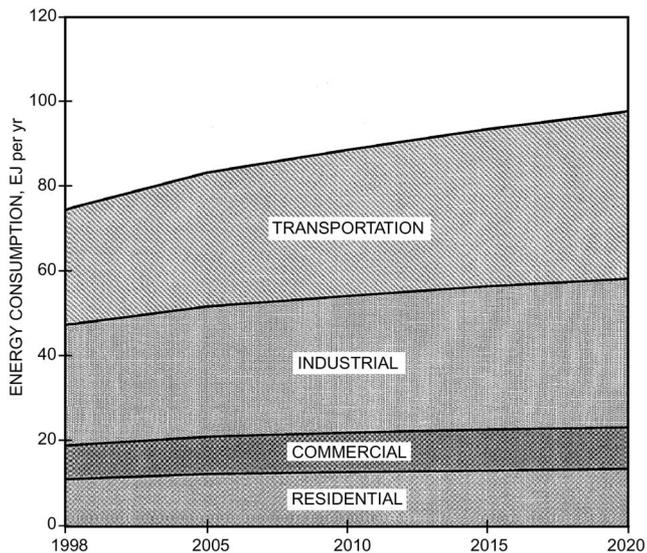

**Per Capita Energy Consumption**

Figure 12, which is based on EIA (1999), presents a capsule overview of past U.S. energy use intensity by relating the growth in per capita energy use since 1949 to population growth. The growth in per capita energy use has varied significantly from the population growth rate. The 1960s experienced a sharp increase in the per capita energy use growth rate, which leveled off during the 1970s due to higher energy prices and the emphasis on energy conservation. [No change in the intensity of energy use would result in a flat (horizontal) energy-per-capita curve]. In the early 1980s,

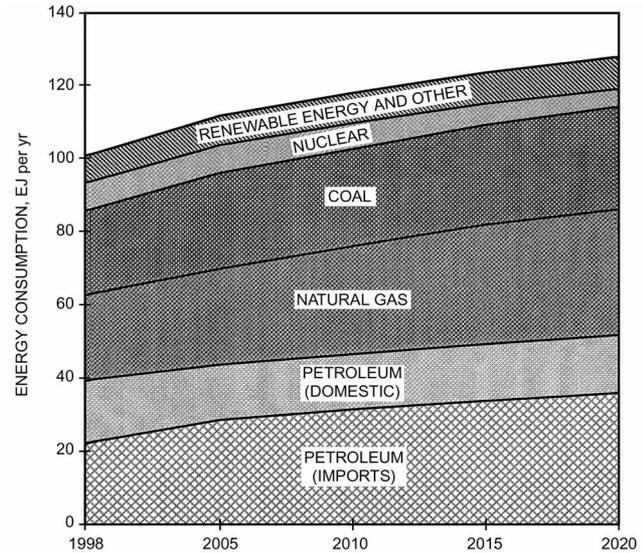

however, a significant drop in the per capita energy use growth rate occurred as industrial output decreased, efficiency of use improved, and global economic pressures mounted. The period since the mid-1980s shows a resumption of per capita energy use growth at a rate at first paralleling that of the population.

The *Annual Energy Outlook* is the basic source of data for projecting the use of energy in the United States (EIA 2000). Figure 13 and Figure 14 are summaries of data from this source.

EIA (2000) presents forecasts of energy trends that are based on macroeconomic growth scenarios prepared by several outside sources. EIA has also added a low and a high world oil price scenario to its mid-growth economic scenario. Thus, the National Energy Modeling System (NEMS), which EIA uses for these forecasts, has yielded three scenarios. Figure 13 and Figure 14 present the baseline or reference case. It assumes average annual growth of the real gross domestic product (GDP) at 2.2%, of the labor force at 0.9%, and of productivity at 1.3%. The forecast, in order to be

**Fig. 13 Projected Total U.S. Energy Consumption by End-Use Sector**

**Fig. 14 Projected Total U.S. Energy Consumption by Resource**

policy-neutral, also assumes that all federal, state, and local laws and regulations in effect as of July 1, 1999, remain unchanged through 2020.

### Projected Overall Energy Consumption

Figure 13 shows energy use by end-use sector, with the major end-use sectors being residential, commercial, industrial, and transportation. HVAC&R engineers are primarily concerned with the first three sectors. Figure 14 shows energy consumption by type of resource. Figure 13 shows less total energy consumption than Figure 14 primarily because it excludes the thermodynamic losses of electricity generation and the processing and delivery burdens of various energy forms.

The following observations apply to the overall picture of projected energy use in the United States over the next two decades (Figures 13 and 14):

- Although a major issue in energy markets is carbon emissions, impacts of programs to reduce them are not reflected in these forecasts because no specific policies for carbon reductions have been enacted.
- Given the above premise, carbon emissions from energy use will increase by an average of 1.3% per year through 2020 due to rising energy demand, declining nuclear power generation, improvements in efficiency, and slow growth in the use of renewable sources. The 2020 level of carbon emissions will thus be almost 33% higher than the 1998 levels.
- Though average crude oil prices are expected to remain low over the next several years, unanticipated changes in supply or political events could change that scenario.
- The wellhead price of natural gas is expected to increase at an average annual rate of 1.7% up to 2020, reflecting exploration and production improvements balanced by greater demand.
- The price of coal, on the other hand, is expected to decline by 28% over the same period as a result of better productivity, more low-cost western coal production, and competitive labor pressures.
- Ongoing changes in the financial structure of the electricity industry and resulting cost reductions due to increased competition are reflected. Transitions to retail competitive pricing have been assumed in areas where legislation has been enacted, and stranded cost recovery will be phased out by 2008.
- Electricity prices will decline an average of 19% per megajoule between 1997 and 2020 due to lower operating, maintenance, and administrative costs resulting from industry restructuring.
- More than half of the nuclear electricity generating capacity existing in 1998 will be retired by 2020 as operating licenses expire with no new plants having been built.
- Offsetting this decline, electricity generation from both coal and natural gas is projected to increase significantly, with the share of natural gas in 2020 more than doubling the 1998 level.
- Electricity generation using renewable sources (which includes cogenerators) will increase by only 0.5% per year, held back in large measure by the fact that electric industry restructuring tends to favor natural gas over renewables or coal.
- Petroleum consumption will grow by 1.3% annually, led by the transportation sector, which is where most of it (70%) is used.
- The share of petroleum consumption met by net imports will reach 64% in 2020. (This is up from 52% in 1998.) Over this period, U.S. crude oil production will decline at an annual rate of 0.8%, with declining resources overshadowing improvements in exploration and processing technologies.
- Natural gas consumption will increase by 1.8% per year, with demand increases in all sectors and led by its use for electricity generation.
- Coal consumption will increase at an average annual rate of 0.9%. Most of it (90%) will be used for electricity generation, but its share for that purpose will decline by 2020.
- Consumption of renewable energy (including using ethanol in gasoline) will increase by only 0.8% per year, however, with about 60% going toward electricity generation.
- Electricity demand will grow by 1.4% annually, with efficiency gains offset by growth in the use of new electricity-using equipment.
- Total energy demand in the commercial and residential sectors will grow at 0.9% and 0.8% per year, respectively. This results from greater use of computers, telecommunications, and other office appliances, but it is offset by somewhat improved building and building equipment efficiencies.
- Energy use by the transportation sector will grow at an average of 1.7% per year, with variations from this average very dependent on prevailing fuel prices.
- Per capita energy use will remain stable through 2020 as overall efficiency gains offset higher per capita demand.

- Total energy use per dollar of gross domestic product (energy intensity), however, will continue to fall at an average rate of about 1.1% per year through 2020.

### Outlook Summary

In general, the following key issues will dominate energy matters in the next two decades:

- Rising dependency of the United States on imported oil
- Expected retirement of more than half of the existing nuclear power plants
- Role of technology developments, including energy conservation and energy efficiency as alternatives to energy production
- Deregulation of the utility industry and the growth of independent power producers
- Dealing with the increasing rate of carbon emissions, especially in light of international agreements with, and moral pressure from, others of the global community
- Growth of population, coupled with the shift of “baby boomers” into retirement

## ENERGY RESOURCE PLANNING

The energy supplier (or suppliers) in a particular jurisdiction must plan for the future energy needs of that jurisdiction. For competitive energy markets where these decisions do not have high societal costs, these plans are made by the energy suppliers as part of their business. These decisions are not revealed to governmental authorities or the public more than is absolutely necessary, because significant competitive advantages could be gained by knowledge of a competitor’s future plans. For electricity (and to a lesser extent natural gas) significant societal issues are involved in energy resource planning decisions, and these decisions cannot be made by energy suppliers without approval by many different groups and entities. These issues include:

- Reliability, which is affected by the diversity of supply sources available. This would include the number of geographic supply sources and pipelines in the case of gas and would include the percentage of generation from various fuel sources in the case of electricity. Due consideration should be given to the projected future supply and reliability of energy resources, including the possibility of supply disruption due to natural or political events, and to the likelihood of future supply shortages, which could reduce reliability.
- Reserve margins, or the ratio of total supply sources to expected peak supply source needs. Reserve levels that are too high result in the waste of resources, higher environmental costs, and possibly poor financial health of the energy suppliers. Reserves that are too low result in volatile and very high peak energy prices and reduced reliability.
- The production and transmission of energy often requires governmental cooperation to condemn private property for use in energy production and transmission facilities. The construction and maintenance of this property are also regulated due to wetlands, prevention of toxic waste releases, and other environmental issues.

### Integrated Resource Planning

Integrated resource planning (IRP) is a process commonly used for the planning of significant new energy facilities. The steps in this planning process include: (1) forecasting the amount of new resources needed and (2) determining the type of resource to be provided and who will provide this resource. Traditionally, the local utility provider forecasts the future needs of a given energy resource, then either builds the necessary facility with the approval of regulators or uses a standard offer bid to determine

what non-utility provider (or the utility itself) would provide the new energy resource. However, with increasing deregulation of energy providers, a single energy provider may no longer be responsible for maintaining an adequate supply. This forecasting task may be provided by a regulatory body, or it could be by a consensus decision of the various competing energy suppliers, with oversight and approval of regulators.

Supplying new energy resources through either a standard bid process by a supplier or traditional utility regulation will usually result in the selection of the lowest cost supply option, without regard for environmental costs or other societal needs. IRP allows for the choice of a greater variety of resource options and allows environmental costs and other indirect costs to society to be given greater consideration.

IRP addresses a wider population of stakeholders than do most other planning processes. Many regulatory agencies involve the public in the formulation and review of integrated resource plans. Customers, environmentalists, and other public interest groups are often prominent in these proceedings.

Prior to the deregulation of energy suppliers, **demand-side management** (DSM) was a common option for providing new energy resources, especially for electricity. These are actions taken to reduce the demand for energy, rather than increase the supply of energy. DSM is desirable because the environmental costs of DSM are almost always lower than the environmental costs of building new energy facilities. However, several factors have caused a decline in the number of DSM programs:

- Lower cost supply options, especially for natural gas-fired generation, make it more difficult to implement DSM options that do not result in higher total costs.
- Building and equipment codes and standards are a highly efficient form of DSM, providing reduced energy use with much lower administrative costs than programs that reward the installation of more efficient equipment at a single site. However, they are more subtle than traditional DSM programs and may not always be recognized as a form of DSM.
- The opening of markets to competing suppliers makes it more difficult to administer and implement DSM programs. However, they are still possible if the regulators wish to continue them, and set appropriate rules and regulations for the energy market to allow the implementation of DSM programs.

Many participants in IRP processes may be interested in only one aspect of the process. For example, the energy industry’s main interest may be cost minimization, while environmentalists may want to minimize pollutant emissions and prevent environmental damage from the construction of energy facilities. Participation by all affected interest groups helps provide the best overall solution for society, including the indirect costs and benefits from these energy resource decisions.

## TRADABLE EMISSION CREDITS

Increasingly, quotas and limits apply to the emissions of various pollutants. These currently include sulphur dioxide (SO<sub>2</sub>) and nitrogen oxides (NO<sub>x</sub>) but may someday include carbon dioxide (CO<sub>2</sub>). Often a market-based system of **tradable credits** is used with these quotas. A company is given the right to produce a given level of emissions and it earns a credit, which can be sold to others, if it produces fewer emissions than that level. If one company can reduce its emissions at a lower cost than another, it can do so and sell the emissions credit to the second company and earn a profit from its pollution control efforts. To date, this type of activity has largely involved large industrial plants, but it can also involve commercial buildings with on-site emissions, such as generation equipment or gas engine-driven cooling.

Designers must be aware of any regulations concerning pollutant emissions; failure to comply with these regulations may result in civil or criminal penalties for designers or their clients. However, designers should understand the options available under these regulations. The purchase or sale of emissions credits may allow reduced construction or building operations costs if the equipment can “overcomply” at a lower cost than the cost of another source of emissions to comply, or vice versa. In some cases, documentation of energy savings beyond what codes and regulations require can result in receiving emissions credits that may be sold later.

### AGENCIES AND ASSOCIATIONS IN THE UNITED STATES

## CHAPTER 18

# COMBUSTION AND FUELS

<i>Principles of Combustion</i> .....	18.1	<i>Solid Fuels</i> .....	18.6
<i>Fuel Classification</i> .....	18.3	<i>Combustion Calculations</i> .....	18.8
<i>Gaseous Fuels</i> .....	18.4	<i>Efficiency Calculations</i> .....	18.12
<i>Liquid Fuels</i> .....	18.4	<i>Combustion Considerations</i> .....	18.13

### PRINCIPLES OF COMBUSTION

**C**OMBUSTION is a chemical reaction in which an oxidant reacts rapidly with a fuel to liberate stored energy as thermal energy, generally in the form of high-temperature gases. Small amounts of electromagnetic energy (light), electric energy (free ions and electrons), and mechanical energy (noise) are also produced during combustion. Except in special applications, the oxidant for combustion is oxygen in the air.

Conventional hydrocarbon fuels contain primarily hydrogen and carbon, in elemental form or in various compounds. Their complete combustion produces mainly carbon dioxide ( $\text{CO}_2$ ) and water ( $\text{H}_2\text{O}$ ); however, small quantities of carbon monoxide (CO) and partially reacted flue gas constituents (gases and liquid or solid aerosols) may form. Most conventional fuels also contain small amounts of sulfur, which is oxidized to sulfur dioxide ( $\text{SO}_2$ ) or sulfur trioxide ( $\text{SO}_3$ ) during combustion, and noncombustible substances such as mineral matter (ash), water, and inert gases. Flue gas is the product of complete or incomplete combustion and includes excess air (if present), but not dilution air.

Fuel combustion rate depends on (1) the rate of the chemical reaction of the combustible fuel constituents with oxygen, (2) the rate at which oxygen is supplied to the fuel (the mixing of air and fuel), and (3) the temperature in the combustion region. The reaction rate is fixed by fuel selection. Increasing the mixing rate or temperature increases the combustion rate.

With **complete combustion** of hydrocarbon fuels, all hydrogen and carbon in the fuel are oxidized to  $\text{H}_2\text{O}$  and  $\text{CO}_2$ . Generally, for complete combustion, excess oxygen or excess air must be supplied beyond the amount theoretically required to oxidize the fuel. Excess air is usually expressed as a percentage of the air required to completely oxidize the fuel.

In **stoichiometric combustion** of a hydrocarbon fuel, fuel is reacted with the exact amount of oxygen required to oxidize all carbon, hydrogen, and sulfur in the fuel to  $\text{CO}_2$ ,  $\text{H}_2\text{O}$ , and  $\text{SO}_2$ . Therefore, exhaust gas from stoichiometric combustion theoretically contains no incompletely oxidized fuel constituents and no unreacted oxygen (i.e., no carbon monoxide and no excess air or oxygen). The percentage of  $\text{CO}_2$  contained in products of stoichiometric combustion is the maximum attainable and is referred to as the **stoichiometric  $\text{CO}_2$** , **ultimate  $\text{CO}_2$** , or **maximum theoretical percentage of  $\text{CO}_2$** .

Stoichiometric combustion is seldom realized in practice because of imperfect mixing and finite reaction rates. For economy and safety, most combustion equipment should operate with some excess air. This ensures that fuel is not wasted and that combustion is complete despite variations in fuel properties and in the supply rates of fuel and air. The amount of excess air to be supplied to any combustion equipment depends on (1) expected variations in fuel properties and in fuel and air supply rates, (2) equipment applica-

tion, (3) degree of operator supervision required or available, and (4) control requirements. For maximum efficiency, combustion at low excess air is desirable.

**Incomplete combustion** occurs when a fuel element is not completely oxidized during combustion. For example, a hydrocarbon may not completely oxidize to carbon dioxide and water, but may form partially oxidized compounds, such as carbon monoxide, aldehydes, and ketones. Conditions that promote incomplete combustion include (1) insufficient air and fuel mixing (causing local fuel-rich and fuel-lean zones), (2) insufficient air supply to the flame (providing less than the required quantity of oxygen), (3) insufficient reactant residence time in the flame (preventing completion of combustion reactions), (4) flame impingement on a cold surface (quenching combustion reactions), or (5) flame temperature that is too low (slowing combustion reactions).

Incomplete combustion uses fuel inefficiently, can be hazardous because of carbon monoxide production, and contributes to air pollution.

### Combustion Reactions

The reaction of oxygen with the combustible elements and compounds in fuels occurs according to fixed chemical principles, including

- Chemical reaction equations
- Law of matter conservation: the mass of each element in the reaction products must equal the mass of that element in the reactants
- Law of combining masses: chemical compounds are formed by elements combining in fixed mass relationships
- Chemical reaction rates

Oxygen for combustion is normally obtained from air, which is a physical mixture of nitrogen, oxygen, small amounts of water vapor, carbon dioxide, and inert gases. For practical combustion calculations, dry air consists of 20.95% oxygen and 79.05% inert gases (nitrogen, argon, and so forth) by volume, or 23.15% oxygen and 76.85% inert gases by mass. For calculation purposes, nitrogen is assumed to pass through the combustion process unchanged (although small quantities of nitrogen oxides form). Table 1 lists oxygen and air requirements for stoichiometric combustion and the products of stoichiometric combustion of some pure combustible materials (or constituents) found in common fuels.

### Flammability Limits

Fuel burns in a self-sustained reaction only when the volume percentages of fuel and air in a mixture at standard temperature and pressure are within the upper and lower flammability limits or explosive limits (UEL and LEL). See Table 2. Both temperature and pressure affect these limits. As the temperature of the mixture increases, the upper limit increases and the lower limit decreases. As the pressure of the mixture decreases below atmospheric pressure, the upper limit decreases and the lower limit increases.

The preparation of this chapter is assigned to TC 6.10, Fuels and Combustion.

Table 1 Combustion Reactions of Common Fuel Constituents

Constituent	Molecular Formula	Combustion Reactions	Stoichiometric Oxygen and Air Requirements				Flue Gas from Stoichiometric Combustion with Air					
			kg/kg Fuel <sup>a</sup>		m <sup>3</sup> /m <sup>3</sup> Fuel		Ultimate CO <sub>2</sub> , %	Dew Point, <sup>c</sup> °C	m <sup>3</sup> /m <sup>3</sup> Fuel		kg/kg Fuel	
			O <sub>2</sub>	Air	O <sub>2</sub>	Air			CO <sub>2</sub>	H <sub>2</sub> O	CO <sub>2</sub>	H <sub>2</sub> O

Adapted, in part, from *Gas Engineers Handbook* (1965)<sup>a</sup>Atomic masses: H = 1.008, C = 12.01, O = 16.00, S = 32.06.<sup>b</sup>Volume ratios are not given for fuels that do not exist in vapor form at reasonable temperatures or pressure.<sup>c</sup>Dew point is determined from Figure 2.

Table 2 Flammability Limits and Ignition Temperatures of Common Fuels in Fuel-Air Mixtures

Substance	Molecular Formula	Lower Flammability Limit, %	Upper Flammability Limit, %	Ignition Temperature, °C	References
Carbon (activated coke)	C	—	—	660	Hartman (1958)
Carbon monoxide	CO	12.5	74	609	Scott et al. (1948)
Hydrogen	H <sub>2</sub>	4.0	75.0	520	Zabetakis (1956)
Methane	CH <sub>4</sub>	5.0	15.0	705	<i>Gas Engineers Handbook</i> (1965)
Ethane	C <sub>2</sub> H <sub>6</sub>	3.0	12.5	520 to 630	Trinks (1947)
Propane	C <sub>3</sub> H <sub>8</sub>	2.1	10.1	466	NFPA (1962)
n-Butane	C <sub>4</sub> H <sub>10</sub>	1.86	8.41	405	NFPA (1962)
Ethylene	C <sub>2</sub> H <sub>4</sub>	2.75	28.6	490	Scott et al. (1948)
Propylene	C <sub>3</sub> H <sub>6</sub>	2.00	11.1	450	Scott et al. (1948)
Acetylene	C <sub>2</sub> H <sub>2</sub>	2.50	81	406 to 440	Trinks (1947)
Sulfur	S	—	—	190	Hartman (1958)
Hydrogen sulfide	H <sub>2</sub> S	4.3	45.50	292	Scott et al. (1948)

Flammability limits adapted from Coward and Jones (1952). All values corrected to 16°C, 104 kPa, dry.

However, as pressure increases above atmospheric pressure, the upper limit increases and the lower limit is relatively constant.

### Ignition Temperature

**Ignition temperature** is the lowest temperature at which heat is generated by combustion faster than heat is lost to the surroundings and combustion becomes self-propagating. See Table 2. The fuel-air mixture will not burn freely and continuously below the ignition temperature unless heat is supplied, but chemical reaction between the fuel and air may occur. Ignition temperature is affected by a large number of factors.

The ignition temperature and flammability limits of a fuel-air mixture, together, are a measure of the potential for ignition (*Gas Engineers Handbook* 1965).

### Combustion Modes

Combustion reactions occur in either continuous or pulse flame modes. **Continuous combustion** burns fuel in a sustained manner as long as fuel and air are continuously fed to the combustion zone and the fuel-air mixture is within the flammability limits. Continuous combustion is more common than pulse combustion and is used in most fuel-burning equipment.

**Pulse combustion** is an acoustically resonant process that burns various fuels in small, discrete fuel-air mixture volumes in a very rapid series of combustions.

The introduction of fuel and air into the pulse combustor is controlled by mechanical or aerodynamic valves. Typical combustors consist of one or more valves, a combustion chamber, an exit pipe, and a control system (ignition means, fuel-metering devices, etc.). Typically, combustors for warm air furnace, hot water boiler, and

commercial cooking equipment use mechanical valves. Aerodynamic valves are usually used in higher pressure applications, such as thrust engines. Separate valves for air and fuel, a single valve for premixed air and fuel, or multiple valves of either type can be used. Premix valve systems may require a flame trap at the combustion chamber entrance to prevent flashback.

In a mechanically valved pulse combustor, air and fuel are forced into the combustion chamber through the valves under pressures less than 3.5 kPa. An ignition source, such as a spark, ignites the fuel-air mixture, causing a positive pressure buildup in the combustion chamber. The positive pressure causes the valves to close, leaving only the exit pipe of the combustion chamber as a pressure relief opening. The combustion chamber and exit pipe geometry determine the resonant frequency of the combustor.

The pressure wave from the initial combustion travels down the exit pipe at sonic velocity. As this wave exits the combustion chamber, most of the flue gases present in the chamber are carried with it into the exit pipe. Flue gases remaining in the combustion chamber begin to cool immediately. The contraction of the cooling gases and the momentum of gases in the exit pipe create a vacuum inside the chamber that opens the valves and allows more fuel and air into the chamber. While the fresh charge of fuel-air enters the chamber, the pressure wave reaches the end of the exit pipe and is partially reflected from the open end of the pipe. The fresh fuel-air charge is ignited by residual combustion and/or heat. The resulting combustion starts another cycle.

Typical pulse combustors operate at 30 to 100 cycles per second and emit resonant sound, which must be considered in their application. The pulses produce high convective heat transfer rates.

**Heating Value**

Combustion produces thermal energy or heat. The quantity of heat generated by complete combustion of a unit of specific fuel is constant and is termed the **heating value** or **heat of combustion** of that fuel. The heating value of a fuel can be determined by measuring the heat evolved during combustion of a known quantity of the fuel in a calorimeter, or it can be estimated from chemical analysis of the fuel and the heating values of the various chemical elements in the fuel. For information on calculating heating values, see the sections on Characteristics of Fuel Oils and Characteristics of Coals.

**Higher heating value, gross heating value, or total heating value** includes the latent heat of vaporization and is determined when water vapor in the fuel combustion products is condensed. Conversely, **lower heating value** or **net heating value** is obtained when the latent heat of vaporization is *not* included. When the heating value of a fuel is specified without designating higher or lower, it generally means the higher heating value in the United States. (Lower heating value is mainly used for internal combustion engine fuels.)

Heating values are usually expressed in kilojoules per litre or megajoules per cubic metre for gaseous fuels, megajoules per litre for liquid fuels, and megajoules per kilogram for solid fuels. Heating values are always given in relation to a certain reference temperature and pressure, usually 16, 20, or 25°C and 101.325 kPa, depending on the particular industry practice. Heating values of several substances in common fuels are listed in Table 3.

With incomplete combustion, not all fuel is completely oxidized, and the heat produced is less than the heating value of the fuel. Therefore, the quantity of heat produced per unit of fuel consumed decreases, implying lower combustion efficiency.

Not all heat produced during combustion can be used effectively. The greatest heat loss is the thermal energy of the increased temperature of hot exhaust gases above the temperature of incoming air and fuel. Other heat losses include radiation and convection heat transfer from the outer walls of combustion equipment to the environment.

**Table 3 Heating Values of Substances Occurring in Common Fuels**

Substance	Molecular Formula	Higher Heating	Lower Heating	Density, <sup>b</sup> kg/m <sup>3</sup>
		Values, <sup>a</sup> MJ/kg	Values, <sup>a</sup> MJ/kg	
Carbon (to CO)	C	9.188	9.188	—
Carbon (to CO <sub>2</sub> )	C	32.780	32.780	—
Carbon monoxide	CO	10.111	10.111	1.187
Hydrogen	H <sub>2</sub>	142.107	120.075	0.085
Methane	CH <sub>4</sub>	55.533	49.997	0.679
Ethane	C <sub>2</sub> H <sub>6</sub>	51.923	47.492	1.28
Propane	C <sub>3</sub> H <sub>8</sub>	50.402	46.373	1.92
Butane	C <sub>4</sub> H <sub>10</sub>	49.593	45.771	2.53
Ethylene	C <sub>2</sub> H <sub>4</sub>	50.325	47.160	—
Propylene	C <sub>3</sub> H <sub>6</sub>	48.958	45.792	1.78
Acetylene	C <sub>2</sub> H <sub>2</sub>	50.014	48.309	1.120
Sulfur (to SO <sub>2</sub> )	S	9.257	9.257	—
Sulfur (to SO <sub>3</sub> )	S	13.816	13.816	—
Hydrogen sulfide	H <sub>2</sub> S	16.508	15.205	1.456

Adapted from *Gas Engineers Handbook* (1965).  
<sup>a</sup>All values corrected to 16°C, 101.4 kPa, dry. For gases saturated with water vapor at 16°C, deduct 1.74% of the value to adjust for gas volume displaced by water vapor.  
<sup>b</sup>At 0°C and 101.3 kPa.

**Altitude Compensation**

Air at altitudes above sea level is less dense and has less oxygen per unit volume. Therefore, combustion at altitudes above sea level has less available oxygen to burn with the fuel unless compensation is made for the altitude. Combustion occurs, but the amount of excess air is reduced. If excess air is reduced enough by an increase in altitude, combustion is incomplete or ceases.

Altitude compensation is achieved by matching the fuel and air supply rates to attain complete combustion without too much excess air or too much fuel. Fuel and air supply rates can be matched by increasing the air supply rate to the combustion zone or by decreasing the fuel supply rate to the combustion zone. The air supply rate can be increased with a combustion air blower, and the fuel supply rate can be reduced by decreasing the fuel input (derating).

Power burners use combustion air blowers and can increase the air supply rate to compensate for altitude. The combustion zone can be pressurized to attain the same air density in the combustion chamber as that attained at sea level.

Derating can be used as an alternative to power combustion. In the United States, the fuel gas codes generally do not require derating of nonpower burners at altitudes up to 600 m. At altitudes above 600 m, burners should be derated 4% for each 300 m above sea level (NFPA/IAS *National Fuel Gas Code*). Chimney or vent operation also must be considered at high altitudes (see Chapter 30 of the 2000 *ASHRAE Handbook—Systems and Equipment*).

**FUEL CLASSIFICATION**

Generally, hydrocarbon fuels are classified according to physical state (gas, liquid, or solid). Different types of combustion equipment are usually needed to burn fuels in the different physical states. Gaseous fuels can be burned in premix or diffusion burners. Liquid fuel burners must include a means for atomizing or vaporizing fuel into small droplets or a vapor and must provide adequate mixing of fuel and air. Solid fuel combustion equipment must (1) heat fuel to vaporize sufficient volatiles to initiate and sustain combustion, (2) provide residence time to complete combustion, and (3) provide space for ash containment.

Principal fuel applications include space heating and cooling of residential, commercial, industrial, and institutional buildings; service water heating; steam generation; and refrigeration. Major fuels for these applications are natural and liquefied petroleum gases, fuel

oils, diesel and gas turbine fuels (for on-site energy applications), and coal.

Fuels of limited use, such as manufactured gases, kerosene, briquettes, wood, and coke, are not discussed here. Fuel choice is based on one or more of the following:

#### Fuel factors

- Availability, including dependability of supply
- Convenience of use and storage
- Economy
- Cleanliness

#### Combustion equipment factors

- Operating requirements
- Cost
- Service requirements
- Ease of control

## GASEOUS FUELS

Although various gaseous fuels have been used as energy sources in the past, heating and cooling applications are presently limited to natural gas and liquefied petroleum gases.

### Types and Properties

**Natural gas** is a nearly odorless and colorless gas that accumulates in the upper parts of oil and gas wells. Raw natural gas is a mixture of methane (55 to 98%), higher hydrocarbons (primarily ethane), and noncombustible gases. Some constituents, principally water vapor, hydrogen sulfide, helium, and gases for liquefied petroleum gases and gasoline are removed prior to distribution.

Natural gas used as fuel typically contains methane,  $\text{CH}_4$  (70 to 96%); ethane,  $\text{C}_2\text{H}_6$  (1 to 14%); propane,  $\text{C}_3\text{H}_8$  (0 to 4%); butane,  $\text{C}_4\text{H}_{10}$  (0 to 2%); pentane,  $\text{C}_5\text{H}_{12}$  (0 to 0.5%); hexane,  $\text{C}_6\text{H}_{14}$  (0 to 2%); carbon dioxide,  $\text{CO}_2$  (0 to 2%); oxygen,  $\text{O}_2$  (0 to 1.2%); and nitrogen,  $\text{N}_2$  (0.4 to 17%).

The composition of natural gas depends on its geographical source. Because the gas is drawn from various sources, the composition of gas distributed in a given location can vary slightly, but a fairly constant heating value is usually maintained for control and safety. Local gas utilities are the best sources of current gas composition data for a particular area.

Heating values of natural gases vary from 34 to 45  $\text{MJ/m}^3$ ; the usual range is 37.3 to 39.1  $\text{MJ/m}^3$  at sea level. The heating value for a particular gas can be calculated from the composition data and values in Table 3.

For safety purposes, odorants (such as mercaptans) are added to natural gas and LPG to give them noticeable odors.

**Liquefied petroleum gases (LPG)** consist primarily of propane and butane, and are usually obtained as a byproduct of oil refinery operations or by stripping natural gas. Propane and butane are gaseous under usual atmospheric conditions, but can be liquefied under moderate pressures at normal temperatures.

**Commercial propane** consists primarily of propane but generally contains about 5 to 10% propylene. It has a heating value of about 50.15  $\text{MJ/kg}$ , about 93  $\text{MJ/m}^3$  of gas, or about 25.4  $\text{GJ/m}^3$  of liquid propane. At atmospheric pressure, commercial propane has a boiling point of about  $-40^\circ\text{C}$ . The low boiling point of propane allows it to be used during winter in the northern United States and in Canada. Tank heaters and vaporizers permit its use in colder climates and where high fuel flow rates are required. Propane is available in cylinders, bottles, tank trucks, or tank cars.

Propane-air mixtures are used in place of natural gas in small communities and by natural gas companies to supplement normal supplies at peak loads. Table 4 lists heating values and densities for various fuel-air ratios.

**Table 4 Propane-Air and Butane-Air Gas Mixtures**

Heating Value, $\text{MJ/m}^3$	Propane-Air <sup>a</sup>			Butane-Air <sup>b</sup>		
	% Gas	% Air	Density, $\text{kg/m}^3$	% Gas	% Air	Density, $\text{kg/m}^3$
18	19.16	80.84	1.41	14.81	85.19	1.48
22	23.41	76.59	1.44	18.11	81.89	1.52
26	27.67	72.33	1.46	21.40	78.60	1.56
30	31.93	68.07	1.49	24.69	75.31	1.60
34	36.18	63.82	1.52	27.98	72.02	1.64
38	40.44	59.56	1.54	31.27	68.73	1.68
42	44.70	55.30	1.57	34.57	65.43	1.72
46	48.95	51.05	1.60	37.86	62.14	1.76
50	53.21	46.79	1.63	41.15	58.85	1.80
54	57.47	42.53	1.65	44.44	55.56	1.84
58	61.72	38.28	1.68	47.74	52.26	1.88
62	65.98	34.02	1.71	51.03	48.97	1.92
66	70.24	29.76	1.73	54.32	45.68	1.96

Adapted from *Gas Engineers Handbook* (1965).

Air density at  $0^\circ\text{C}$  and 101.325 kPa is 1.292  $\text{kg/m}^3$ .

<sup>a</sup>Values used for calculation: 93.97  $\text{MJ/m}^3$ ; propane = 1.92  $\text{kg/m}^3$ .

<sup>b</sup>Values used for calculation: 121.5  $\text{MJ/m}^3$ ; butane = 2.53  $\text{kg/m}^3$ .

**Commercial butane** consists primarily of butane but may contain up to 5% butylene. It has a heating value of about 49.3  $\text{MJ/kg}$ , about 120  $\text{MJ/m}^3$  of gas, or about 28.4  $\text{GJ/m}^3$  of liquid butane. At atmospheric pressure, commercial butane has a relatively high boiling point of about  $0^\circ\text{C}$ . Therefore, butane cannot be used in cold weather unless the gas temperature is maintained above  $0^\circ\text{C}$  or the partial pressure is decreased by dilution with a gas having a lower boiling point. Butane is usually available in bottles, tank trucks, or tank cars, but not in cylinders.

Butane-air mixtures are used in place of natural gas in small communities and by natural gas companies to supplement normal supplies at peak loads. Table 4 lists heating values and densities for various fuel-air ratios.

**Commercial propane-butane mixtures** with various ratios of propane and butane are available. Their properties generally fall between those of the unmixed fuels.

**Manufactured gases** are combustible gases produced from coal, coke, oil, liquefied petroleum gases, or natural gas. For more detailed information, see *Gas Engineers Handbook* (1965). These fuels are used primarily for industrial in-plant operations or as specialty fuels (e.g., acetylene for welding).

## LIQUID FUELS

Significant liquid fuels include various fuel oils for firing combustion equipment and engine fuels for on-site energy systems. Liquid fuels, with few exceptions, are mixtures of hydrocarbons derived by refining crude petroleum. In addition to hydrocarbons, crude petroleum usually contains small quantities of sulfur, oxygen, nitrogen, vanadium, other trace metals, and impurities such as water and sediment. Refining produces a variety of fuels and other products. Nearly all lighter hydrocarbons are refined into fuels (e.g., liquefied petroleum gases, gasoline, kerosene, jet fuels, diesel fuels, and light heating oils). Heavy hydrocarbons are refined into residual fuel oils and other products (e.g., lubricating oils, waxes, petroleum coke, and asphalt).

Crude petroleum from different oil fields vary in hydrocarbon molecular structure. Crude is paraffin-base (principally chain-structured paraffin hydrocarbons), naphthene- or asphaltic-base (containing relatively large quantities of saturated ring-structural naphthenes), aromatic-base (containing relatively large quantities of unsaturated, ring-structural aromatics), or mixed- or intermediate-base (between paraffin- and naphthene-base crudes). Except for heavy fuel oils, the crude type has little significant effect on resultant products and combustion applications.

**Types of Fuel Oils**

Fuel oils for heating are broadly classified as **distillate fuel oils** (lighter oils) or **residual fuel oils** (heavier oils). ASTM *Standard D 396* has specifications for fuel oil properties that subdivide the oils into various grades. Grades No. 1 and 2 are distillate fuel oils. Grades 4, 5 (Light), 5 (Heavy), and 6 are residual fuel oils. Specifications for the grades are based on required characteristics of fuel oils for use in different types of burners.

*Grade No. 1* is a light distillate intended for vaporizing-type burners. High volatility is essential to continued evaporation of the fuel oil with minimum residue.

*Grade No. 2* is a heavier distillate than No. 1. It is used primarily with pressure-atomizing (gun) burners that spray the oil into a combustion chamber. The atomized oil vapor mixes with air and burns. This grade is used in most domestic burners and many medium-capacity commercial-industrial burners. A dewaxed No. 2 oil with a pour point of  $-50^{\circ}\text{C}$  is supplied only to areas where regular No. 2 oil would jell.

*Grade No. 4* is an intermediate fuel that is considered either a heavy distillate or a light residual. Intended for burners that atomize oils of higher viscosity than domestic burners can handle, its permissible viscosity range allows it to be pumped and atomized at relatively low storage temperatures.

*Grade No. 5 (Light)* is a residual fuel of intermediate viscosity for burners that handle fuel more viscous than No. 4 without preheating. Preheating may be necessary in some equipment for burning and, in colder climates, for handling.

*Grade No. 5 (Heavy)* is a residual fuel more viscous than No. 5 (Light), but intended for similar purposes. Preheating is usually necessary for burning and, in colder climates, for handling.

*Grade No. 6*, sometimes referred to as Bunker C, is a high-viscosity oil used mostly in commercial and industrial heating. It requires preheating in the storage tank to permit pumping, and additional preheating at the burner to permit atomizing.

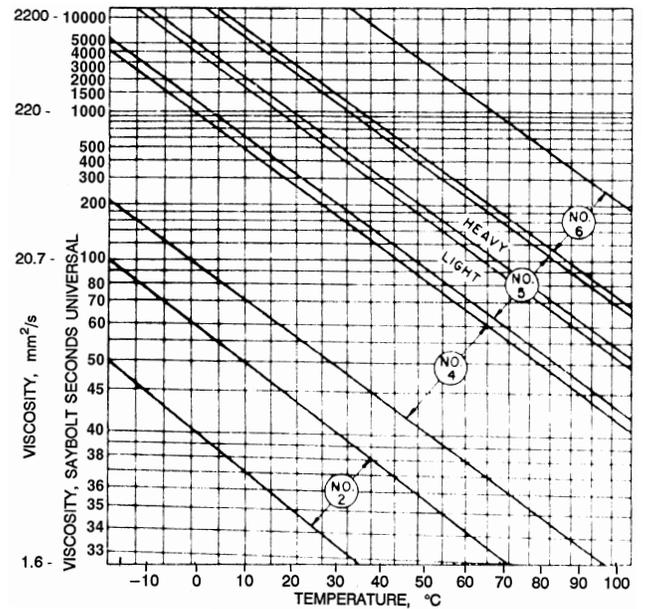

Low-sulfur residual oils are marketed in many areas to permit users to meet sulfur dioxide emission regulations. These fuel oils are produced (1) by refinery processes that remove sulfur from the oil (hydrodesulfurization), (2) by blending high-sulfur residual oils with low-sulfur distillate oils, or (3) by a combination of these methods. These oils have significantly different characteristics from regular residual oils. For example, the viscosity-temperature relationship can be such that low-sulfur fuel oils have viscosities of No. 6 fuel oils when cold, and of No. 4 when heated. Therefore, normal guidelines for fuel handling and burning can be altered when using these fuels.

Fuel oil grade selection for a particular application is usually based on availability and economic factors, including fuel cost, clean air requirements, preheating and handling costs, and equipment cost. Installations with low firing rates and low annual fuel consumption cannot justify the cost of preheating and other methods that use residual fuel oils. Large installations with high annual fuel consumption cannot justify the premium cost of distillate fuel oils.

**Characteristics of Fuel Oils**

Characteristics that determine grade classification and suitability for given applications are (1) viscosity, (2) flash point, (3) pour point, (4) water and sediment content, (5) carbon residue, (6) ash, (7) distillation qualities or distillation temperature ranges, (8) density, (9) sulfur content, (10) heating value, and (11) carbon-hydrogen content. Not all of these are included in ASTM *Standard D 396*.

**Viscosity** is an oil's resistance to flow. It is significant because it indicates the ease at which oil flows or can be pumped and the ease of atomization. Differences in fuel oil viscosities are caused by variations in the concentrations of fuel oil constituents and different

**Fig. 1 Approximate Viscosity of Fuel Oils**

refining methods. Approximate viscosities of fuel oils are shown in Figure 1.

**Flash point** is the lowest temperature to which an oil must be heated for its vapors to ignite in a flame. Minimum permissible flash point is usually prescribed by state and municipal laws.

**Pour point** is the lowest temperature at which a fuel can be stored and handled. Fuels with higher pour points can be used when heated storage and piping facilities are provided.

**Water and sediment content** should be low to prevent fouling the facilities. Sediment accumulates on filter screens and burner parts. Water in distillate fuels can cause tanks to corrode and emulsions to form in residual oil.

**Carbon residue** is obtained by a test in which the oil sample is destructively distilled in the absence of air. When commercial fuels are used in proper burners, this residue has almost no relationship to soot deposits, except indirectly when deposits are formed by vaporizing burners.

**Ash** is the noncombustible material in an oil. An excessive amount indicates the presence of materials that cause high wear on burner pumps.

The **distillation** test shows the volatility and ease of vaporization of a fuel.

**Relative density** is the ratio of the density of a fuel oil to the density of water at a specific temperature. Relative densities cover a range in each grade, with some overlap between distillate and residual grades.

Air pollution considerations are important in determining the allowable **sulfur content** of fuel oils. Sulfur content is frequently limited by legislation aimed at reducing sulfur oxide emissions from combustion equipment. These laws require sulfur content to be below a certain level, usually 1.0, 0.5, or 0.3%. Table 5 lists sulfur levels of some marketed fuel oils.

Sulfur in fuel oils is also undesirable because of the corrosiveness of sulfur compounds in the flue gas. Although low-temperature corrosion can be minimized by maintaining the stack at temperatures above the dew point of the flue gas, this limits the overall thermal efficiency of combustion equipment.

For certain industrial applications, the sulfur content of a fuel must be limited because of adverse effects on product quality. The

Table 5 Sulfur Content of Marketed Fuel Oils

Grade of Oil	No. 1		No. 2		No. 4		No. 5 (Light)	No. 5 (Heavy)	No. 6
	No. 1	No. 2	No. 4	No. 5 (Light)	No. 5 (Heavy)	No. 6

Data for No. 4, 5, and 6 oil derived from Shelton (1974).

Table 6 Typical Density and Higher Heating Value of Standard Grades of Fuel Oil

Grade No.	Density, kg/m <sup>3</sup>	Higher Heating Value, GJ/m <sup>3</sup>
1	833 to 800	38.2 to 37.0
2	874 to 834	39.5 to 38.2
4	933 to 886	41.3 to 39.9
5L	951 to 921	41.8 to 40.9
5H	968 to 945	42.4 to 41.6
6	1012 to 965	43.5 to 42.2

applications include direct-fired metallurgy where work is performed in the combustion zone.

**Heating value** is an important property, although ASTM *Standard D 396* does not list it as one of the criteria for fuel oil classification. Heating value can generally be correlated with the API gravity. Table 6 shows the relationship between heating value, API gravity, and density for several oil grades. In the absence of more specific data, heating values can be calculated as derived from the *North American Combustion Handbook* (1978):

$$\begin{aligned} \text{Higher heating value, MJ/kg} \\ = 51.92 - 8.79 \times 10^{-6} \rho^2 \end{aligned} \quad (1)$$

where  $\rho$  is oil density in kilograms per cubic metre.

Distillate fuel oils (Grades 1 and 2) have a carbon-hydrogen content of 84 to 86% carbon, with the remainder predominantly hydrogen. The heavier residual fuel oils (Grades 4, 5, and 6) may contain up to 88% carbon and as little as 11% hydrogen. An approximate relationship for determining the hydrogen content of fuel oils is

$$\text{Hydrogen, \%} = 26 - \left( \frac{15\rho}{1000} \right) \quad (2)$$

ASTM *Standard D 396* is more a classification than a specification, distinguishing between six generally nonoverlapping grades, one of which characterizes any commercial fuel oil. Quality is not defined, as a refiner might control it; for example, the standard lists the distillation temperature 90% point for Grade No. 2 as having a maximum of 338°C, whereas commercial practice rarely exceeds 315°C.

### Types and Properties of Liquid Fuels for Engines

The primary stationary engine fuels are diesel and gas turbine oils, natural gases, and liquefied petroleum gases. Other fuels include sewage gas, manufactured gas, and gas mixtures. Gasoline

and the JP series of gas turbine fuels are rarely used for stationary engines.

Only properties of diesel and gas turbine fuel oils are covered here; properties of natural and liquefied petroleum gases are found in the section on Gaseous Fuels. For properties of gasolines and JP turbine fuel, consult texts on internal combustion engines and gas turbines. Properties of currently marketed gasolines can be found in the latest volumes of *Mineral Industry Surveys, Motor Gasolines*, issued semiannually by the U.S. Bureau of Mines.

Properties of the three grades of diesel fuel oils (1-D, 2-D, and 4-D) are listed in ASTM *Standard D 975*.

*Grade No. 1-D* includes the class of volatile fuel oils from kerosene to intermediate distillates. These fuels are used in high-speed engines with frequent and relatively wide variations in loads and speeds and where abnormally low fuel temperatures are encountered.

*Grade No. 2-D* includes the class of lower volatility distillate gas oils. These fuels are used in high-speed engines with relatively high loads and uniform speeds, or in engines not requiring fuels with the higher volatility or other properties specified for Grade No. 1-D.

*Grade No. 4-D* covers the class of more viscous distillates and blends of these distillates with residual fuel oils. These fuels are used in low- and medium-speed engines involving sustained loads at essentially constant speed.

Property specifications and test methods for Grade No. 1-D, 2-D, and 4-D diesel fuel oils are essentially identical to specifications of Grade No. 1, 2, and 4 fuel oils, respectively. However, diesel fuel oils have an additional specification for **cetane number**, which measures ignition quality and influences combustion roughness. Cetane number requirements depend on engine design, size, speed and load variations, and starting and atmospheric conditions. An increase in cetane number over values actually required does not improve engine performance. Thus, the cetane number should be as low as possible to assure maximum fuel availability. ASTM *Standard D 975* provides several methods for estimating cetane number from other fuel oil properties.

ASTM *Standard D 2880* for gas turbine fuel oils relates gas turbine fuel oil grades to fuel and diesel fuel oil grades. Test methods for determining properties of gas turbine fuel oils are essentially identical to those for fuel oils. However, gas turbine specifications contain quantity limits on some trace elements that may be present. These limits are intended to prevent excessive corrosion in gas turbine engines. For a detailed discussion of fuels for gas turbines and combustion in gas turbines, see Chapters 5 and 9, respectively, in Hazard (1971).

### SOLID FUELS

Solid fuels include coal, coke, wood, and waste products of industrial and agricultural operations. Of these, only coal is widely used for heating and cooling applications.

The complex composition of coal makes classification difficult. Chemically, coal consists of carbon, hydrogen, oxygen, nitrogen, sulfur, and a mineral residue, ash. Chemical analysis provides some indication of coal quality, but does not define its burning characteristics sufficiently. The coal user is principally interested in the available heat per unit mass of coal and the amount of ash and dust produced, but is also interested in burning characteristics and handling and storing properties. A description of coal qualities and their characteristics can be obtained from the U.S. Bureau of Mines.

### Types of Coals

Commonly accepted definitions for classifying coals are listed in Table 7. This classification is arbitrary because there are no distinct demarcation lines between coal types.

**Anthracite** is a clean, dense, hard coal that creates little dust in handling. It is comparatively hard to ignite, but burns freely once

Table 7 Classification of Coals by Rank<sup>a</sup>

Class	Group	Limits of Fixed Carbon or Energy Content, Mineral-Matter-Free Basis	Requisite Physical Properties
I Anthracite	1. Metaanthracite	Dry FC, 98% or more (Dry VM, 2% or less)	Nonagglomerating
	2. Anthracite	Dry FC, 92% or more, and less than 98% (Dry VM, 8% or less, and more than 2%)	
	3. Semianthracite	Dry FC, 86% or more, and less than 92% (Dry VM, 14% or less, and more than 8%)	
II Bituminous <sup>d</sup>	1. Low-volatile bituminous coal	Dry FC, 78% or more, and less than 86% (Dry VM, 22% or less, and more than 14%)	Either agglomerating <sup>b</sup> or nonweathering <sup>f</sup>
	2. Medium-volatile bituminous coal	Dry FC, 69% or more, and less than 78% (Dry VM, 31% or less, and more than 22%)	
	3. High-volatile A bituminous coal	Dry FC, less than 69% (Dry VM, more than 31%), and moist <sup>c</sup> , about 32.6 MJ/kg <sup>e</sup> or more	
	4. High-volatile B bituminous coal	Moist <sup>c</sup> , about 30.2 MJ/kg or more, and less than 32.6 MJ/kg <sup>e</sup>	
	5. High-volatile C bituminous coal	Moist <sup>c</sup> , about 25.6 MJ/kg or more, and less than 30.2 MJ/kg <sup>e</sup>	
III Subbituminous	1. Subbituminous A coal	Moist <sup>c</sup> , about 25.6 MJ/kg or more, and less than 30.2 MJ/kg <sup>e</sup>	Both weathering and nonagglomerating <sup>b</sup>
	2. Subbituminous B coal	Moist <sup>c</sup> , about 22.1 MJ/kg or more, and less than 25.6 MJ/kg <sup>e</sup>	
	3. Subbituminous C coal	Moist <sup>c</sup> , about 19.3 MJ/kg or more, and less than 22.1 MJ/kg <sup>e</sup>	
IV Lignitic	1. Lignite	Moist <sup>c</sup> , less than 19.3 MJ/kg	Consolidated
	2. Brown coal	Moist <sup>c</sup> , less than 19.3 MJ/kg	Unconsolidated

Source: Adapted from ASTM Standard D 388, Standard Classification of Coals by Rank. FC = Fixed Carbon; VM = Volatile Matter.

<sup>a</sup>This classification does not include a few coals of unusual physical and chemical properties which come within the limits of fixed carbon or Btu of high-volatile bituminous and subbituminous ranks. All these coals either contain less than 48% dry, mineral-matter-free fixed carbon, or have more than about 36.1 MJ/kg, which is moist, mineral-matter-free.

<sup>b</sup>If agglomerating, classify in low-volatile group of the bituminous class.

<sup>c</sup>Moist refers to coal containing its natural bed moisture but not including visible water on the coal surface.

<sup>d</sup>There may be noncaking varieties in each group of the bituminous class.

<sup>e</sup>Coals having 69% or more fixed carbon on the dry, mineral-matter-free basis shall be classified according to fixed carbon, regardless of energy content.

<sup>f</sup>There are three varieties of coal in the high-volatile C bituminous coal group: Variety 1, agglomerating and nonweathering; Variety 2, agglomerating and weathering; and Variety 3, nonagglomerating and nonweathering.

started. It is noncaking and burns uniformly and smokelessly with a short flame.

**Semianthracite** has a higher volatile content than anthracite. It is not as hard and ignites more easily. Otherwise, its properties are similar to those of anthracite.

**Bituminous coal** includes many types of coal with distinctly different compositions, properties, and burning characteristics. Coals range from high-grade bituminous, such as those found in the eastern United States, to low-rank coals, such as those found in the western United States. Caking properties range from coals that melt or become fully plastic, to those from which volatiles and tars are distilled without changing form (classed as noncaking or free-burning). Most bituminous coals are strong and nonfriable enough to permit screened sizes to be delivered free of fines. Generally, they ignite easily and burn freely. Flame length is long and varies with different coals. If improperly fired, much smoke and soot are possible, especially at low burning rates.

**Semibituminous coal** is soft and friable, and handling creates fines and dust. It ignites slowly and burns with a medium-length flame. Its caking properties increase as volatile matter increases, but the coke formed is weak. With only half the volatile matter content of bituminous coals, burning produces less smoke; hence, it is sometimes called smokeless coal.

**Subbituminous coal**, such as that found in the western United States, is high in moisture when mined and tends to break up as it dries or is exposed to the weather; it is likely to ignite spontaneously when piled or stored. It ignites easily and quickly, has a medium-length flame, and is noncaking and free-burning. The lumps tend to break into small pieces if poked. Very little smoke and soot are formed.

**Lignite** is woody in structure, very high in moisture when mined, of low heating value, and clean to handle. It has a greater tendency than subbituminous coals to disintegrate as it dries and is also more likely to ignite spontaneously. Because of its high moisture, freshly

mined lignite ignites slowly and is noncaking. The char left after moisture and volatile matter are driven off burns very easily, like charcoal. The lumps tend to break up in the fuel bed and pieces of char that fall into the ash pit continue to burn. Very little smoke or soot forms.

**Characteristics of Coal**

The characteristics of coals that determine classification and suitability for given applications are the proportions of (1) volatile matter, (2) fixed carbon, (3) moisture, (4) sulfur, and (5) ash. Each of these is reported in the proximate analysis. Coal analyses can be reported on several bases: as-received, moisture-free (or dry), and mineral-matter-free (or ash-free). As-received is applicable for combustion calculations; moisture-free and mineral-matter-free, for classification purposes.

**Volatile matter** is driven off as gas or vapor when the coal is heated according to a standard temperature test. It consists of a variety of organic gases, generally resulting from distillation and decomposition. Volatile products given off by coals when heated differ materially in the ratios (by mass) of the gases to oils and tars. No heavy oils or tars are given off by anthracite, and very small quantities are given off by semianthracite. As volatile matter in the coal increases to as much as 40% of the coal (dry and ash-free basis), increasing amounts of oils and tars are released. However, for coals of higher volatile content, the quantity of oils and tars decreases and is relatively low in the subbituminous coals and in lignite.

**Fixed carbon** is the combustible residue left after the volatile matter is driven off. It is not all carbon. Its form and hardness are an indication of fuel coking properties and, therefore, guide the choice of combustion equipment. Generally, fixed carbon represents that portion of fuel that must be burned in the solid state.

**Moisture** is difficult to determine accurately because a sample can lose moisture on exposure to the atmosphere, particularly when

Table 8 Typical Ultimate Analyses for Coals

Rank	As Received, MJ/kg	Constituents, % by Mass					Ash
		Oxy-gen	Hydro-gen	Car-bon	Nitro-gen	Sul-fur	
Anthracite	29.5	5.0	2.9	80.0	0.9	0.7	10.5
Semianthracite	31.6	5.0	3.9	80.4	1.1	1.1	8.5
Low-volatile bituminous	33.4	5.0	4.7	81.7	1.4	1.2	6.0
Medium-volatile bituminous	32.6	5.0	5.0	81.4	1.4	1.5	6.0
High-volatile bituminous A	32.1	9.3	5.3	75.9	1.5	1.5	6.5
High-volatile bituminous B	29.1	13.8	5.5	67.8	1.4	3.0	8.5
High-volatile bituminous C	25.6	20.6	5.8	59.6	1.1	3.5	9.4
Subbituminous B	20.9	29.5	6.2	52.5	1.0	1.0	9.8
Subbituminous C	19.8	35.7	6.5	46.4	0.8	1.0	9.6
Lignite	16.0	44.0	6.9	40.1	0.7	1.0	7.3

reducing the sample size for analysis. To correct for this loss, total moisture content of a sample is customarily determined by adding the moisture loss obtained when air-drying the sample to the measured moisture content of the dried sample. Moisture does not represent all of the water present in coal; water of decomposition (combined water) and of hydration are not given off under standardized test conditions.

**Ash** is the noncombustible residue remaining after complete coal combustion. Generally, the mass of ash is slightly less than that of mineral matter before burning.

**Sulfur** is an undesirable constituent in coal, because the sulfur oxides formed when it burns contribute to air pollution and cause combustion system corrosion. Table 8 lists the sulfur content of typical coals. Legislation has limited the sulfur content of coals burned in certain locations.

**Heating value** may be reported on an as-received, dry, dry and mineral-matter-free, or moist and mineral-matter-free basis. Higher heating values of coals are frequently reported with their proximate analysis. When more specific data are lacking, the higher heating value of higher quality coals can be calculated by the Dulong formula:

$$\begin{aligned} \text{Higher heating value, MJ/kg} \\ = 33.829C + 144.28[H - (O/8)] + 9.42S \end{aligned} \quad (3)$$

where C, H, O, and S are the mass fractions of carbon, hydrogen, oxygen, and sulfur in the coal.

Other important parameters in judging coal suitability include

1. **Ultimate analysis**, which is another method of reporting coal composition. Percentages of C, H, O, N, S, and ash in the coal sample are reported. Ultimate analysis is used for detailed fuel studies and for computing a heat balance when required in heating device testing. Typical ultimate analyses of various coals are shown in Table 8.
2. **Ash-fusion temperature**, which indicates the fluidity of the ash at elevated temperatures. It is helpful in selecting coal to be burned in a particular furnace and in estimating the possibility of ash handling and slagging problems.
3. The **grindability index**, which indicates the ease with which a coal can be pulverized and is helpful in estimating ball mill capacity with various coals. There are two common methods for determining the index—Hardgrove and ball mill.

4. The **free-swelling index**, which denotes the extent of coal swelling on combustion on a fuel bed and indicates the coking characteristics of coal.

## COMBUSTION CALCULATIONS

Calculations of the quantity of air required for combustion and the quantity of flue gas products generated during combustion are frequently needed for sizing system components and as input to efficiency calculations. Other calculations, such as values for excess air and theoretical CO<sub>2</sub>, are useful in estimating combustion system performance.

Frequently, combustion calculations can be simplified by using relative molecular mass. The relative molecular mass of a compound equals the sum of the atomic masses of the elements in the compound. Molecular mass can be expressed in any mass units. The gram molecular mass or gram mole is the molecular mass of the compound expressed in grams. The molecular mass of any substance contains the same number of molecules as the molecular mass of any other substance.

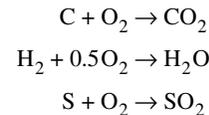

Corresponding to measurement standards common to the industries, calculations involving gaseous fuels are generally based on volume, and calculations involving liquid and solid fuels are generally based on mass.

Some calculations described here require data on concentrations of carbon dioxide, carbon monoxide, and oxygen in the flue gas. Gas analyses for CO<sub>2</sub>, CO, and O<sub>2</sub> can be obtained by volumetric chemical analysis and other analytical techniques, including electromechanical cells used in portable electronic flue gas analyzers.

### Air Required for Combustion

Stoichiometric or theoretical air is the exact quantity of air required to provide oxygen for complete combustion.

The three most prevalent components in hydrocarbon fuels (C, H<sub>2</sub>, and S) are completely combusted as in the following reactions:

In the reactions, C, H<sub>2</sub>, and S can be taken to represent 1 kg mole of carbon, hydrogen, and sulfur, respectively. Using approximate atomic masses (C = 12, H = 1, S = 32, and O = 16), 12 kg of C are oxidized by 32 kg of O<sub>2</sub> to form 44 kg of CO<sub>2</sub>, 2 kg of H<sub>2</sub> are oxidized by 16 kg of O<sub>2</sub> to form 18 kg of H<sub>2</sub>O, and 32 kg of S are oxidized by 32 kg of O<sub>2</sub> to form 64 kg of SO<sub>2</sub>. These relationships can be extended to include hydrocarbons.

The mass of dry air required to supply a given quantity of oxygen is 4.32 times the mass of the oxygen. The mass of air required to oxidize the fuel constituents listed in Table 1 was calculated on this basis. Oxygen contained in the fuel, except that contained in ash, should be deducted from the amount of oxygen required, because this oxygen is already combined with fuel components. In addition, when calculating the mass of air to be supplied for combustion, allowance should be made for water vapor, which is always present in atmospheric air.

As stated previously, combustion calculations for gaseous fuels are based on volume. Avogadro's law states that, for any gas, one mole occupies the same volume at a given temperature and pressure. Therefore, in reactions involving gaseous compounds, the gases react in volume ratios identical to the pound mole ratios. That is, for the oxidation of hydrogen in the above reaction, one volume (or one kg mole) of hydrogen reacts with one-half volume (or one-half kg mole) of oxygen to form one volume (or one kg mole) of water vapor.

The volume of air required to supply a given volume of oxygen is 4.78 times the volume of oxygen. The volumes of dry air required to oxidize the fuel constituents listed in Table 1 were calculated on this basis. Volume ratios are not given for fuels that do not exist in vapor form at reasonable temperatures or pressures. Again, oxygen contained in the fuel should be deducted from the quantity of oxygen required, because this oxygen is already combined with fuel components. Allowance should be made for water vapor, which increases the volume of dry air by 1 to 3%.

From the relationships just described, the theoretical mass  $m_a$  of dry air required for stoichiometric combustion of a unit mass of any hydrocarbon fuel is

$$m_a = 0.0144(8C + 24H + 3S - 3O) \tag{4}$$

where C, H, S, and O are the mass percentages of carbon, hydrogen, sulfur, and oxygen in the fuel.

Analyses of gaseous fuels are generally based on hydrocarbon components rather than elemental content.

If the fuel analysis is based on mass, the theoretical mass  $m_a$  of dry air required for stoichiometric combustion of a unit mass of gaseous fuel is

$$m_a = 2.47CO + 34.28H_2 + 17.24CH_4 + 16.09C_2H_6 + 15.68C_3H_8 + 15.47C_4H_{10} + 13.27C_2H_2 + 14.78C_2H_4 + 6.08H_2S - 4.32O_2 \tag{5}$$

If the fuel analysis is reported on a volumetric or molecular basis, it is simplest to calculate air requirements based on volume and, if necessary, convert to mass. The theoretical volume  $V_a$  of air required for stoichiometric combustion of a unit volume of gaseous fuels is

$$V_a = 2.39CO + 2.39H_2 + 9.57CH_4 + 16.75C_2H_6 + 23.95C_3H_8 + 31.14C_4H_{10} + 11.96C_2H_2 + 14.38C_2H_4 + 7.18H_2S - 4.78O_2 + 30.47 \text{ illuminants} \tag{6}$$

where CO, H<sub>2</sub>, and so forth are the volumetric fractions of each constituent in the fuel gas.

**Illuminants** include a variety of compounds not separated by usual gas analysis. In addition to ethylene (C<sub>2</sub>H<sub>4</sub>) and acetylene (C<sub>2</sub>H<sub>2</sub>), the principal illuminants included in Equation (7), and the dry air required for combustion, per unit volume of each gas, are: propylene (C<sub>3</sub>H<sub>6</sub>), 21.44; butylene (C<sub>4</sub>H<sub>8</sub>), 28.58; pentene (C<sub>5</sub>H<sub>10</sub>), 35.73; benzene (C<sub>6</sub>H<sub>6</sub>); 35.73, toluene (C<sub>7</sub>H<sub>8</sub>), 42.88; and xylene (C<sub>8</sub>H<sub>10</sub>), 50.02. Because toluene and xylene are normally scrubbed from the gas before distribution, they can be disregarded in computing air required for combustion of gaseous fuels. The percentage of illuminants present in gaseous fuels is small, so the values can be lumped together, and an approximate value of 30 unit volumes of dry air per unit volume of gas can be used. If ethylene and acetylene are included as illuminants, a value of 20 unit volumes of dry air per unit volume of gaseous illuminants can be used.

For many combustion calculations, only approximate values of air requirements are necessary. If approximate values for theoretical air are sufficient, or if complete information on the fuel is not available, the values in Tables 9 and 10 can be used. Another value used for estimating air requirements is 0.24 m<sup>3</sup> of air for 1 MJ of fuel.

In addition to the amount theoretically required for combustion, **excess air** must be supplied to most practical combustion systems to ensure complete combustion.

**Table 9 Approximate Air Requirements for Stoichiometric Combustion of Fuels**

Type of Fuel	Air Required		Approx. Precision, %	Exceptions
	kg/kg Fuel	m <sup>3</sup> /Unit Fuel <sup>a</sup>		
Solid	MJ/kg × 0.314	MJ/kg × 0.26	3	Fuels containing more than 30% water
Liquid	MJ/kg × 0.305	MJ/kg × 0.35	3	Results low for gasoline and kerosene
Gas	MJ/kg × 0.288	MJ/m <sup>3</sup> × 0.24	5	11.2 MJ/m <sup>3</sup> or less

<sup>a</sup>Unit fuel for solid and liquid fuels in kg, for gas in m<sup>3</sup>.

**Table 10 Approximate Air Requirements for Stoichiometric Combustion of Various Fuels**

Type of Fuel	Theoretical Air Required for Combustion
Solid fuels	kg/kg fuel
Anthracite	9.6
Semibituminous	11.2
Bituminous	10.3
Lignite	6.2
Coke	11.2
Liquid fuels	Mg/m <sup>3</sup> fuel
No. 1 fuel oil	12.34
No. 2 fuel oil	12.70
No. 5 fuel oil	13.42
No. 6 fuel oil	13.66
Gaseous fuels	m <sup>3</sup> /m <sup>3</sup> fuel
Natural gas	9.6
Butane	31.1
Propane	24.0

$$\text{Excess air, \%} = \frac{\text{Air supplied} - \text{Theoretical air}}{\text{Theoretical air}} \tag{7}$$

The excess air level at which a combustion process operates significantly affects its overall efficiency. Too much excess air dilutes flue gas excessively, lowering its heat transfer temperature and increasing sensible flue gas loss. Conversely, if the level of excess air is too low, incomplete combustion and loss of unburned combustible gases from the equipment can result. The highest combustion efficiency is usually obtained when just enough excess air is supplied and properly mixed with combustible gases to ensure complete combustion. The general practice is to supply from 5 to 50% excess air, the exact amount depending on the type of fuel burned, combustion equipment, and other factors.

The amount of dry air supplied per unit mass of fuel burned can be obtained from the following equation, which is reasonably precise for most solid and liquid fuels.

$$\text{Dry air supplied} = \frac{C(3.04N_2)}{CO_2 + CO} \tag{8}$$

where

Dry air supplied = unit mass per unit mass of fuel

C = unit mass of carbon burned per unit mass of fuel, corrected for carbon in the ash

CO<sub>2</sub>, CO, N<sub>2</sub> = percentages by volume from the flue gas analysis

These values of dry air supplied and theoretical air can be used in Equation (7) to determine excess air.

Excess air can also be calculated from unit volumes of stoichiometric combustion products and air, and from volumetric analysis of the flue gas:

$$\text{Excess air, \%} = 100 \left( \frac{P}{A} \right) \left( \frac{U - \text{CO}_2}{\text{CO}_2} \right) \quad (9)$$

where

$U$  = ultimate carbon dioxide of flue gases resulting from stoichiometric combustion, %

$\text{CO}_2$  = carbon dioxide content of flue gases, %

$P$  = dry products from stoichiometric combustion, unit volume per unit volume of gas burned

$A$  = air required for stoichiometric combustion, unit volume per unit volume of gas burned

As the ratio  $P/A$  is approximately 0.9 for most natural gases, a value of 90 can be substituted for 100 ( $P/A$ ) in Equation (9) for rough calculation.

Because excess air calculations are almost invariably made from flue gas analysis results and theoretical air requirements are not always known, another convenient method of expressing the relation of Equation (7) is

$$\text{Excess air, \%} = \frac{100[\text{O}_2 - (\text{CO}/2)]}{0.264\text{N}_2 - [\text{O}_2 - (\text{CO}/2)]} \quad (10)$$

where  $\text{O}_2$ ,  $\text{CO}$ , and  $\text{N}_2$  are percentages by volume from the flue gas analysis.

### Theoretical $\text{CO}_2$

The theoretical  $\text{CO}_2$ , ultimate  $\text{CO}_2$ , stoichiometric  $\text{CO}_2$ , or maximum  $\text{CO}_2$  concentration attainable in the products from the combustion of a hydrocarbon fuel with air is obtained when the fuel is completely burned with the theoretical quantity of air and zero excess air. Theoretical  $\text{CO}_2$  varies with the carbon-hydrogen ratio of the fuel. For combustion with excess air present, theoretical  $\text{CO}_2$  values can be calculated from the flue gas analysis:

$$\text{Theoretical } \text{CO}_2, \% = U = \frac{\text{CO}_2}{1 - (\text{O}_2/20.95)} \quad (11)$$

where  $\text{CO}_2$  and  $\text{O}_2$  are percentages by volume from the flue gas analysis.

Table 11 gives approximate theoretical  $\text{CO}_2$  values for stoichiometric combustion of several common types of fuel, as well as  $\text{CO}_2$  values attained with different amounts of excess air. In practice, desirable  $\text{CO}_2$  values depend on the excess air, fuel, firing method, and other considerations.

### Quantity of Flue Gas Produced

The mass of dry flue gas produced per mass of fuel burned is required in heat loss and efficiency calculations. This mass is equal to the sum of the mass of (1) fuel (minus ash retained in the furnace), (2) air theoretically required for combustion, and (3) excess air. For solid fuels, this mass, determined from the flue gas analysis, is

$$\text{Dry flue gas} = \frac{11\text{CO}_2 + 8\text{O}_2 + 7(\text{CO} + \text{N}_2)}{3(\text{CO}_2 + \text{CO})} C \quad (12)$$

where

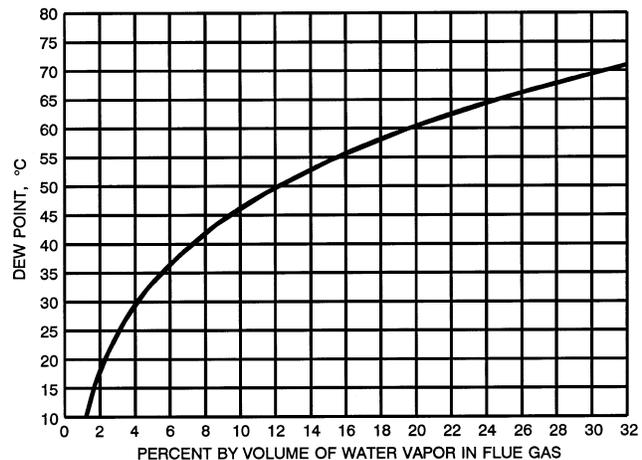

Dry flue gas = kg/kg of fuel

$C$  = kg of carbon burned per kg of fuel, corrected for carbon in the ash

$\text{CO}_2$ ,  $\text{O}_2$ ,  $\text{CO}$ ,  $\text{N}_2$  = percentages by volume from flue gas analysis

**Table 11 Approximate Maximum Theoretical (Stoichiometric)  $\text{CO}_2$  Values, and  $\text{CO}_2$  Values of Various Fuels with Different Percentages of Excess Air**

Type of Fuel	Theoretical or Maximum $\text{CO}_2$ , %	Percent $\text{CO}_2$ at Given Excess Air Values		
		20%	40%	60%
<b>Gaseous Fuels</b>				
Natural gas	12.1	9.9	8.4	7.3
Propane gas (commercial)	13.9	11.4	9.6	8.4
Butane gas (commercial)	14.1	11.6	9.8	8.5
Mixed gas (natural and carbureted water gas)	11.2	12.5	10.5	9.1
Carbureted water gas	17.2	14.2	12.1	10.6
Coke oven gas	11.2	9.2	7.8	6.8
<b>Liquid Fuels</b>				
No. 1 and 2 fuel oil	15.0	12.3	10.5	9.1
No. 6 fuel oil	16.5	13.6	11.6	10.1
<b>Solid Fuels</b>				
Bituminous coal	18.2	15.1	12.9	11.3
Anthracite	20.2	16.8	14.4	12.6
Coke	21.0	17.5	15.0	13.0

**Fig. 2 Water Vapor and Dew Point of Flue Gas**

Adapted from *Gas Engineers Handbook* (1965). Printed with permission of Industrial Press and American Gas Association.

The total dry gas volume of flue gases from combustion of one unit volume of gaseous fuels for various percentages of  $\text{CO}_2$  is

$$\text{Dry flue gas} = \left( \frac{\text{vol. of } \text{CO}_2 \text{ produced}}{\text{unit vol. of gas burned}} \right) \left( \frac{100}{\text{CO}_2} \right) \quad (13)$$

where

Dry flue gas = unit volume per unit volume of gaseous fuel

$\text{CO}_2$  = percentage by volume from the flue gas analysis

Excess air quantity can be estimated by subtracting the quantity of dry flue gases resulting from stoichiometric combustion from the total volume of flue gas.

### Water Vapor and Dew Point of Flue Gas

Water vapor in flue gas is the total of (1) the water contained in the fuel; (2) the water contained in the stoichiometric and excess air; and (3) the water produced from the combustion of hydrogen or hydrocarbons in the fuel. The amount of water vapor in the stoichi-

ometric combustion products may be calculated from the fuel burned by using the water data in Table 1.

The dew point is the temperature at which condensation begins and can be determined using Figure 2. The volume fraction of water vapor in the flue gas can be determined as follows:

$$P_{wv} = \frac{V_w}{(100V_c/P_c) + V_w} \tag{14}$$

where

- $V_w$  = total water vapor volume (from fuel; from stoichiometric, excess, and dilution air; and from combustion)
- $V_c$  = unit volume of CO<sub>2</sub> produced per unit volume of gaseous fuel
- $P_c$  = percent CO<sub>2</sub> in flue gas

Using Figure 3, the dew points of solid, liquid, or gaseous fuels may be estimated. For example, to find the dew point of flue gas resulting from the combustion of a solid fuel with a mass ratio (hydrogen to carbon-plus-sulfur) of 0.088 and sufficient excess air to produce 11.4% oxygen in the flue gas, start with the mass ratio of 0.088. Proceed vertically to the intersection of the solid fuels curve and then to the theoretical dew point of 46°C on the dew-point scale (see dotted lines in Figure 3). Follow the curve fixed by this point (down and to the right) to 11.4% oxygen in the flue gas (on the abscissa). The actual dew point is 34°C and is found on the dew-point scale.

An estimation can be made of the dew point of the flue gas from natural gas having a higher heating value (HHV) of 38 MJ/m<sup>3</sup> with 6.3% oxygen or 31.5% air. Start with 38 MJ/m and proceed vertically to the intersection of the gaseous fuels curve and then to the theoretical dew point of 59°C on the dew-point scale. Follow the

curve fixed by this point to 6.3% oxygen or 31.5% air in the flue gas. The actual dew point is 53°C.

The presence of sulfur dioxide, and particularly sulfur trioxide, influences the vapor pressure of condensate in flue gas, and the dew point can be raised by as much as 14 to 42 K, as shown in Figure 4. To illustrate the use of Figure 4, for a manufactured gas with a HHV of 20.5 MJ/m<sup>3</sup> containing 340 mg of sulfur per cubic metre being burned with 40% excess air, the proper curve in Figure 4 is determined as follows:

$$\frac{\text{Mass of sulfur in fuel, mg/m}^3}{\text{Fuel heating value, MJ/m}^3} = \frac{340}{20.5} = 16.6 \tag{15}$$

This curve lies between the 0 and 20 curves and is close to the 20 curve. The dew point for any percentage of excess air from zero to 100% can be determined on this curve. For this flue gas with 40% excess air, the dew point is about 71°C, instead of 53°C for zero sulfur at 40% excess air.

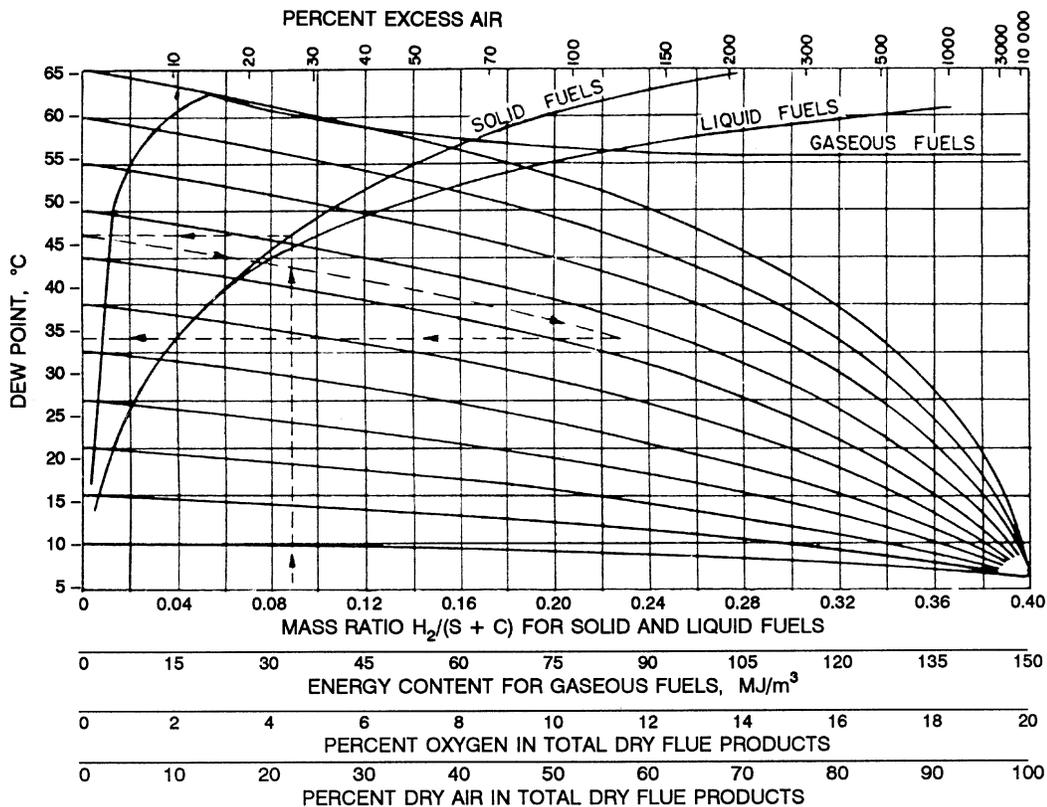

**Sample Combustion Calculations**

**Example 1.** Analysis of flue gases from the burning of a natural gas shows 10.0% CO<sub>2</sub>, 3.1% O<sub>2</sub>, and 86.9% N<sub>2</sub> by volume. Analysis of the fuel is 90% CH<sub>4</sub>, 5% N<sub>2</sub>, and 5% C<sub>2</sub>H<sub>6</sub> by volume. Find *U* (maximum theoretical percent CO<sub>2</sub>), and the percentage of excess air.

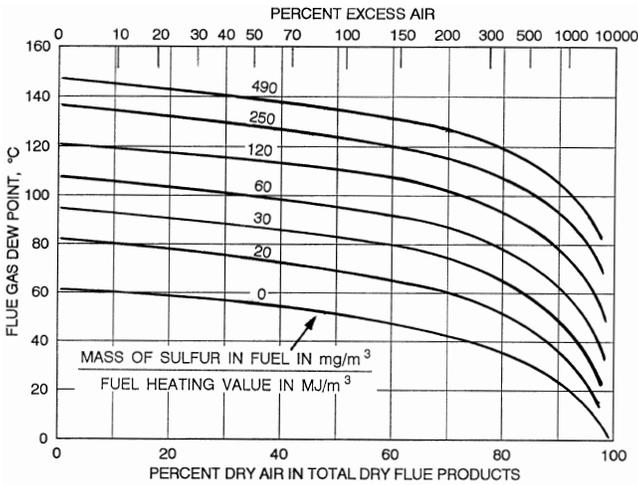

**Solution:** From Equation (11),

$$U = \frac{10.0}{1 - (3.1/20.95)} = 11.74\% \text{ CO}_2$$

From Equation (9), using 100 (*P/A*) = 90,

**Fig. 3 Theoretical Dew Points of Combustion Products of Industrial Fuels**  
Adapted from *Gas Engineers Handbook* (1965). Printed with permission of Industrial Press and American Gas Association.

**Fig. 4 Influence of Sulfur Oxides on Flue Gas Dew Point**  
(Stone 1969)

$$\text{Excess air} = \frac{(11.74 - 10.0)90}{10} = 15.7\%$$

**Example 2.** For the same analysis as in Example 1, find, per cubic metre of fuel gas, the volume of dry air required for combustion, the volume of each constituent in the flue gases, and the total volume of dry and wet flue gases.

**Solution:** From Equation (6), the volume of dry air required for combustion is:

$$\begin{aligned} 9.57\text{CH}_4 + 16.75\text{C}_2\text{H}_6 &= (9.57 \times 0.90) + (16.75 \times 0.05) \\ &= 9.45 \text{ m}^3 \text{ per m}^3 \text{ of fuel gas} \end{aligned}$$

(The volume of dry air may also be calculated using Table 10.)

From Table 1, the cubic metres of flue gas constituents per cubic metre of fuel gas are as follows:

Nitrogen, N <sub>2</sub>			
From methane	(0.9CH <sub>4</sub> )(9.57 - 2.0)	=	6.81
From ethane	(0.05C <sub>2</sub> H <sub>6</sub> )(16.75 - 3.5)	=	0.66
Nitrogen in fuel		=	0.05
Nitrogen in excess air	0.791 × 0.157 × 9.45	=	1.17
	Total nitrogen	=	8.69 m <sup>3</sup>

Oxygen, O <sub>2</sub>			
In excess air	0.209 × 0.157 × 9.45	=	0.31 m <sup>3</sup>

Carbon dioxide, CO <sub>2</sub>			
From methane	(0.9CH <sub>4</sub> )(1.0)	=	0.90
From ethane	(0.05C <sub>2</sub> H <sub>6</sub> )(2.0)	=	0.10
	Total carbon dioxide	=	1.00 m <sup>3</sup>

Water vapor, H <sub>2</sub> O (does not appear in some flue gas analyses)			
From methane	(0.9CH <sub>4</sub> )(2.0)	=	1.8
From ethane	(0.05C <sub>2</sub> H <sub>6</sub> )(3.0)	=	0.15
	Total water vapor	=	1.95 m <sup>3</sup>

Total volume of dry gas per cubic metre of fuel gas  
8.69 + 0.31 + 1.00 = 10.0 m<sup>3</sup>

Total volume of wet gases per cubic metre of fuel gas (neglecting water vapor in combustion air)  
10.0 + 1.95 = 11.95 m<sup>3</sup>

The cubic metres of dry flue gas per cubic metre of fuel gas can also be computed from Equation (13):

$$(1.00)(100)/10.0 = 10.0 \text{ m}^3$$

## EFFICIENCY CALCULATIONS

In analyzing heating appliance efficiency, an energy balance is made that accounts (as much as possible) for disposition of all thermal energy released by combustion of the fuel quantity consumed. The various components of this balance are generally expressed in terms of megajoules per kilogram of fuel burned or as a percentage of its higher heating value. The following are major components of an energy balance and their calculation methods:

- Useful heat, or heat transferred to the heated medium; for convection heating equipment, this value  $q_1$  is computed as the product of the mass rate of flow and enthalpy change.
- Heat loss as sensible heat in the dry flue gases

$$q_2 = m_g c_{pg} (t_g - t_a) \quad (16)$$

where  $m_g$  is calculated as in Equation (12).

- Heat loss in water vapor in products formed by combustion of hydrogen

$$q_3 = (9H_2/100)[(h)_{tg} - (h_f)_{ta}] \quad (17)$$

- Heat loss in water vapor in the combustion air

$$q_4 = M m_a [(h)_{tg} - (h_g)_{ta}] \quad (18)$$

where  $m_a$  is calculated as in Equations (4) and (5).

- Heat loss from incomplete combustion of carbon

$$q_5 = 23\,591 \text{ C} \left( \frac{\text{CO}}{\text{CO}_2 + \text{CO}} \right) \quad (19)$$

- Heat loss from unburned carbon in the ash or refuse

$$q_6 = 33\,957 [(C_u/100) - C] \quad (20)$$

- Unaccounted-for heat losses,  $q_7$

The following symbols are used in Equations (16) through (20):

$q_1$  = useful heat, kJ/kg of fuel

$q_2$  = heat loss in dry flue gases, kJ/kg of fuel

$q_3$  = heat loss in water vapor from combustion of hydrogen, kJ/kg of fuel

$q_4$  = heat loss in water vapor in combustion air, kJ/kg of fuel

$q_5$  = heat loss from incomplete combustion of carbon, kJ/kg of fuel

$q_6$  = heat loss from unburned carbon in ash, kJ/kg of fuel

$q_7$  = unaccounted-for heat losses, kJ/kg of fuel

$c_{pg}$  = mean specific heat of flue gases at constant pressure ( $c_{pg}$  ranges from 1.01 to 1.06 kJ/(kg·K) for flue gas temperatures from 150 to 540°C), kJ/(kg·K)

$(h)_{tg}$  = enthalpy of superheated steam at flue gas temperature and 101.3 kPa, kJ/kg

$(h_p)_{ta}$  = enthalpy of saturated water vapor at air temperature, kJ/kg

$(h_g)_{ta}$  = enthalpy of saturated steam at combustion air temperature, kJ/kg

$m_a$  = mass of combustion air per mass of fuel used, kg/kg of fuel

$m_g$  = mass of dry flue gas per mass of fuel, kg/kg of fuel

$t_a$  = temperature of combustion air, °C

$t_g$  = temperature of flue gases at exit of heating device, °C

$H_2$  = hydrogen in fuel, % by mass (from ultimate analysis of fuel)

$M$  = humidity ratio of combustion air, mass of water vapor per mass of dry air

CO, CO<sub>2</sub> = carbon monoxide and carbon dioxide in flue gases, % by volume

$C$  = mass of carbon burned per unit of mass of fuel, corrected for carbon in ash, kg/kg of fuel

$$C = \frac{WC_u - W_a C_a}{100W} \tag{21}$$

where

- $C_u$  = percentage of carbon in fuel by mass from ultimate analysis
- $W_a$  = mass of ash and refuse
- $C_a$  = percent of combustible in ash by mass (combustible in ash is usually considered to be carbon)
- $W$  = mass of fuel used

Useful heat (item 1) is generally measured for a particular piece of combustion equipment.

Flue gas loss is the sum of items 2 through 6. However, for clean-burning gas- and oil-fired equipment, items 5 and 6 are usually negligible and flue gas loss is the sum of items 2, 3, and 4.

Flue gas losses (the sum of items 2, 3, and 4) can be determined with sufficient precision for most purposes from the curves in Figure 5, if O<sub>2</sub> content and flue gas temperature are known. Values of the losses were computed from typical ultimate analyses, assuming 1% water vapor (by mass) in the combustion air. Curves for medium-volatile bituminous coal can be used for high-volatile bituminous coal with no appreciable error.

Generally, item 5 is negligible for modern combustion equipment in good operating condition.

Item 6 is generally negligible for gas and oil firing, but should be determined for coal-firing applications.

Item 7 consists primarily of radiation and convection losses from combustion equipment surfaces and losses caused by incomplete combustion not included in items 5 and 6. Heat loss from incomplete combustion is determined by subtracting the sum of items 1 through 6 from the fuel heating value.

Radiation and convection losses are not usually determined by direct measurement. But if the heating appliance is located within the heated space, radiation and convection losses can be considered useful heat rather than lost heat and can be omitted from heat loss calculations or added to item 1.

If CO is present in flue gases, small amounts of unburned hydrogen and hydrocarbons may also be present. The small losses caused by incomplete combustion of these gases would be included in item 7, if item 7 was determined by subtracting items 1 through 6 from the fuel heating value.

The overall thermal efficiency of combustion equipment is defined as

$$\text{Thermal efficiency, \%} = 100 \frac{\text{Useful heat}}{\text{Heating value of fuel}} \tag{22}$$

The following equation can be used to estimate efficiency for equipment where item 7 is small or radiation and convection are useful heat:

Thermal efficiency, % =

$$100 \frac{\text{Heating value of fuel} - (q_2 + q_3 + q_4 + q_5 + q_6)}{\text{Heating value of fuel}} \tag{23}$$

Using heating values based on gas volume, the thermal efficiency of a gas appliance can be computed with sufficient precision by the following equation:

$$\eta = \frac{100(Q_h - Q_{fl})}{Q_h} \tag{24}$$

where

- $\eta$  = thermal efficiency, %
- $Q_h$  = higher heating value of fuel gas per unit volume
- $Q_{fl}$  = flue gas losses per unit volume of fuel gas

To produce heat efficiently by burning any common fuel, flue gas losses must be minimized by (1) providing adequate heat-absorbing surface in the appliance, (2) maintaining clean heat transfer surfaces on both fire and water or air sides, and (3) reducing excess air to the minimum level consistent with complete combustion and discharge of combustion products.

### Seasonal Efficiency

The method just presented is useful for calculating the steady-state efficiency of a heating system or device. Unfortunately, the seasonal efficiency of a combustion heating system can be significantly different from the steady-state efficiency. The primary factor affecting the seasonal efficiency is flue loss during the burner-off period. The warm stack that exists at the end of the firing period can cause airflow in the stack while the burner is off. This airflow can remove heat from furnace and heat exchanger components, from the structure itself, and from pilot flames. Also, if combustion air is drawn from the heated space within the structure, the heated air lost must be at least partly replaced with cold infiltrated air. For further discussion of seasonal efficiency, see Chapter 9 of the 2000 *ASHRAE Handbook—Systems and Equipment*.

## COMBUSTION CONSIDERATIONS

### Air Pollution

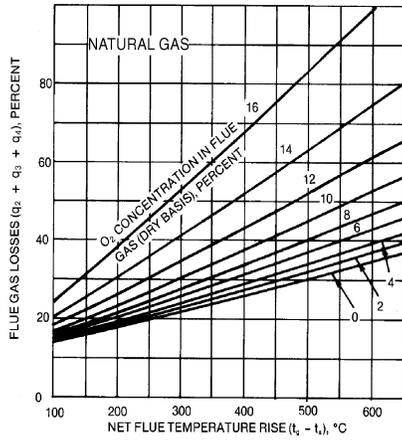

Combustion processes constitute the largest single source of air pollution. Pollutants can be grouped into four categories:

1. Products of incomplete fuel combustion
  - Combustible aerosols (solid and liquid), including smoke, soot, and organics, but excluding ash
  - Carbon monoxide, CO
  - Gaseous hydrocarbons
2. Oxides of nitrogen (generally grouped and referred to as NO<sub>x</sub>)
  - Nitric oxide, NO
  - Nitrogen dioxide, NO<sub>2</sub>
3. Emissions resulting from fuel contaminants
  - Sulfur oxides, primarily sulfur dioxide, SO<sub>2</sub>, and small quantities of sulfur trioxide, SO<sub>3</sub>
  - Ash
  - Trace metals
4. Emissions resulting from additives
  - Combustion-controlling additives
  - Other additives

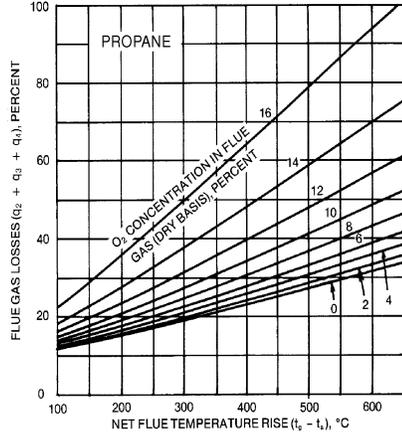

Emission levels of nitrogen oxides and products of incomplete combustion are directly related to the combustion process and can be controlled, to some extent, by process modification. Emissions due to fuel contaminants are related to fuel selection and are slightly affected by the combustion process. Emissions due to additives must be considered in the overall evaluation of the merits of using additives.

Nitrogen oxides are produced during the combustion process, either (1) by thermal fixation (reaction of nitrogen and oxygen at high combustion temperatures), or (2) from fuel nitrogen (oxidation of organic nitrogen in fuel molecules). Unfortunately, high excess air and high flame temperature techniques, which ensure complete fuel combustion, tend to promote NO<sub>x</sub> formation.

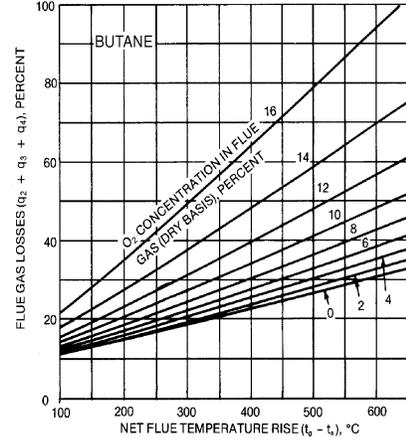

Table 12 lists NO<sub>x</sub> emission factors for uncontrolled fuel-burning equipment (i.e., equipment that does not have exhaust gas recirculation, low-NO<sub>x</sub> burners, or other emission controls). Differences in the NO<sub>x</sub> emissions of fuels are caused by the flame temperature and different levels of fuel nitrogen. The data in Table 12 are adapted from EPA (1993), *Compilation of Air Pollutant Emission Factors*, which lists emission factors of a wide variety of equipment, as well as emission reduction options. Carbon monoxide emissions are less dependent on fuel type and typically range from

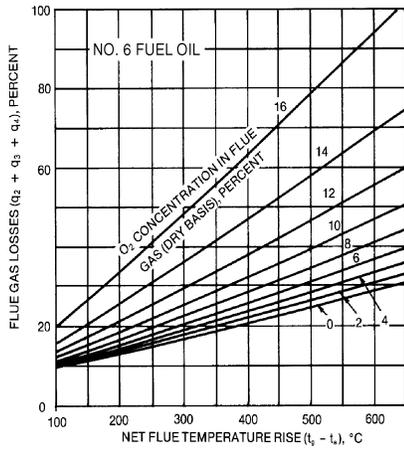

FUEL: NATURAL GAS  
HEATING VALUE: 51.97 MJ/kg COMBUSTIBLES

(Flue gas temperature rise shown. Loss is based on 18°C room temperature.)

**Table 12 NO<sub>x</sub> Emission Factors for Combustion Sources Without Emission Controls**

Source	NO <sub>x</sub> Emission Factor, mg/MJ of Heat Input
<b>Gas-Fired Equipment</b>	
Small industrial boilers	60
Commercial boilers	43
Residential furnaces	39
<b>Distillate-oil-fired small industrial boilers, commercial boilers, and residential furnaces</b>	
Residual oil-fired small industrial boilers and commercial boilers	160

13 to 17 mg/MJ of heat input. For gas-fired commercial and industrial boilers, particulate emissions range from 2.2 to 2.6 mg/ MJ. For distillate-oil-fired commercial and industrial boilers, particulates are typically 6.0 mg/MJ. For residential oil-fired equipment, particulate emission factors are 1.3 mg/MJ. For residual-oil-fired equipment, particulate emissions depend on the sulfur content. For a sulfur content of 1%, the particulate emission rate is typically 36 mg/MJ.

Emission levels of products of incomplete fuel combustion can be reduced by reducing burner cycling, ensuring adequate excess air, improving the mixing of air and fuel (by increasing turbulence, improving distribution, and improving liquid fuel atomization), increasing residence time in the hot combustion zone (possibly by decreasing the firing rate), increasing combustion zone temperatures (to speed reactions), and avoiding quenching the flame before reactions are completed.

The relative contribution of each of these mechanisms to the total NO<sub>x</sub> emissions depends on the amount of organic nitrogen in the fuel. Natural gas contains very little nitrogen. Virtually all NO<sub>x</sub> emissions with gas firing are due to the thermal mechanism. The nitrogen content of distillate oil varies, but an average of 20 ppm of fuel NO<sub>x</sub> is produced (about 20 to 30% of the total NO<sub>x</sub>). The fuel nitrogen in residual oil can be significantly higher, with fuel NO<sub>x</sub> contributing heavily to the total emissions.

Thermal fixation is strongly dependent on flame maximum temperature. For example, increasing the flame temperature from 1400 to 1500°C increases thermal NO<sub>x</sub> tenfold. Therefore, methods to control thermal NO<sub>x</sub> are based on methods to reduce the maximum flame temperature. Flue gas recirculation is perhaps the most effective method of reducing thermal NO<sub>x</sub> in commercial and industrial boilers. In gas-fired boilers, NO<sub>x</sub> reductions of 70% can be realized with 15-20% recirculation of flue gas into the flame. The NO<sub>x</sub> reduction decreases with increasing fuel nitrogen content. With distillate-oil firing, reductions of 60-70% can be achieved. In residual-oil-fired boilers, flue gas recirculation can reduce NO<sub>x</sub> emissions by 15 to 30%. The maximum rate of flue gas recirculation is limited by combustion instability and CO production.

Two-stage firing is the only technique that reduces NO<sub>x</sub> produced both by thermal fixation and fuel nitrogen in industrial and utility applications. The fuel-rich or air-deficient primary combustion zone retards NO<sub>x</sub> formation early in the combustion process (when NO<sub>x</sub> forms most readily from fuel nitrogen), and avoids peak temperatures, reducing thermal NO<sub>x</sub>. Retrofit low-NO<sub>x</sub> burners that control air distribution and fuel air mixing in the flame zone can be used to achieve staged combustion. With oil firing, NO<sub>x</sub> reductions of 20 to 50% can be obtained with low-NO<sub>x</sub> burners. The application of flue gas recirculation and other control methods to residential, oil-fired warm air furnaces was reviewed by Butcher et al. (1994).

The following are some methods of reducing NO<sub>x</sub> emissions from gas-fired appliances (Murphy and Putnam 1985):

- Burner adjustment
- Flame inserts (radiation screens or rods)

- Staged combustion and delayed mixing
- Secondary air baffling
- Catalytic and radiant burners
- Total premix
- Pulse

Radiation screens or rods (flame inserts) surrounding or inserted into the flame absorb radiation to reduce flame temperature and retard NO<sub>x</sub> formation. Proprietary appliance burners with no flame inserts have been developed and produced to comply with the very strict NO<sub>x</sub> emission limitations of California's Air Quality Management Districts.

The U.S. EPA sets limits on air pollutant emissions (Source Performance Standards) from boilers larger than 3 MW of heat input. In addition, states set emission regulations that are at least as strict as the federal limits and may apply to smaller equipment.

The EPA's automobile emission standard is 0.62 g of NO<sub>2</sub> per kilometre, which is equivalent to 750 ng/J of NO<sub>x</sub> emission. California's maximum is 0.25 g/km, equivalent to 300 ng/J. California's Air Quality Management Districts for the South Coast (Los Angeles) and the San Francisco Bay Area limit NO<sub>x</sub> emission to 40 ng/J of useful heat for some natural gas-fired residential heating appliances.

For further discussion of air pollution aspects of fuel combustion, see EPA (1971a and 1971b).

**Condensation and Corrosion**

Fuel-burning systems that cycle on and off to meet demand cool down during the off-cycle. When the appliance starts again, condensate forms briefly on surfaces until they are heated above the dew-point temperature. Low-temperature corrosion occurs in system components (heat exchangers, flues, vents, chimneys) when their surfaces remain below the dew-point temperature of flue gas constituents (water vapor, sulfides, chlorides, fluorides, etc.) long enough to cause condensation. Corrosion increases as condensate dwell time increases.

Acids in the flue gas condensate are the principle substances responsible for low-temperature corrosion in fuel-fired systems. Sulfuric, hydrochloric, and other acids are formed when acidic compounds in fuel and air combustion products combine with condensed moisture in appliance heat exchangers, flues, or vents. Corrosion can be avoided by maintaining these surfaces above the flue gas dew point.

In high-efficiency, condensing-type appliances and economizers, flue gas temperatures are intentionally reduced below the flue gas dew-point temperatures to achieve efficiencies approaching 100%. In these systems, the surfaces subjected to condensate must be made of corrosion-resistant materials. The most corrosive conditions exist at the leading edge of the condensing region, especially those areas that experience evaporation during each cycle (Strickland et al. 1987). Drainage of condensate retards the concentration of acids on system surfaces. Regions from which condensate partially or completely drains away before evaporation are less severely attacked than regions from which condensate does not drain before evaporation.

The metals most resistant to condensate corrosion are stainless-steel alloys with high chromium and molybdenum content, and nickel-chromium alloys with high molybdenum content (Stickford et al. 1988). Aluminum experiences general corrosion rather than pitting when exposed to flue gas condensate. If applied in sufficiently thick cross section to allow for metal loss, aluminum can be used in condensing regions. Most ceramic and high-temperature polymer materials resist the corrosive effects of flue gas condensate. These materials may have application in the condensing regions, if they can meet the structural and temperature requirements of a particular application.

In coal-fired power plants, the rate of corrosion for carbon steel condensing surfaces by the mixed acids (primarily sulfuric and hydrochloric) is reported to be maximum at about  $50 \pm 10^\circ\text{C}$  (Davis 1987). Mitigation techniques include (1) acid neutralization with a base such as  $\text{NH}_3$  or  $\text{Ca}(\text{OH})_2$ ; (2) use of protective linings of glass-filled polyester or coal-tar epoxy; and (3) replacement of steel with molybdenum-bearing stainless steels, nickel alloys, polymers, or other corrosion-resistant materials. Other elements in residual fuel oils and coals that contribute to high-temperature corrosion include sodium, potassium, and vanadium. Each fuel-burning system component should be evaluated during installation, or when modified, to determine the potential for corrosion and the means to retard corrosion (Paul et al. 1988).

### Soot

Soot deposits on flue surfaces of a boiler or heater act as an insulating layer over the surface, reducing heat transfer to the water or air. Soot can also clog flues, reduce draft and available air, and prevent proper combustion. Proper burner adjustment can minimize soot accumulation. The use of off-specification fuel can contribute to the generation of soot.

## CHAPTER 19

# REFRIGERANTS

<i>Phaseout of Refrigerants</i> .....	19.1
<i>Refrigerant Properties</i> .....	19.4
<i>Refrigerant Performance</i> .....	19.6
<i>Safety</i> .....	19.6
<i>Leak Detection</i> .....	19.7
<i>Effect on Construction Materials</i> .....	19.11

**R**EFRIGERANTS are the working fluids in refrigeration, air-conditioning, and heat pumping systems. They absorb heat from one area, such as an air-conditioned space, and reject it into another, such as outdoors, usually through evaporation and condensation, respectively. These phase changes occur both in absorption and mechanical vapor compression systems, but they do not occur in systems operating on a gas cycle using a fluid such as air. (See Chapter 1 for more information on refrigeration cycles.) The design of the refrigeration equipment depends strongly on the properties of the selected refrigerant. Table 1 lists ASHRAE standard refrigerant designations from ASHRAE *Standard 34*.

Refrigerant selection involves compromises between conflicting desirable thermodynamic properties. A refrigerant must satisfy many requirements, some of which do not directly relate to its ability to transfer heat. Chemical stability under conditions of use is the most important characteristic. Safety codes may require a nonflammable refrigerant of low toxicity for some applications. Cost, availability, efficiency, and compatibility with compressor lubricants and materials with which the equipment is constructed are other concerns.

The environmental consequences of a refrigerant that leaks from a system must also be considered. Because of their great stability, fully halogenated compounds, such as **chlorofluorocarbons** (CFCs), persist in the atmosphere for many years and eventually diffuse into the stratosphere. The molecules of CFCs, such as R-11 and R-12, contain only carbon and the halogens chlorine and fluorine. Once in the upper atmosphere, CFC molecules break down and release chlorine, which destroys ozone (**ozone depletion**). In the lower atmosphere, these molecules absorb infrared radiation, which may contribute to the warming of the earth. Substitution of a hydrogen atom for one or more of the halogens in a CFC molecule greatly reduces its atmospheric lifetime and lessens its environmental impact. These compounds are called **hydrochlorofluorocarbons** (HCFCs). A similar class of compounds used as fire extinguishing agents and called halons also cause ozone depletion. **Halons** are compounds containing bromine, fluorine, and carbon. Like CFCs, halons break down, but release bromine, which is even more destructive to stratospheric ozone than chlorine.

Latent heat of vaporization is another important property. On a molar basis, fluids with similar boiling points have almost the same latent heat. Since the compressor operates on volumes of gas, refrigerants with similar boiling points produce similar capacities in a given compressor. On a mass basis, latent heat varies widely among fluids. The maximum efficiency of a theoretical vapor compression cycle is achieved by fluids with low vapor heat capacity. This property is associated with fluids having a simple molecular structure and low molecular weight.

Transport properties of thermal conductivity and viscosity affect the performance of heat exchangers and piping. High thermal conductivity and low viscosity are desirable.

No single fluid satisfies all the attributes desired of a refrigerant; as a result, a variety of refrigerants is used. This chapter describes the basic characteristics of various refrigerants, and Chapter 20 lists thermophysical properties.

### PHASEOUT OF REFRIGERANTS

The Montreal Protocol is an international treaty that controls the production of ozone-depleting substances, including refrigerants containing chlorine and/or bromine (U.N. 1994, 1996). The original Protocol was signed September 16, 1987, by the European Economic Community (currently the European Union) and 24 nations, including the United States. It entered into force on January 1, 1989, and limits the 1998 production of specified CFCs to 50% of their 1986 levels. Starting in 1992, the production of specified halons (including R-13B1) was frozen at 1986 levels. Developing countries were granted additional time to meet these deadlines.

The original Protocol contained provisions for periodic revision. Four such revisions, referred to as the London, Copenhagen, Montreal, and Beijing Amendments, were agreed to in 1990, 1992, 1997 and 1999, respectively. As of February, 2000, the Montreal Protocol had been ratified by 172 parties, the London Amendment by 138 parties, and the Copenhagen Amendment by 104 parties; the Beijing amendment has yet to be ratified.

The Copenhagen Amendment entered into force on June 14, 1994. It called for a complete cessation of the production of CFCs by January 1, 1996, and of halons by January 1, 1994. Continued use from existing (reclaimed or recycled) stock is permitted. Allowance is also provided for continued production for very limited essential uses. In addition, HCFCs (such as R-22 and R-123) are to be phased out relative to a 1989 reference level for developed countries. Production was frozen at the reference level on January 1, 1996. Production will be limited to 65% of the reference level by January 1, 2004; to 35% by January 1, 2010; to 10% by January 1, 2015; and to 0.5% of the reference level by January 1, 2020. Complete cessation of the production of HCFCs is called for by January 1, 2030. In addition to the international agreement, individual countries may have domestic regulations for ozone-depleting compounds.

The Beijing Amendment will regulate the production of HCFCs in developed countries. A production cap will begin in 2004 and will be equal to the original HCFC use cap plus an additional 15% allowance to meet developing country needs. At this time, there is no provision for reductions to this production cap.

The production and use of hydrofluorocarbon (HFC) refrigerants (such as R-32, R-125, R-134a, R-143a, and their mixtures, including R-404A, R-407C, and R-410A) are not regulated by the Montreal Protocol.

The preparation of this chapter is assigned to TC 3.1, Refrigerants and Secondary Coolants.

Table 1 Standard Designation of Refrigerants (ASHRAE Standard 34)

Refrigerant Number	Chemical Name or Composition (% by mass)	Chemical Formula	Refrigerant Number	Chemical Name or Composition (% by mass)	Chemical Formula
<b>Methane Series</b>			403A	R-290/22/218 (5/75/20)

REFRIGERANT PROPERTIES

Physical Properties

Table 2 lists some physical properties of commonly used refrigerants, a few very low-boiling cryogenic fluids, some newer refrigerants, and some older refrigerants of historical interest. These refrigerants are arranged in increasing order of atmospheric boiling point, from helium at -452.1°F to water at 212°F.

Table 2 also includes the freezing point, critical properties, and refractive index. Of these properties, the boiling point is most important because it is a direct indicator of the temperature level at which a refrigerant can be used. The freezing point must be lower than any contemplated usage. The critical properties describe a material at the point where the distinction between liquid and gas is lost. At higher

temperatures, no separate liquid phase is possible. In refrigeration cycles involving condensation, a refrigerant must be chosen that allows this change of state to occur at a temperature somewhat below the critical. Cycles that reject heat at supercritical temperatures (such as cycles using carbon dioxide) are also possible.

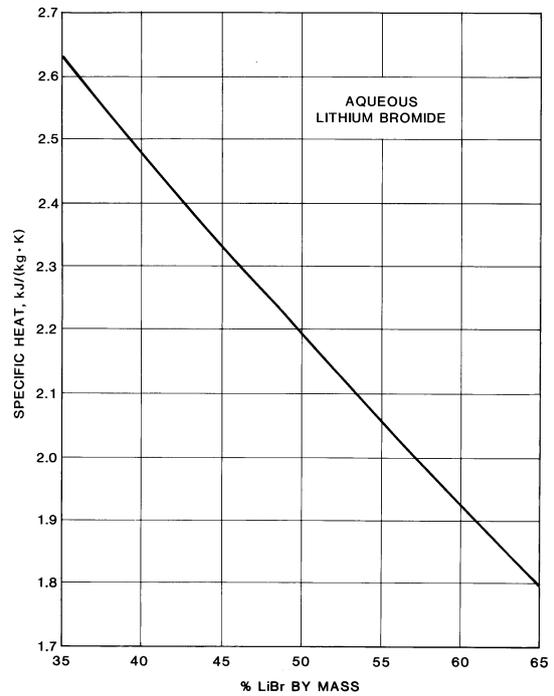

Fig. 2 Specific Heat of Aqueous Lithium Bromide Solutions

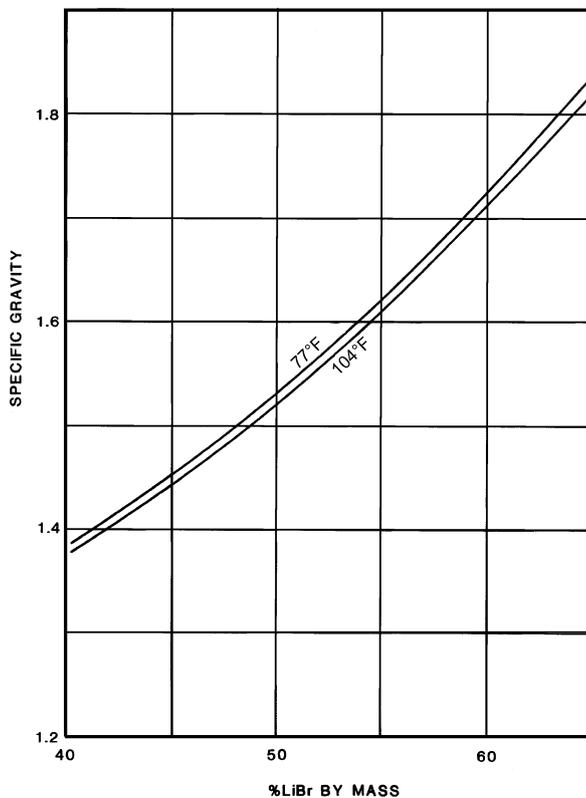

Fig. 1 Specific Gravity of Aqueous Solutions of Lithium Bromide

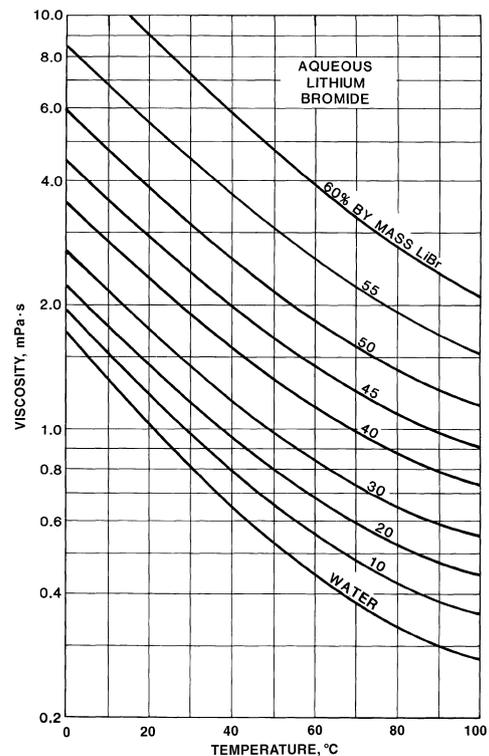

Fig. 3 Viscosity of Aqueous Solutions of Lithium Bromide

**Lithium Bromide-Water and Ammonia-Water Solutions.** These are the most commonly used working fluids in absorption refrigeration systems. Figure 1 shows specific gravity, Figure 2 shows specific heat, and Figure 3 shows viscosity of lithium bromide-water solutions. Chapter 20 has an enthalpy-concentration diagram and a vapor pressure diagram for lithium bromide-water solutions. Chapter 20 also has equilibrium properties of water-ammonia solutions.

**Electrical Properties**

Table 3 and Table 4 list the electrical characteristics of refrigerants that are especially important in hermetic systems.

**Sound Velocity**

Table 5 gives examples of the velocity of sound in the vapor phase of various fluorinated refrigerants. Chapter 20 has sound velocity data for many refrigerants. The velocity increases when the temperature is increased and decreases when the pressure is increased. The velocity of sound can be calculated from the equation

$$V_a = \left( g_c \frac{dp}{d\rho} \right)_S^{0.5} = \left[ \gamma g_c \left( \frac{dp}{d\rho} \right)_T \right]^{0.5} \quad (1)$$

where

- $V_a$  = sound velocity, ft/s
- $g_c$  = gravitational constant = 32.1740 lb<sub>m</sub> · ft/lb<sub>f</sub> · s<sup>2</sup>
- $p$  = absolute pressure, lb<sub>f</sub>/ft<sup>2</sup>
- $\rho$  = density, lb<sub>m</sub>/ft<sup>3</sup>
- $\gamma$  =  $c_p/c_v$  = ratio of specific heats
- $S$  = entropy, Btu/lb · °R
- $T$  = temperature, °R

The sound velocity can be estimated from the tables of thermodynamic properties. The change in pressure with a change in density ( $dp/d\rho$ ) can be estimated either at constant entropy or at constant temperature. It is simpler to estimate at constant temperature but then the ratio of specific heats must also be known. The practical velocity of a gas in piping or through openings is limited by the velocity of sound in the gas.

**Latent Heat of Vaporization**

An empirical rule of chemistry (Trouton's rule) states that the latent heat of vaporization at the boiling point on a molar basis, divided by the temperature in absolute units, is a constant for most materials. This rule is applied to refrigerants in Table 6. It applies fairly well to these refrigerants, although the result is not entirely constant. The rule helps in comparing different refrigerants and in understanding the operation of refrigeration systems.

**REFRIGERANT PERFORMANCE**

Chapter 1 describes several methods of calculating refrigerant performance, and Chapter 20 includes tables of thermodynamic properties of the various refrigerants.

Table 7 shows the theoretical calculated performance of a number of refrigerants for the U.S. standard cycle of 5°F evaporation and 86°F condensation. Calculated data for other conditions are given in Table 8. The tables can be used to compare the properties of different refrigerants, but actual operating conditions are somewhat different from the calculated data. In most cases, the suction vapor is assumed to be saturated, and the compression is assumed adiabatic or at constant entropy. For R-113 and R-114, these assumptions would cause some liquid in the discharge vapor. In these cases, it is assumed that the discharge vapor is saturated and that the suction vapor is slightly superheated. In Section F of Table 8, the temperature of the suction gas is assumed to be 65°F (−10°F saturated evaporating plus 75°F superheat). Comparison with Section E illustrates the effect of suction gas superheating on refrigerant performance.

**SAFETY**

Table 9 summarizes the toxicity and flammability characteristics of many refrigerants. In ASHRAE *Standard* 34, refrigerants are classified according to the hazard involved in their use. The toxicity and flammability classifications yield six safety groups (A1, A2, A3, B1, B2, and B3) for refrigerants. Group A1 refrigerants are the least hazardous, Group B3 the most hazardous.

The safety classification in ASHRAE *Standard* 34 consists of a capital letter and a numeral. The capital letter designates the toxicity of the refrigerant at concentrations below 400 ppm by volume:

- Class A Toxicity not identified
- Class B Evidence of toxicity identified

The numeral denotes the flammability of the refrigerant:

- Class 1 No flame propagation in air at 65°F and 14.7 psia
- Class 2 Lower flammability limit (LFL) greater than 0.00625 lb/ft<sup>3</sup> at 70°F and 14.7 psia *and* heat of combustion less than 8174 Btu/lb
- Class 3 Highly flammable as defined by LFL less than or equal to 0.00625 lb/ft<sup>3</sup> at 70°F and 14.7 psia *or* heat of combustion greater than or equal to 8174 Btu/lb

## LEAK DETECTION

Leak detection in refrigeration equipment is a major problem for manufacturers and service engineers. The following sections describe several leak detection methods.

## Electronic Detection

The electronic detector is widely used in the manufacture and assembly of refrigeration equipment. Instrument operation depends on the variation in current flow caused by ionization of decomposed refrigerant between two oppositely charged platinum electrodes. This instrument can detect any of the halogenated refrigerants except R-14; however, *it is not recommended for use in atmospheres that contain explosive or flammable vapors*. Other vapors, such as alcohol and carbon monoxide, may interfere with the test.

The electronic detector is the most sensitive of the various leak detection methods, reportedly capable of sensing a leak of 1/100 oz of R-12 per year. A portable model is available for field testing. Other models are available with automatic balancing systems that correct for refrigerant vapors that might be present in the atmosphere around the test area.

## Halide Torch

The halide torch is a fast and reliable method of detecting leaks of chlorinated refrigerants. Air is drawn over a copper element heated by a methyl alcohol or hydrocarbon flame. If halogenated vapors are present, they decompose, and the color of the flame changes to bluish-green. Although not as sensitive as the electronic detector, this method is suitable for most purposes.

## Bubble Method

The object to be tested is pressurized with air or nitrogen. A pressure corresponding to operating conditions is generally used. The object is immersed in water, and any leaks are detected by observing bubbles in the liquid. Adding a detergent to the water decreases the surface tension, prevents escaping gas from clinging to the side of the object, and promotes the formation of a regular stream of small bubbles. Kerosene or other organic liquids are sometimes used for the same reason. A solution of soap or detergent can be brushed or poured onto joints or other spots where leakage is suspected. Leaking gas forms soap bubbles that can be readily detected.

Leaks can also be determined by pressurizing or evacuating and observing the change in pressure or vacuum over a period of time. This is effective in checking the tightness of the system but does not locate the point of leakage.

## Ammonia and Sulfur Dioxide Leaks

Ammonia can be detected by burning a sulfur candle in the vicinity of the suspected leak or by bringing a solution of hydrochloric acid near the object. If ammonia vapor is present, a white cloud or smoke of ammonium sulfite or ammonium chloride forms. Ammonia can also be detected with indicator paper that changes color in the presence of a base.

Sulfur dioxide can be detected by the appearance of white smoke when aqueous ammonia is brought near the leak.

**Table 11 Diffusion of Water and R-22 Through Elastomers**

Elastomer	Diffusion Rate	
	Water <sup>a</sup>	R-22 <sup>b</sup>
Neoprene	0.717	1.31
Buna N	0.109	19.7
Hypalon 40	0.457	0.52
Butyl	0.043	0.30
Viton	—	3.61
Polyethylene	0.123	—
Natural	1.428	—

Adapted from Eiseman (1966).

<sup>a</sup> 0.003 in. film, 100% rh at 100°F. Water diffusion rate is in pounds per hour per 1000 ft<sup>2</sup> of elastomer.

<sup>b</sup> Film thickness = 0.001 in.; temperature = 77°F. Gas at 1 atm. and 32°F. Diffusion rate per day in ft<sup>3</sup> of gas per ft<sup>2</sup> of elastomer.

**Table 12 Swelling of Plastics in Liquid Refrigerants at Room Temperature**

Plastic	Linear Swell, %						
	Refrigerant						
	11	12	21	30	113	114a	22
Phenol formaldehyde resin	0	0	0	0	-0.2	-0.2	n.a.
