Halogenated refrigerants can be used satisfactorily under normal conditions with most common metals, such as steel, cast iron, brass, copper, tin, lead, and aluminum. Under more severe conditions, various metals affect such properties as hydrolysis and thermal decomposition in varying degrees. The tendency of metals to promote thermal decomposition of halogenated compounds is in the following order:

(least decomposition) Inconel < 18-8 stainless steel < nickel < copper < 1340 steel < aluminum < bronze < brass < zinc < silver (most decomposition)

This order is only approximate, and exceptions may be found for individual compounds or for special use conditions. The effect of metals on hydrolysis is probably similar.

Magnesium, zinc, and aluminum alloys containing more than 2% magnesium are not recommended for use with halogenated compounds where even trace amounts of water may be present.

**Warning:** Never use methyl chloride with aluminum in any form. A highly flammable gas is formed, and the explosion hazard is great.

Ammonia should never be used with copper, brass, or other alloys containing copper. When water is present in sulfur dioxide systems, sulfurous acid is formed and can attack iron or steel rapidly and other metals at a slower rate.

Further discussion of the compatibility of refrigerants and lubricants with construction materials may be found in Chapter 5 of the 1998 *ASHRAE Handbook—Refrigeration*.

## Elastomers

The linear swelling of some elastomers in the liquid phase of various refrigerants is shown in Table 10. Swelling data can be used to a limited extent in comparing the effect of refrigerants on elastomers. However, other factors, such as the amount of extraction, tensile strength, and degree of hardness of the exposed elastomer must be considered. When other fluids are present in addition to the refrigerant, the combined effect on elastomers should be determined. In some instances, somewhat higher swelling of elastomers is found in mixtures of R-22 and lubricating oil than in either fluid alone. Table 11 shows the diffusion rate of water and R-22 through elastomers.

## Plastics

The effect of a refrigerant on a plastic material should be thoroughly examined under the conditions of intended use. Plastics are often mixtures of two or more basic types, and it is difficult to predict the effect of the refrigerant. The linear swelling of some plastic materials in refrigerants is shown in Table 12. Swelling data can be used as a guide but, as with elastomers, the effect on the properties of the plastic should also be examined. Comparable data for R-22 is limited, but the effect on plastics is generally more severe than that

of R-12, but not as severe as that of R-21. The effect of R-114 is very similar to that of R-114a.

## CHAPTER 20

# THERMOPHYSICAL PROPERTIES OF REFRIGERANTS

**T**HIS CHAPTER presents tabular data for the thermodynamic and transport properties of refrigerants arranged for the occasional user. Most of the refrigerants have a thermodynamic property chart on pressure-enthalpy coordinates with an abbreviated set of tabular data for the saturated liquid and vapor on the facing page. In addition, tabular data in the superheated vapor region are given for R134a to assist students working on compression cycle examples.

For each of the cryogenic fluids, a second table of properties is provided for the vapor at a pressure of one standard atmosphere; these tables provide data needed when these gases are used in heat transfer or purge gas applications. For the zeotropic blends, including R-729 (air), tables are incremented in pressure with properties given for the liquid on the bubble line and vapor on the dew line. This arrangement is chosen because pressure is more commonly measured in the field while servicing equipment; it also highlights the difference between the bubble and dew point temperatures—the so-called temperature glide experienced with blends.

For a few fluids there are gaps in some properties at low temperatures due to limitations in the data and/or the models used.

New for the 2001 *ASHRAE Handbook* are R-143a and R-245fa. Most of the CFC refrigerants have been deleted. Tables for R-11, R-13, R-113, R-114, R-141b, R-142b, R-500, R-502, R-503, and R-720 (neon) may be found in the 1997 *ASHRAE Handbook*. R-12 has been retained to assist in making comparisons. Revised formulations have been used for many of the HFC refrigerants; these conform to international standards, where applicable. The formulations used are detailed in the References section.

The reference states used for most of the refrigerants correspond to the international convention of 200 kJ/kg for enthalpy and 1 kJ/(kg·K) for entropy, both for the saturated liquid at 0°C. The exceptions are water and fluids that have very low critical temperatures, such as ethylene and the cryogenics.

These data are intended to help engineers make preliminary comparisons among unfamiliar fluids. For greater detail and a wider range of data, consult the sources listed in the References section.

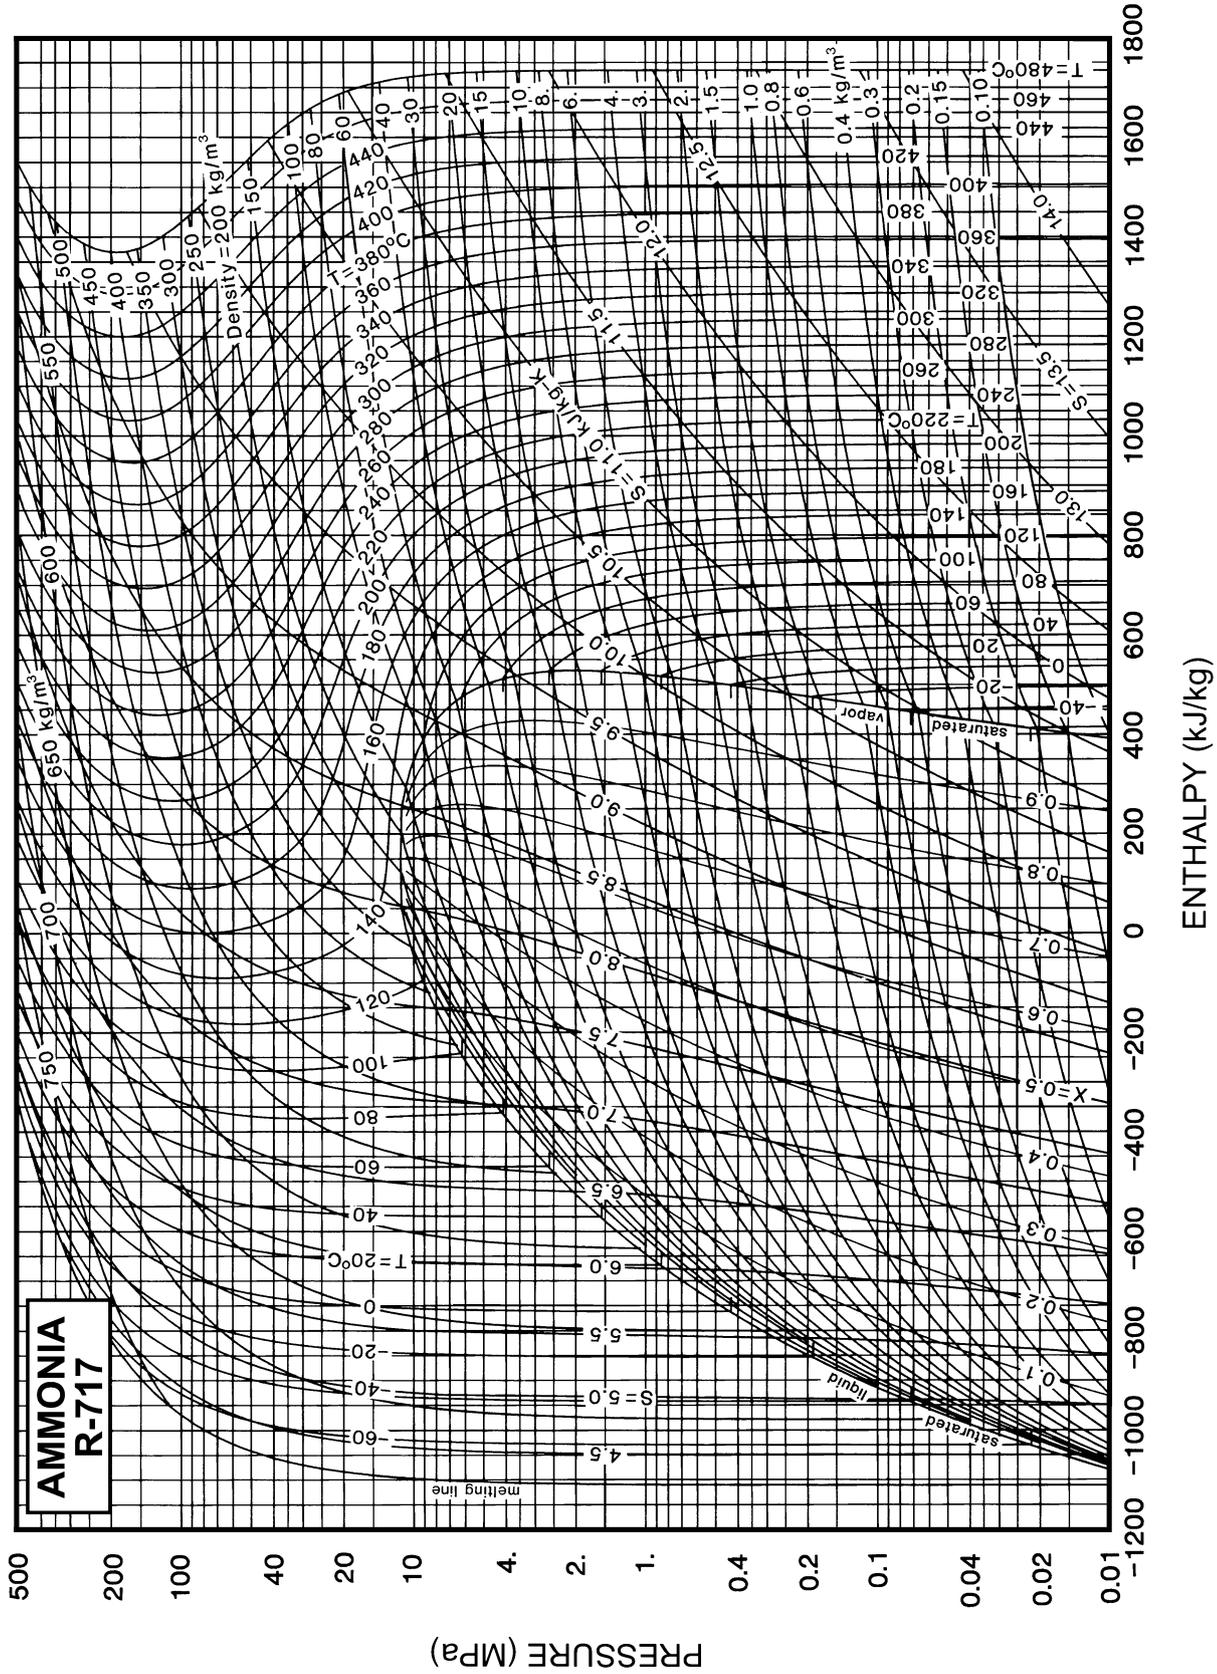

Fig. 12 Pressure-Enthalpy Diagram for Refrigerant 717 (Ammonia)  
Note: The reference states for enthalpy and entropy differ from those in the table.

Refrigerant 717 (Ammonia) Properties of Saturated Liquid and Saturated Vapor

Temp.,* °C	Pres- sure, MPa	Density, kg/m <sup>3</sup>		Volume, m <sup>3</sup> /kg		Enthalpy, kJ/kg		Entropy, kJ/(kg·K)		Specific Heat <i>c<sub>p</sub></i> , kJ/(kg·K)			Velocity of Sound, m/s		Viscosity, μPa·s		Thermal Cond., mW/(m·K)		Surface Tension, mN/m	Temp., °C
		Liquid	Vapor	Liquid	Vapor	Liquid	Vapor	Liquid	Vapor	Liquid	Vapor	Liquid	Vapor	Liquid	Vapor	Liquid	Vapor

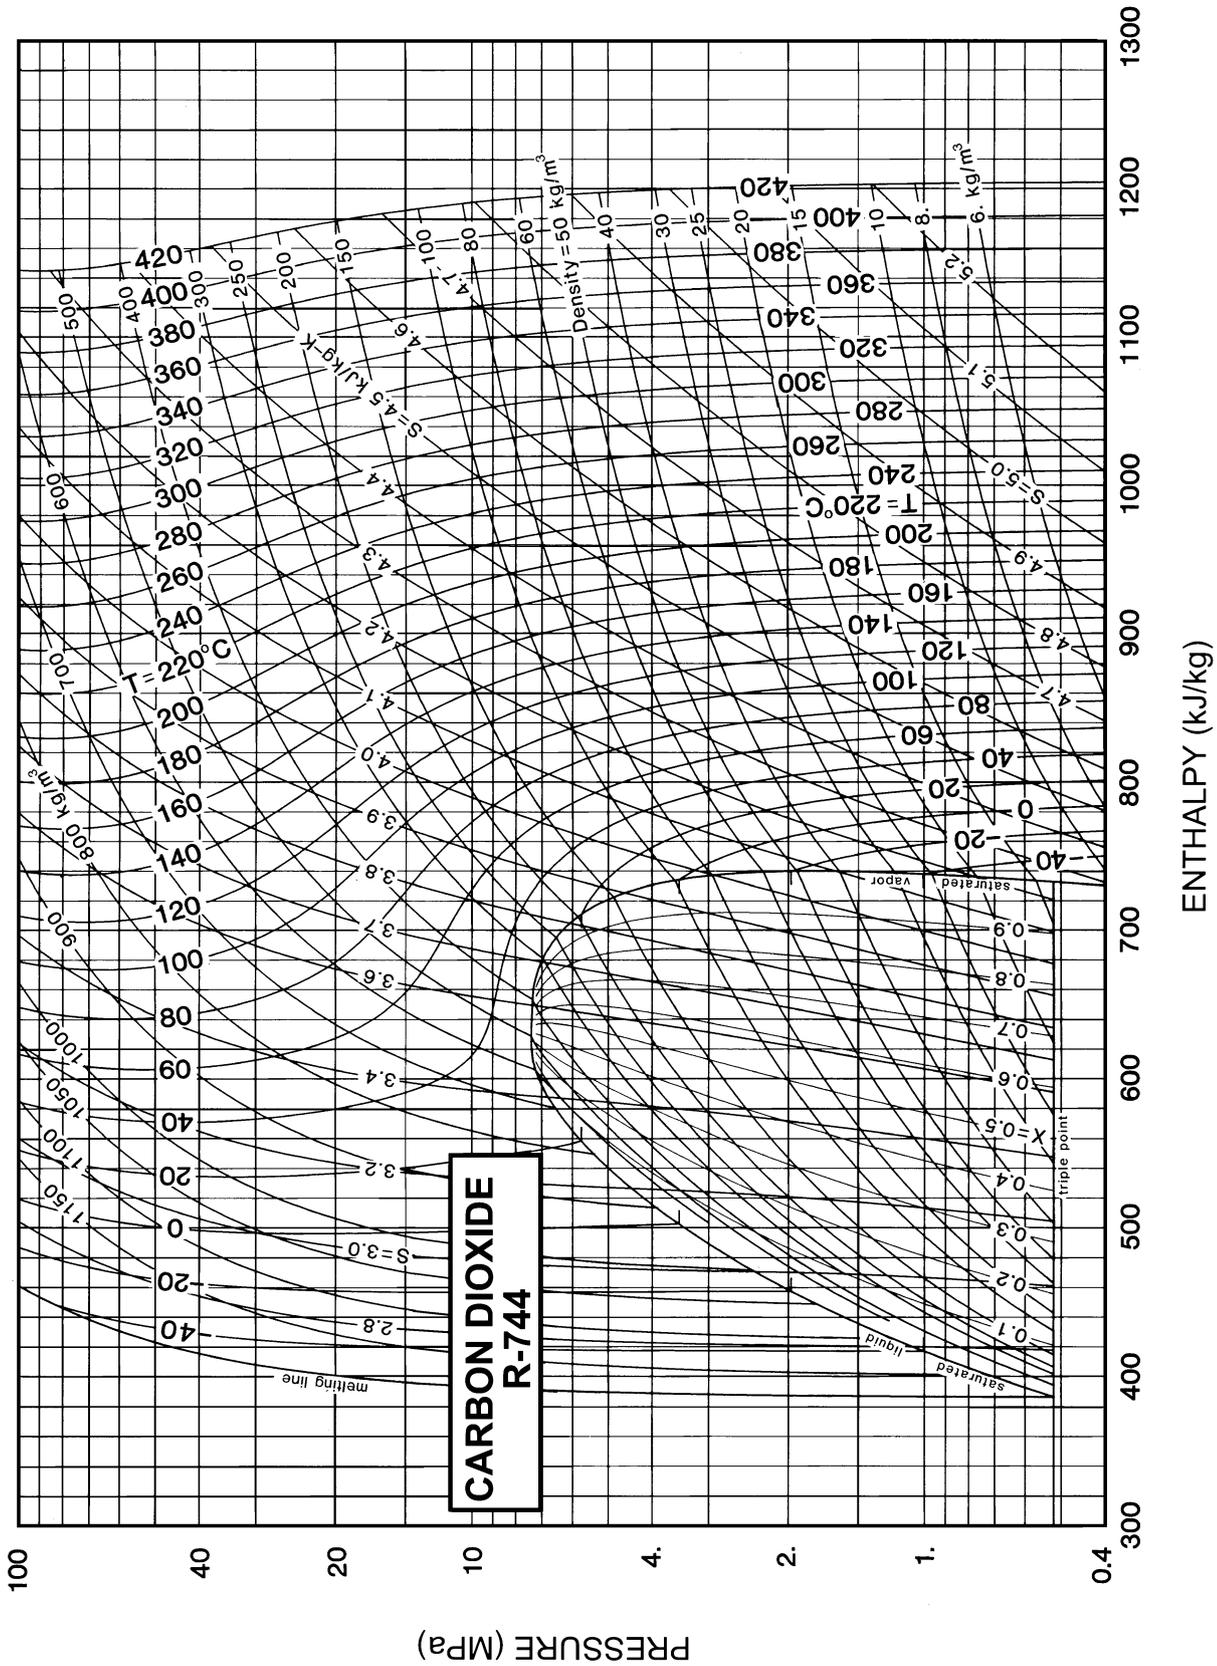

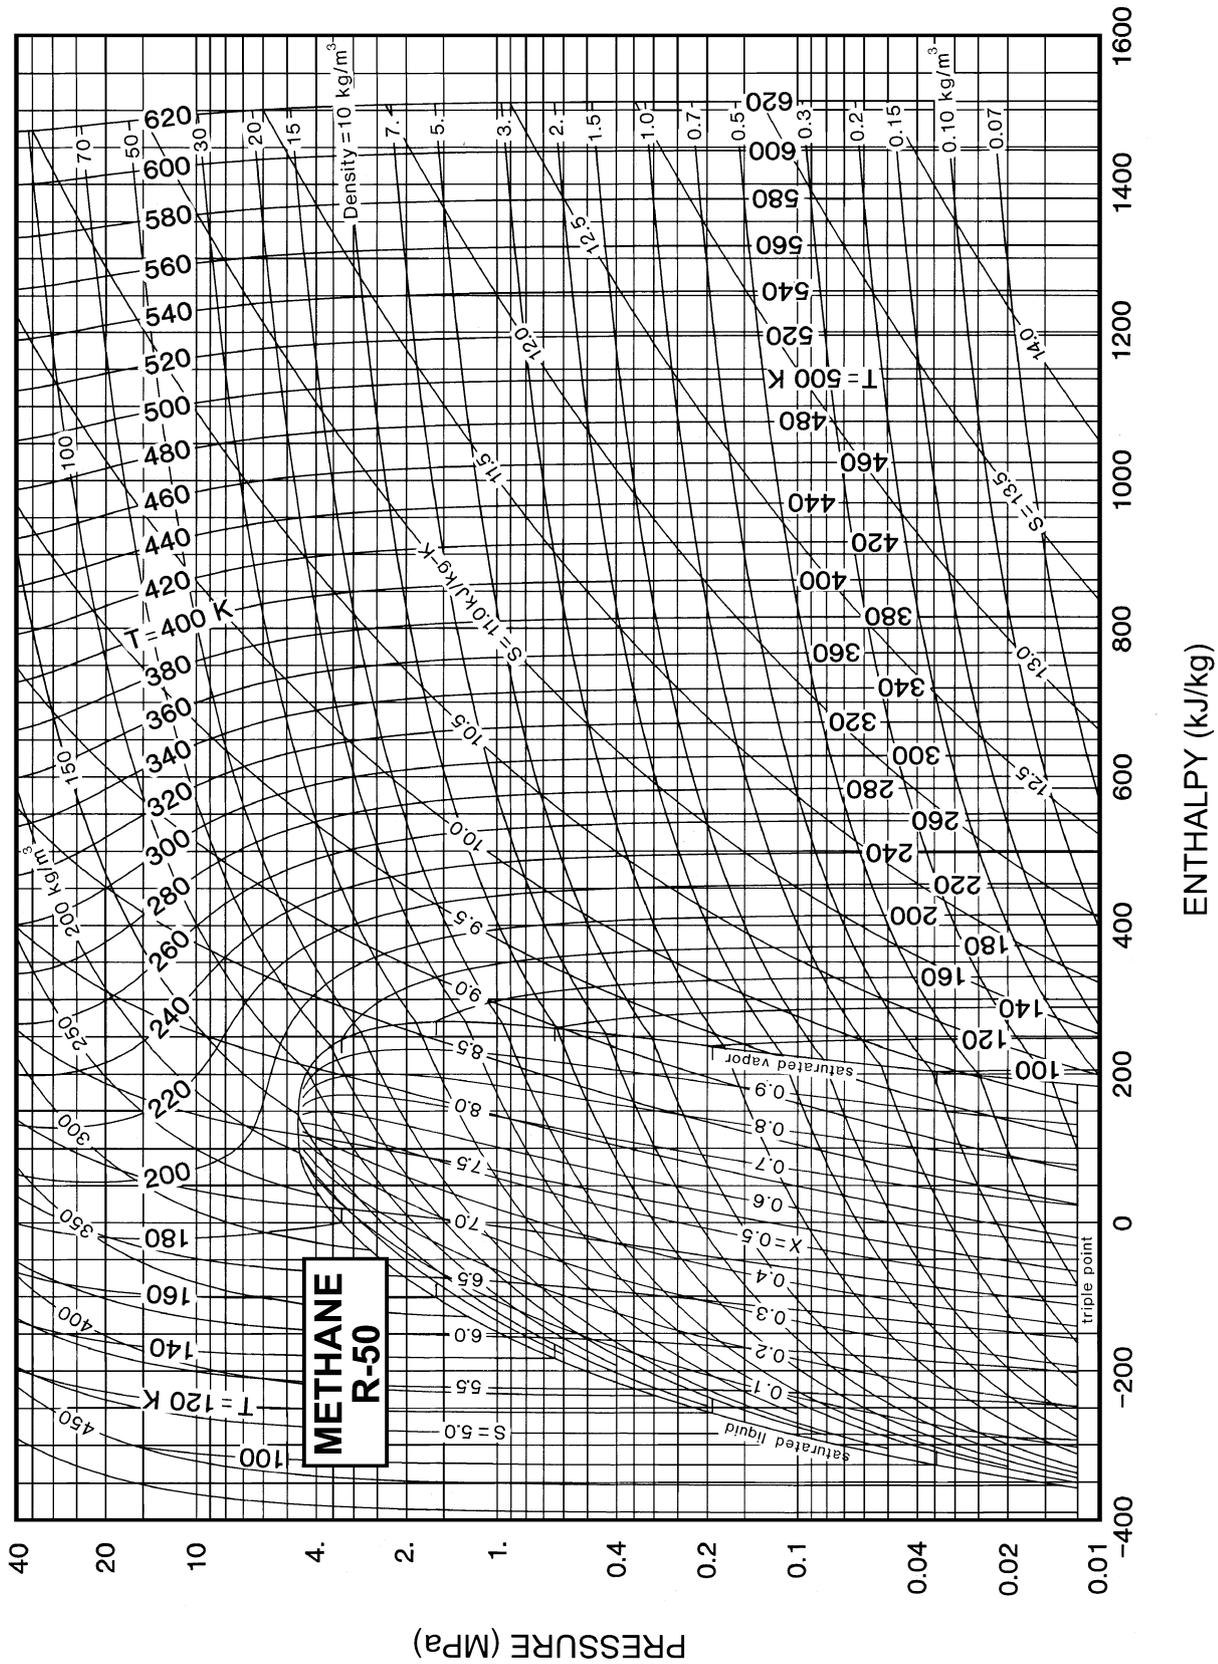

Fig. 14 Pressure-Enthalpy Diagram for Refrigerant 744 (Carbon Dioxide)

Note: The reference states for enthalpy and entropy differ from those in the table.

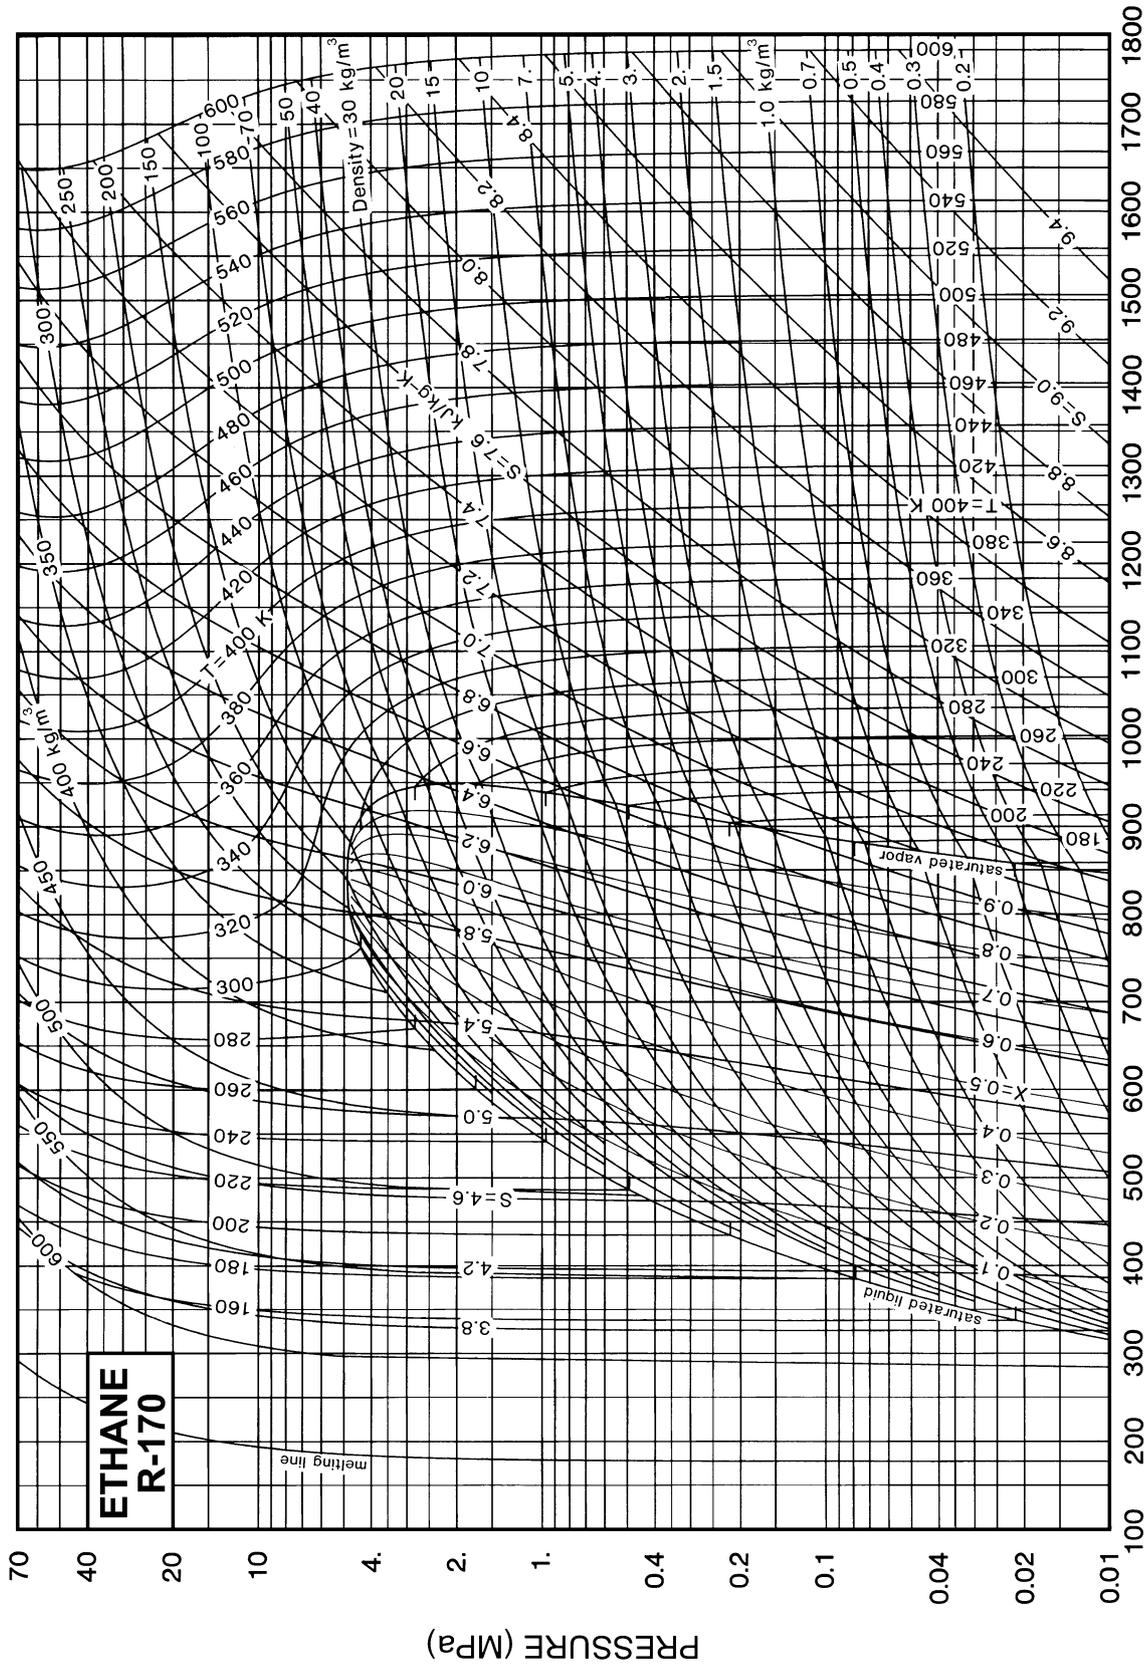

Refrigerant 744 (Carbon Dioxide) Properties of Saturated Liquid and Saturated Vapor

Temp., °C	Pres- sure, MPa	Density, kg/m <sup>3</sup>	Volume, m <sup>3</sup> /kg	Enthalpy, kJ/kg		Entropy, kJ/(kg·K)		Specific Heat $c_p$ , kJ/(kg·K)			Velocity of Sound, m/s		Viscosity, μPa·s		Thermal Cond., mW/(m·K)		Surface Tension, mN/m	Temp., °C
				Liquid	Vapor	Liquid	Vapor	Liquid	Vapor	Vapor	Liquid	Vapor	Liquid	Vapor	Liquid	Vapor

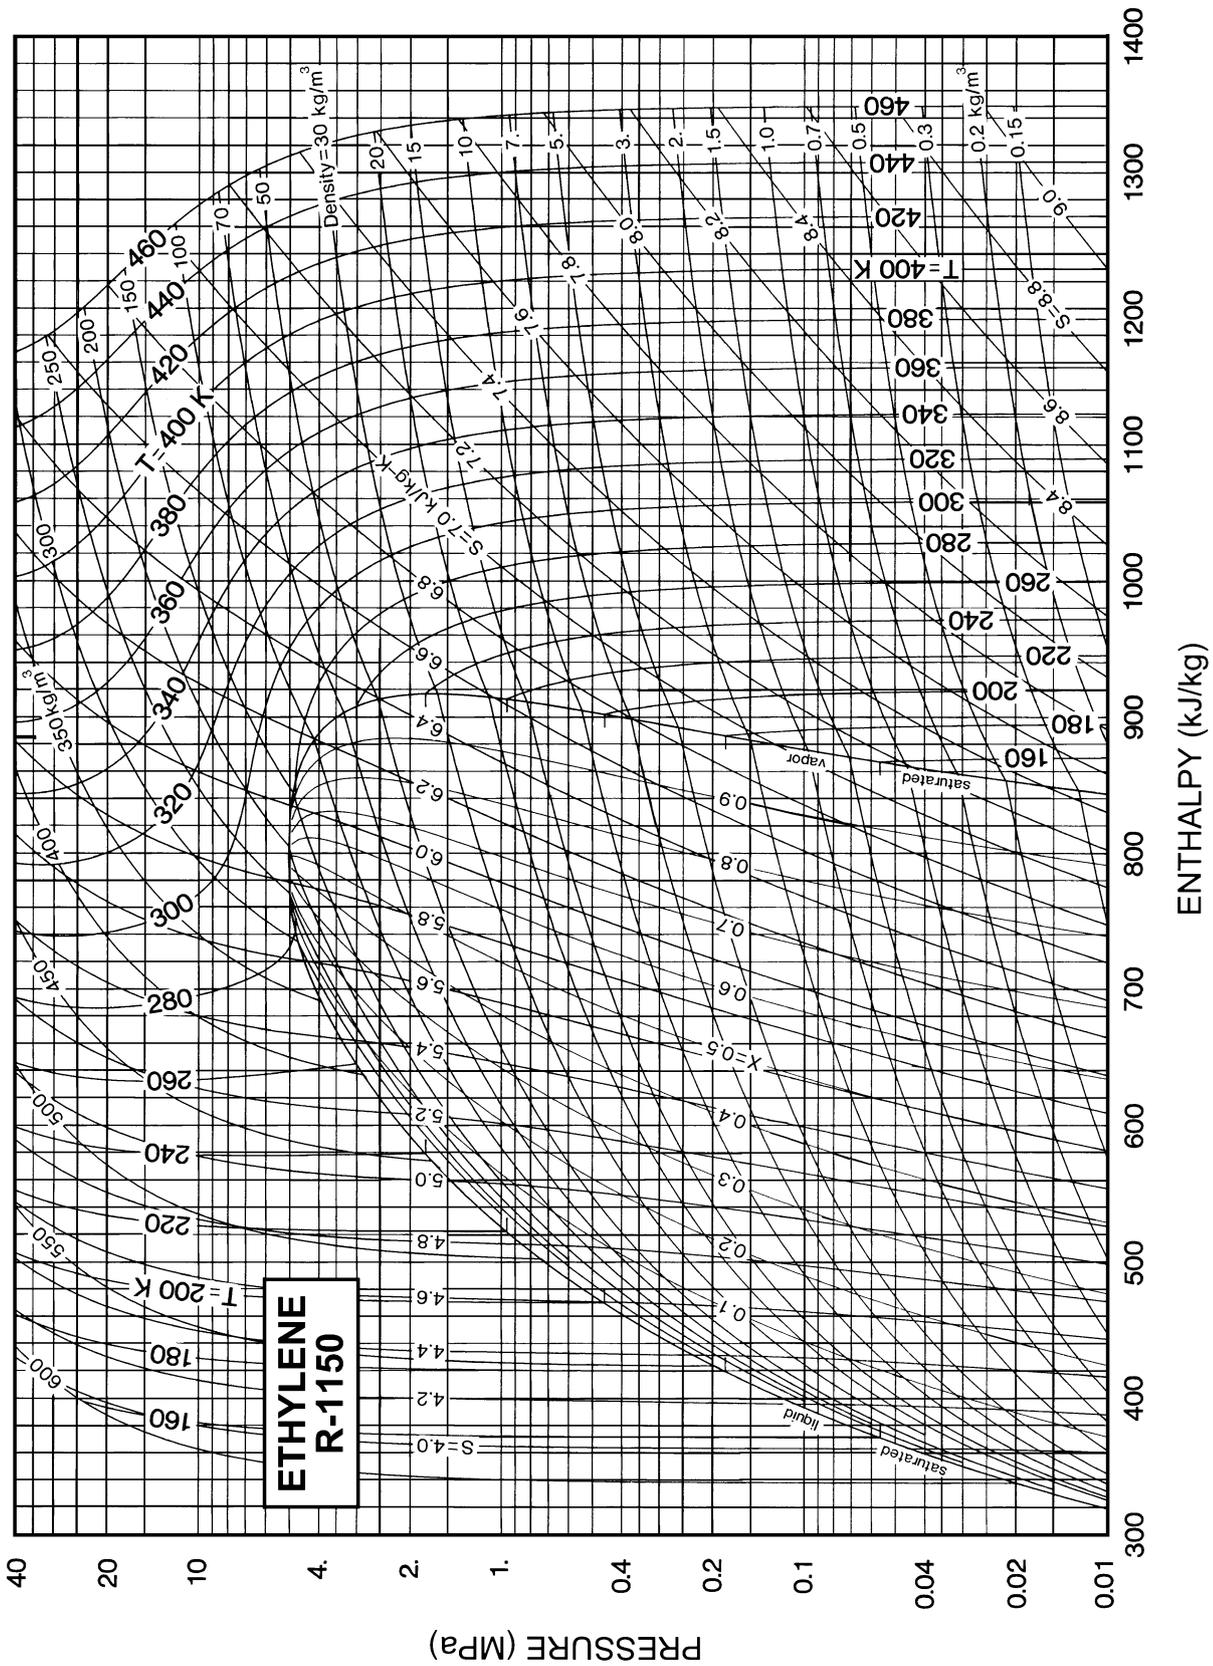

**Fig. 19 Pressure-Enthalpy Diagram for Refrigerant 600a (Isobutane)**

*Note:* The reference states for enthalpy and entropy differ from those in the table.

Refrigerant 600a (Isobutane) Properties of Saturated Liquid and Saturated Vapor

Temp., °C	Pres- sure, MPa	Density, kg/m <sup>3</sup>		Enthalpy, kJ/kg		Entropy, kJ/(kg·K)		Specific Heat <i>c<sub>p</sub></i> , kJ/(kg·K)			Velocity of Sound, m/s		Viscosity, μPa·s		Thermal Cond., mW/(m·K)		Surface Tension, mN/m	Temp., °C
		Liquid	Vapor	Liquid	Vapor	Liquid	Vapor	Liquid	Vapor	Vapor	Liquid	Vapor	Liquid	Vapor	Liquid	Vapor

**Fig. 20 Pressure-Enthalpy Diagram for Refrigerant 1150 (Ethylene)**

*Note:* The reference states for enthalpy and entropy differ from those in the table.

Refrigerant 1150 (Ethylene) Properties of Saturated Liquid and Saturated Vapor

Temp., °C	Pres- sure, MPa	Density, kg/m <sup>3</sup>		Volume, m <sup>3</sup> /kg		Enthalpy, kJ/kg		Entropy, kJ/(kg·K)		Specific Heat $c_p$ , kJ/(kg·K)			Velocity of Sound, m/s		Viscosity, μPa·s		Thermal Cond., mW/(m·K)		Surface Tension, mN/m	Temp., °C
		Liquid	Vapor	Liquid	Vapor	Liquid	Vapor	Liquid	Vapor	Liquid	Vapor	Liquid	Vapor	Liquid	Vapor	Liquid	Vapor

## CHAPTER 21

# PHYSICAL PROPERTIES OF SECONDARY COOLANTS (BRINES)

<i>Brines</i> .....	21.1
<i>Inhibited Glycols</i> .....	21.4
<i>Halocarbons</i> .....	21.12
<i>Nonhalocarbon, Nonaqueous Fluids</i> .....	21.12

**I**N MANY refrigeration applications, heat is transferred to a **secondary coolant**, which can be any liquid cooled by the refrigerant and used to transfer heat without changing state. These liquids are also known as **heat transfer fluids, brines, or secondary refrigerants**.

Other ASHRAE Handbooks describe various applications for secondary coolants. In the 1998 *ASHRAE Handbook—Refrigeration*, refrigeration systems are discussed in Chapter 4, their uses in food processing are found in Chapters 14 through 28, and ice rinks are discussed in Chapter 34. In the 1999 *ASHRAE Handbook—Applications*, solar energy use is discussed in Chapter 32, thermal storage in Chapter 33, and snow melting in Chapter 49.

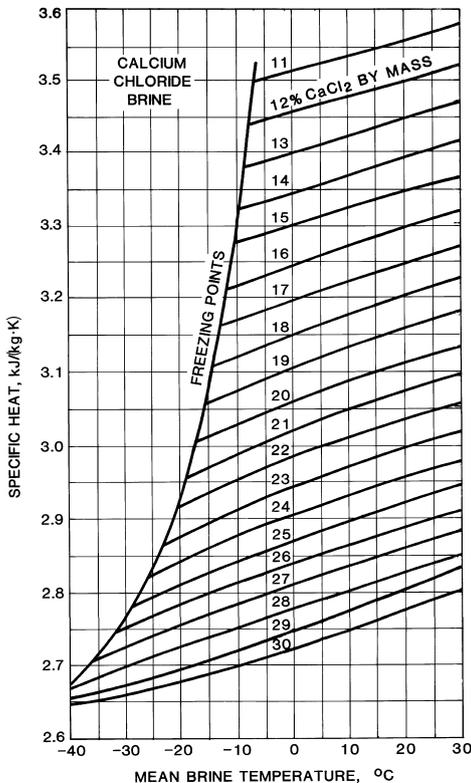

This chapter describes the physical properties of several secondary coolants and provides information on their use. The chapter also includes information on corrosion protection. Additional information on corrosion inhibition can be found in Chapter 47 of the 1999 *ASHRAE Handbook—Applications* and Chapter 4 of the 1998 *ASHRAE Handbook—Refrigeration*.

## BRINES

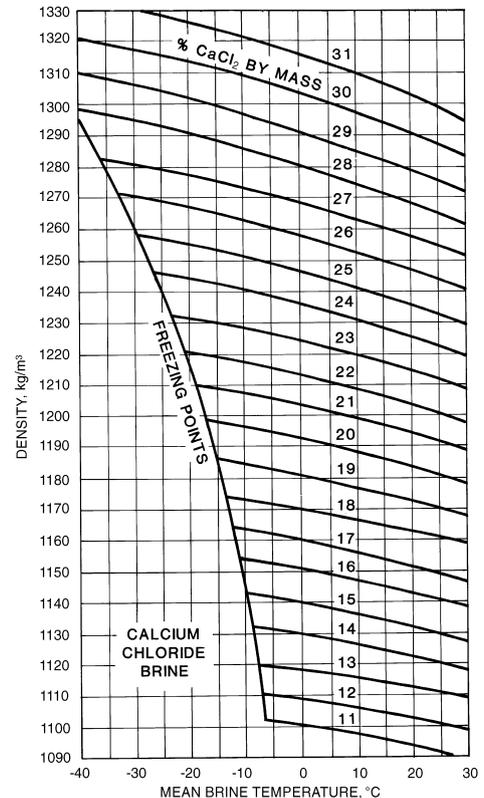

### Physical Properties

Water solutions of calcium chloride and sodium chloride are the most common refrigeration brines. Tables 1 and 2 list the properties of pure calcium chloride brine and sodium chloride brine. For commercial grades, use the formulas in the footnotes to these tables. Figures 1 and 5 give the specific heats for calcium chloride and sodium chloride brines and are used for computation of heat loads with ordinary brine (Carrier 1959). Figures 2 and 6 show the ratio of the mass of the solution to that of water, which is commonly used as the measure of salt concentration. Viscosities are given in Figures 3 and 7. Figures 4 and 8 show thermal conductivity of calcium and sodium brines at varying temperatures and concentrations.

Brine applications in refrigeration are mainly in the industrial machinery field and in skating rinks. Corrosion is the principal problem for calcium chloride brines, especially in ice-making tanks where galvanized iron cans are immersed.

**Fig. 1** Specific Heat of Calcium Chloride Brines

**Fig. 2** Density of Calcium Chloride Brines

The preparation of this chapter is assigned to TC 3.1, Refrigerants and Brines.

<sup>a</sup>Mass of commercial NaCl required = (mass of pure NaCl required)/(% purity).

<sup>b</sup>Mass of water per unit volume = Brine mass minus NaCl mass.

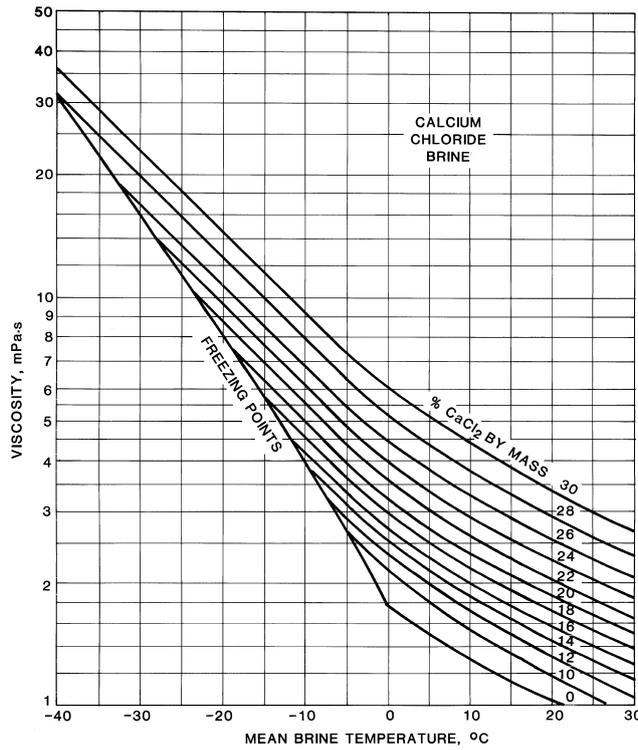

Fig. 3 Viscosity of Calcium Chloride Brines

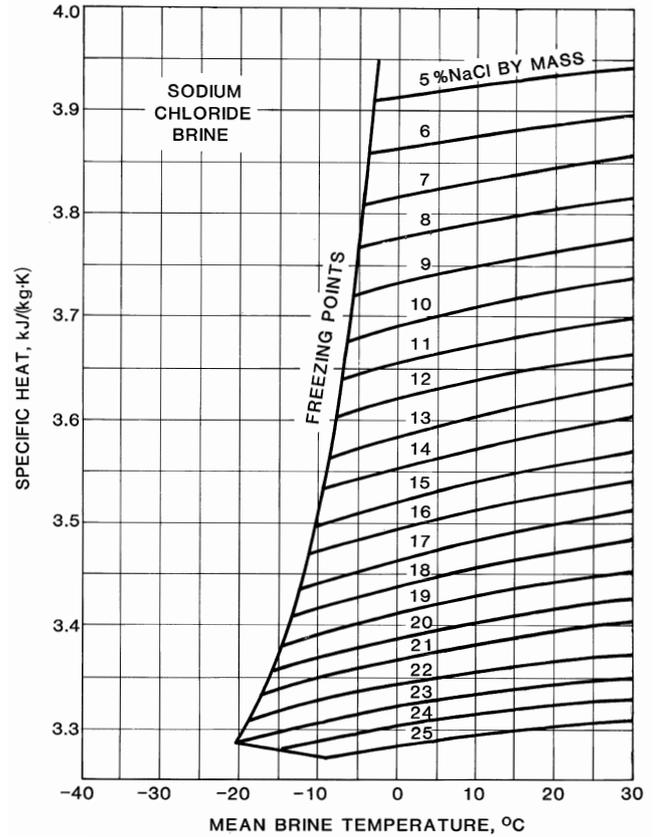

Fig. 5 Specific Heat of Sodium Chloride Brines

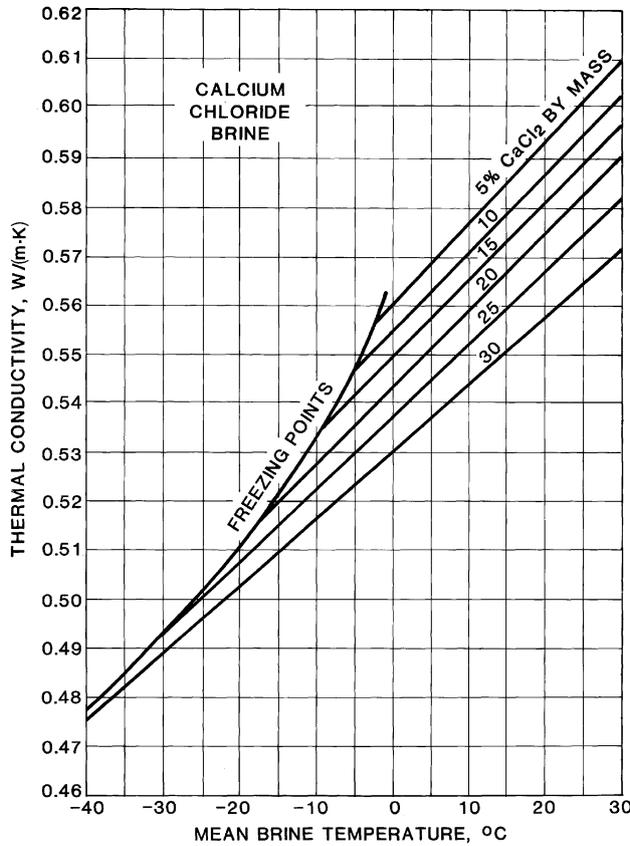

Fig. 4 Thermal Conductivity of Calcium Chloride Brines

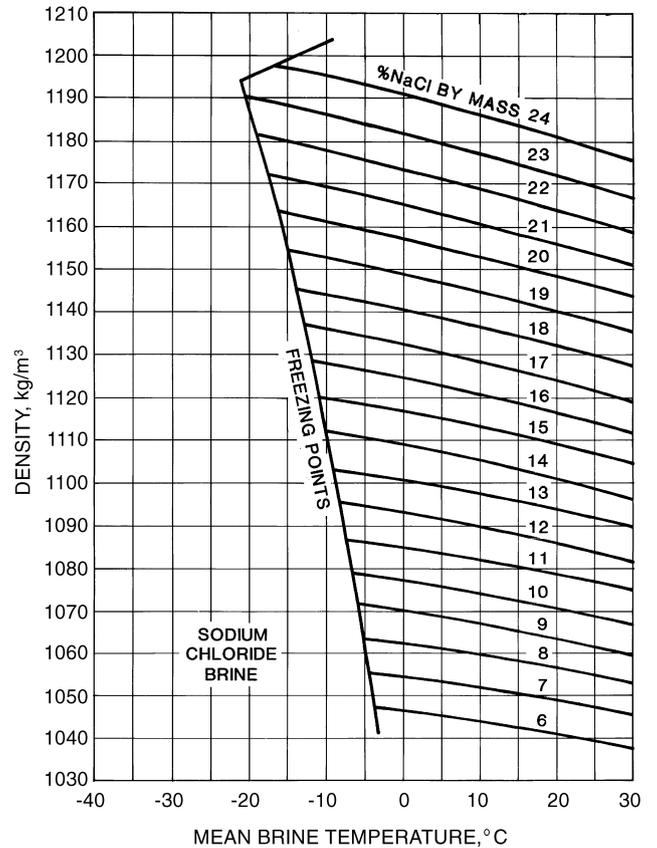

Fig. 6 Density of Sodium Chloride Brines

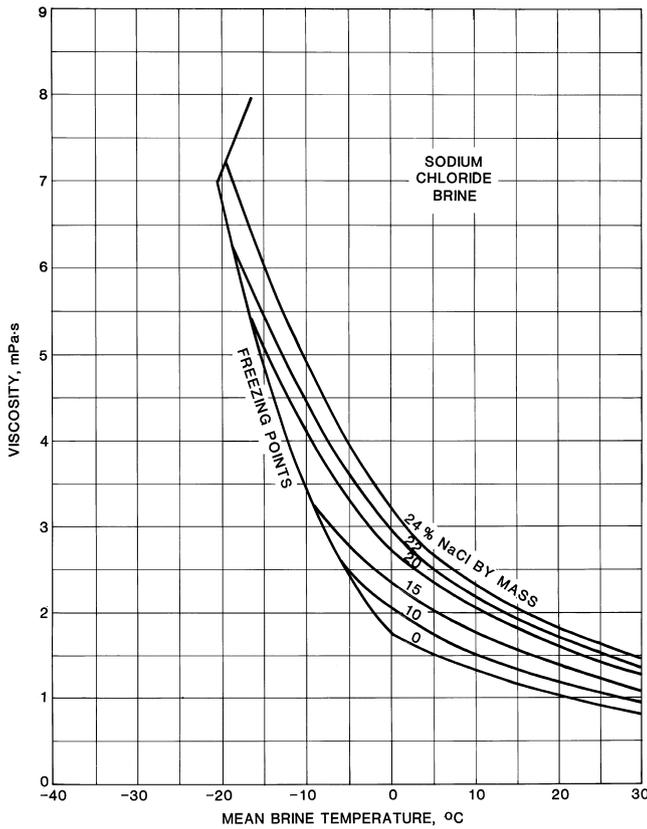

Fig. 7 Viscosity of Sodium Chloride Brines

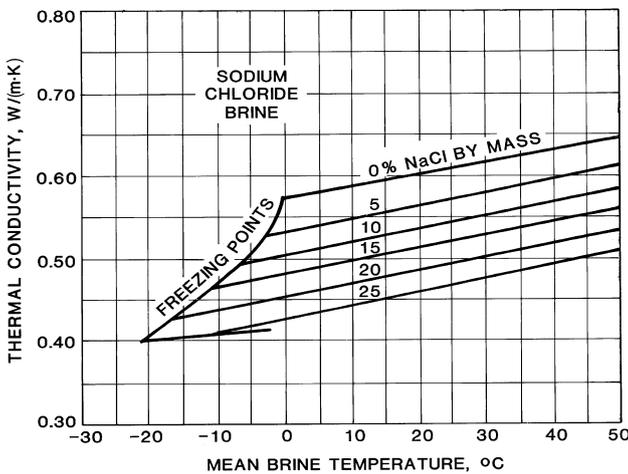

Fig. 8 Thermal Conductivity of Sodium Chloride Brines (Carrier 1959)

Ordinary salt (sodium chloride) is used where contact with calcium chloride is intolerable (e.g., the brine fog method of freezing fish and other foods). It is used as a spray in air cooling of unit coolers to prevent frost formation on coils. In most refrigerating work, the lower freezing point of calcium chloride solution makes it more convenient to use.

Commercial calcium chloride, available as Type 1 (77% minimum) and Type 2 (94% minimum), is marketed in flake, solid, and solution forms; flake form is used most extensively. Commercial sodium chloride is available both in crude (rock salt) and refined grades. Because magnesium salts tend to form sludge, their presence in sodium or calcium chloride is undesirable.

**Corrosion Inhibition**

Brine systems must be treated to control corrosion and deposits. The standard chromate treatment program is the most effective. Calcium chloride brines require a minimum of 1800 mg/kg of sodium chromate with pH 6.5 to 8.5. Sodium chloride brines require a minimum of 3600 mg/kg of sodium chromate and a pH of 6.5 to 8.5. Sodium nitrite at 3000 mg/kg in calcium brines or 4000 mg/kg in sodium brines controls pH between 7.0 and 8.5, and it should provide adequate protection. Organic inhibitors are available that may provide adequate protection where neither chromates nor nitrites can be used.

Before using any chromate-based inhibitor package, review federal, state, and local regulations concerning the use and disposal of chromate-containing fluids. If the regulations prove too restrictive, an alternative inhibition system should be considered.

**INHIBITED GLYCOLS**

Ethylene glycol and propylene glycol, inhibited for corrosion control, are used as aqueous freezing point depressants (antifreeze) and heat transfer media. Their chief attributes are their ability to lower the freezing point of water, their low volatility, and their relatively low corrosivity when properly inhibited. Inhibited ethylene glycol solutions have better physical properties than propylene glycol solutions, especially at lower temperatures. However, the less toxic propylene glycol is preferred for applications involving possible human contact or where mandated by regulations.

**Physical Properties**

Ethylene glycol and propylene glycol are colorless, practically odorless liquids that are miscible with water and many organic compounds. Table 3 shows properties of the pure materials.

The freezing and boiling points of aqueous solutions of ethylene glycol and propylene glycol are given in Tables 4 and 5. Note that increasing the concentration of ethylene glycol above 60% by mass causes the freezing point of the solution to increase. Propylene glycol solutions above 60% by mass do not have freezing points. Instead of freezing, propylene glycol solutions become a glass (glass being an

<sup>a</sup>Freezing points are below -50°C.

amorphous, undercooled liquid of extremely high viscosities that has all the appearances of a solid). On the dilute side of the eutectic, ice forms on freezing; on the concentrated side, solid glycol separates from solution on freezing. The freezing velocity of such solutions is often quite slow; but, in time, they set to a hard, solid mass.

Physical properties (i.e., density, specific heat, thermal conductivity, and viscosity) for aqueous solutions of ethylene glycol can be found in Tables 6 through 9 and Figures 9 through 12; similar data for aqueous solutions of propylene glycol can be found in Tables 10 through 13 and Figures 13 through 16. Densities are for aqueous solutions of industrially inhibited glycols. These densities are somewhat higher than those for pure glycol and water alone. Typical corrosion inhibitor packages do not significantly affect the other physical properties. The physical properties for the two fluids are similar, with the exception of viscosity. At the same concen-

<sup>a</sup>Above 60% by mass, solutions do not freeze but become a glass.

tration, aqueous solutions of propylene glycol are more viscous than solutions of ethylene glycol. This higher viscosity accounts for the majority of the performance difference between the two fluids.

The choice of glycol concentration depends on the type of protection required by the application. If the fluid is being used to prevent equipment damage during idle periods in cold weather, such as winterizing coils in an HVAC system, 30% ethylene glycol or 35% propylene glycol is sufficient. These concentrations will allow the fluid to freeze. As the fluid freezes, it forms a slush that expands and flows into any available space. Therefore, expansion volume must be included with this type of protection. If the application requires that the fluid remain entirely liquid, a concentration with a freezing point 3°C below the lowest expected temperature should be chosen. Avoid excessive glycol concentration because it increases initial cost and adversely affects the physical properties of the fluid.

Additional physical property data is available from suppliers of industrially inhibited ethylene and propylene glycol.

### Corrosion Inhibition

Commercial ethylene glycol or propylene glycol, when pure, is generally less corrosive than water to common metals used in construction. However, aqueous solutions of these glycols assume the corrosivity of the water from which they are prepared and can become increasingly corrosive with use if they are not properly inhibited. Without inhibitors, glycols oxidize into acidic end products. The amount of oxidation is influenced by temperature, degree of aeration, and, to some extent, the particular combination of metal components to which the glycol solution is exposed.

Corrosion inhibition can be described by classifying additives as either (1) corrosion inhibitors, or (2) environmental stabilizers and adjusters. **Corrosion inhibitors** form a surface barrier that protects the metal from attack. These barriers are usually formed by adsorption of the inhibitor by the metal, by reaction of the inhibitor with the metal, or by the incipient reaction product. In most cases, metal surfaces are covered by films of their oxides that inhibitors reinforce.

**Environmental stabilizers or adjusters**, while not corrosion inhibitors in the strict sense, decrease corrosion by stabilizing or favorably altering the overall environment. An alkaline buffer such as borax is an example of an environmental stabilizer, since its prime purpose is to maintain an alkaline condition (pH above 7). Some chelating agents function as stabilizers by removing from the solution certain deleterious ions that accelerate the corrosion process or mechanism; however, exercise caution in their use because improper combinations of pH and concentration may lead to excessive corrosion.

Certain oxidants, such as sodium chromate, should not be used with glycol solutions, because the glycol can oxidize prematurely. Generally, combinations of the two types of additives, inhibitors, and stabilizers offer the best corrosion resistance in a given system. Commercial inhibited glycols are available from several suppliers.

### Service Considerations

**Design Considerations.** Inhibited glycols can be used at temperatures as high as 175°C. However, maximum-use temperatures vary from fluid to fluid. Therefore, the manufacturer's suggested temperature-use ranges should be followed. In systems with a high degree of aeration, the bulk fluid temperature should not exceed 82°C; however, temperatures up to 175°C are permissible in a pressurized system if air intake is eliminated. Maximum film temperatures should not exceed 28°C above the bulk temperature. Nitrogen blanketing minimizes oxidation when the system operates at elevated temperatures for extended periods.

Minimum operating temperatures are typically -23°C for ethylene glycol solutions and -18°C for propylene glycol solutions. Operation below these temperatures is generally impractical, because the viscosity of the fluids builds dramatically, thus increasing pumping power requirements and reducing heat transfer film coefficients.

Standard materials can be used with most inhibited glycol solutions except galvanized steel, because the galvanizing material, zinc, reacts with a portion of the inhibitor package found in most formulated glycols.

Because the removal of sludge and other contaminants is critical, install suitable filters. If inhibitors are rapidly and completely adsorbed by such contamination, the fluid is ineffective for corrosion inhibition. Consider such adsorption when selecting filters.

**Storage and Handling.** Inhibited glycol concentrates are stable, relatively noncorrosive materials with high flash points. These fluids can be stored in mild steel, stainless steel, or aluminum vessels. However, aluminum should be used only when the fluid temperature is below 66°C. Corrosion in the vapor space of vessels may be a problem, because the fluid's inhibitor package cannot reach these surfaces to protect them. To prevent this problem, a coating may be used. Suitable coatings include novolac-based vinyl ester resins, high-bake phenolic resins, polypropylene, and polyvinylidene fluoride. To ensure the coating is suitable for a particular application and temperature, the manufacturer should be consulted. Since the chemical properties of an inhibited glycol concentrate differ from those of its dilutions, the effect of the concentrate on different containers should be known when selecting storage.

Choose transfer pumps only after considering temperature-viscosity data. Centrifugal pumps with electric motor drives are often used. Materials compatible with ethylene or propylene glycol should be used for pump packing material. Mechanical seals are also satisfactory. Welded mild steel transfer piping with a minimum diameter is normally used in conjunction with the piping, although flanged and gasketed joints are also satisfactory.

**Preparation Before Application.** Before an inhibited glycol is charged into a system, remove residual contaminants such as sludge, rust, brine deposits, and oil so the contained inhibitor functions properly. Avoid strong acid cleaners; if they are required, consider inhibited acids. Completely remove the cleaning agent before charging with inhibited glycol.

**Dilution Water.** Use distilled, deionized, or condensate water, because water from some sources contains elements that reduce the effectiveness of the inhibited formulation. If water of this quality is unavailable, water containing less than 25 mg/kg chloride, less than 25 mg/kg sulfate, and less than 100 mg/kg of total hardness may be used.

**Fluid Maintenance.** Glycol concentrations can be determined by refractive index, gas chromatography, or Karl Fischer analysis for water (assuming that the concentration of other fluid components, such as inhibitor, is known). Using density to determine glycol concentration is unsatisfactory because (1) density measurements are temperature sensitive, (2) inhibitor concentrations can change density, (3) values for propylene glycol are close to those of water, and (4) propylene glycol values are maximum at 70 to 75% concentration.

A rigorous inhibitor monitoring and maintenance schedule is essential to maintain a glycol solution in relatively noncorrosive condition for a long period. However, a specific schedule is not always easy to establish, because inhibitor depletion rate depends on the particular conditions of use. Analysis of samples immediately after installation, after two to three months, and after six months should establish the pattern for the schedule. Visually inspecting the solution and filter residue can detect active corrosion.

Many manufacturers of inhibited glycol-based heat transfer fluids provide analytical service to ensure that their heat transfer fluid remains in good condition. This analysis may include some or all of the following: percent of ethylene and/or propylene glycol, freezing point, pH, reserve alkalinity, corrosion inhibitor evaluation, contaminants, total hardness, metal content, and degradation products. If maintenance on the fluid is required, recommendations may be given along with the analysis results.

Properly inhibited and maintained glycol solutions provide better corrosion protection than brine solutions in most systems. A long, though not indefinite, service life can be expected. Avoid indiscriminate mixing of inhibited formulations. Exercise caution in replacing brine systems with inhibited glycols because brine components are incompatible with glycol formulations.

## HALOCARBONS

Many common refrigerants are used as secondary coolants as well as primary refrigerating media. Their favorable properties as heat transfer fluids include low freezing points, low viscosities, nonflammability, and good stability. Chapters 19 and 20 present physical and thermodynamic properties for common refrigerants. Table 14 lists two halocarbon compounds that are commonly used as secondary coolants. Table 15 gives vapor pressure, specific heat, thermal conductivity, density, and viscosity values for methylene chloride (R-30). Table 16 gives the same properties for trichloroethylene (R-1120).

Table 9 in Chapter 19 summarizes comparative safety characteristics for halocarbons. *Threshold Limit Values and Biological Exposure Indices* (ACGIH) has more information on halocarbon toxicity.

Construction materials and stability factors in halocarbon use are discussed in Chapter 19 of this volume and Chapter 5 of the 1998 *ASHRAE Handbook—Refrigeration*. Note particularly that methylene chloride and trichloroethylene should not be used in contact with aluminum components.

## NONHALOCARBON, NONAQUEOUS FLUIDS

In addition to the aforementioned fluids, numerous other secondary refrigerants are available. These fluids have been used primarily by the chemical processing and pharmaceutical industries. They have been used rarely in the HVAC and allied industries due to their

Note: Properties are estimated or based on incomplete data.

d-limonene is limited; it is based on measurements made over small data temperature ranges or simply on standard physical property estimation techniques. The compound is an optically active terpene (molecular formula C<sub>10</sub>H<sub>16</sub>) derived as an extract from orange and lemon oils. The “d” indicates that the material is dextrorotatory, which is a physical property of the material that does not affect the transport properties of the material significantly.

The mixture of dimethylsiloxane polymers can be used with most standard construction materials; d-limonene, however, can be quite corrosive, easily autooxidizing at ambient temperatures. This fact should be understood and considered before using d-limonene in a system.

## SORBENTS AND DESICCANTS

<i>Desiccant Applications</i> .....	22.1
<i>Desiccant Cycle</i> .....	22.1
<i>Types of Desiccants</i> .....	22.3
<i>Desiccant Isotherms</i> .....	22.5
<i>Desiccant Life</i> .....	22.5
<i>Cosorption of Water Vapor and Indoor Air Contaminants</i> .....	22.6

**S**ORPTION refers to the binding of one substance to another. **Sorbents** are materials that have an ability to attract and hold other gases or liquids. They can be used to attract gases or liquids other than water vapor, a characteristic that makes them very useful in chemical separation processes. **Desiccants** are a subset of sorbents; they have a particular affinity for water.

Virtually all materials are desiccants; that is, they attract and hold water vapor. Wood, natural fibers, clays, and many synthetic materials attract and release moisture as commercial desiccants do, but they lack the holding capacity. For example, woolen carpet fibers attract up to 23% of their dry mass in water vapor, and nylon can take up almost 6% of its mass in water. In contrast, a commercial desiccant takes up between 10 and 1100% of its dry mass in water vapor, depending on its type and on the moisture available in the environment. Furthermore, commercial desiccants continue to attract moisture even when the surrounding air is quite dry, a characteristic that other materials do not share.

All desiccants behave in a similar way—they attract moisture until they reach equilibrium with the surrounding air. Moisture is usually removed from the desiccant by heating it to temperatures between 50 and 260°C and exposing it to a scavenger airstream. After the desiccant dries, it must be cooled so that it can attract moisture once again. Sorption always generates sensible heat equal to the latent heat of the water vapor taken up by the desiccant plus an additional heat of sorption that varies between 5 and 25% of the latent heat of the water vapor. This heat is transferred to the desiccant and to the surrounding air.

The process of attracting and holding moisture is described as either adsorption or absorption, depending on whether the desiccant undergoes a chemical change as it takes on moisture. **Adsorption** does not change the desiccant, except by the addition of the mass of water vapor; it is similar in some ways to a sponge soaking up water. **Absorption**, on the other hand, changes the desiccant. An example of an absorbent is table salt, which changes from a solid to a liquid as it absorbs moisture.

## DESICCANT APPLICATIONS

Desiccants can dry either liquids or gases, including ambient air, and are used in many air-conditioning applications, particularly when

- The latent load is large in comparison to the sensible load.
- The cost of energy to regenerate the desiccant is low compared to the cost of energy to dehumidify the air by chilling it below its dew point.
- The moisture control level for the space would require chilling the air to subfreezing dew points if compression refrigeration alone were used to dehumidify the air.

The preparation of this chapter is assigned to TC 3.5, Desiccant and Sorption Technology.

- The temperature control level for the space or process requires continuous delivery of air at subfreezing temperatures.

In any of these situations, the cost of running a vapor compression cooling system can be very high. A desiccant process may offer considerable advantages in energy, initial cost of equipment, and maintenance.

Because desiccants are able to attract and hold more than simply water vapor, they can remove contaminants from airstreams to improve indoor air quality. Desiccants have been used to remove organic vapors and, in special circumstances, to control microbiological contaminants (Batelle 1971, Buffalo Testing Laboratory 1974). Hines et al. (1991) have also confirmed the usefulness of desiccants in removing vapors that can degrade indoor air quality. Desiccant materials are capable of adsorbing hydrocarbon vapors while they are collecting moisture from air. These desiccant cosorption phenomena show promise of improving indoor air quality in typical building HVAC systems.

Desiccants are also used in drying compressed air to low dew points. In this application, moisture can be removed from the desiccant without heat. Desorption is accomplished using differences in vapor pressures compared to the total pressures of the compressed and ambient pressure airstreams.

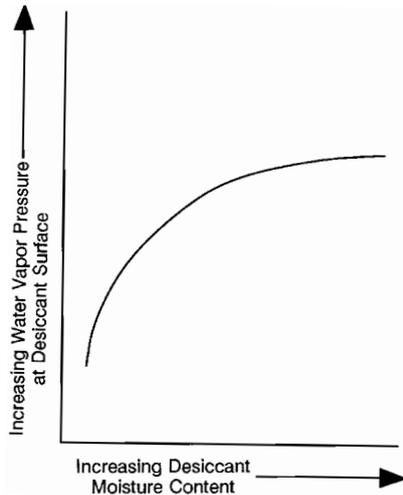

Finally, desiccants are used to dry the refrigerant circulating in air-conditioning and refrigeration systems. This reduces corrosion in refrigerant piping and prevents valves and capillaries from becoming clogged with ice crystals. In this application, the desiccant is not regenerated; it is discarded when it has adsorbed its limit of water vapor.

This chapter discusses the water sorption characteristics of desiccant materials and explains some of the implications of those characteristics in ambient pressure air-conditioning applications. Information on other applications for desiccants can be found in Chapters 14 and 29 of this volume, Chapters 6, 25, 34, 41, and 46 of the 1998 *ASHRAE Handbook—Refrigeration*, Chapters 1, 2, 5, 8, 15, 17, 20, 27, and 44 of the 1999 *ASHRAE Handbook—Applications*, and Chapters 22 and 44 of the 2000 *ASHRAE Handbook—Systems and Equipment*.

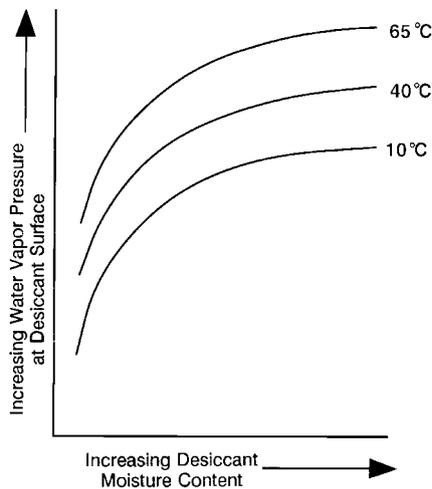

## DESICCANT CYCLE

Practically speaking, all desiccants function by the same mechanism—transferring moisture because of a difference between the water vapor pressure at their surface and that of the surrounding air. When the vapor pressure at the desiccant surface is lower than that of the air, the desiccant attracts moisture. When the surface vapor pressure is higher than that of the surrounding air, the desiccant releases moisture.

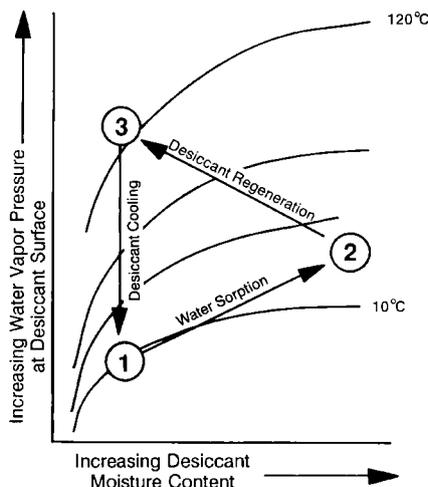

Figure 1 shows the relationship between the moisture content of the desiccant and its surface vapor pressure. As the moisture content of the desiccant rises, so does the water vapor pressure at its surface. At some point, the vapor pressure at the desiccant surface is the

**Fig. 1 Desiccant Water Vapor Pressure as Function of Moisture Content**  
(Harriman 1990)

**Fig. 2 Desiccant Water Vapor Pressure as Function of Desiccant Moisture Content and Temperature**  
(Harriman 1990)

**Fig. 3 Desiccant Cycle**  
(Harriman 1990)

same as that of the air—the two are in equilibrium. Then, moisture cannot move in either direction until some external force changes the vapor pressure at the desiccant or in the air.

Figure 2 shows the effect of temperature on the vapor pressure at the desiccant surface. Both higher temperature and increased moisture content increase the vapor pressure at the surface. When the surface vapor pressure exceeds that of the surrounding air, moisture leaves the desiccant—a process called **reactivation** or **regeneration**. After the desiccant is dried (reactivated) by the heat, its vapor pressure remains high, so that it has very little ability to absorb moisture. **Cooling** the desiccant reduces its surface vapor pressure so that it can absorb moisture once again. The complete cycle is illustrated in Figure 3.

The economics of desiccant operation depend on the energy cost of moving a given material through this cycle. The dehumidification of air (loading the desiccant with water vapor) generally proceeds without energy input other than fan and pump costs. The major portion of energy is invested in regenerating the desiccant (moving from point 2 to point 3) and cooling the desiccant (point 3 to point 1).

**Regeneration energy** is equal to the sum of three variables:

1. The heat necessary to raise the desiccant to a temperature high enough to make its surface vapor pressure higher than that of the surrounding air
2. The heat necessary to vaporize the moisture it contains (about 2465 kJ/kg)
3. The small amount of heat from desorption of the water from the desiccant

The **cooling energy** is proportional to (1) the mass of the desiccant and (2) the difference between its temperature after regeneration and the lower temperature that allows the desiccant to remove water from the airstream once again.

The cycle is similar when desiccants are regenerated using pressure differences in a compressed air application. The desiccant is saturated in a high-pressure chamber (i.e., that of the compressed air). Then valves open, isolating the compressed air from the material, and the desiccant is exposed to air at ambient pressure. The vapor pressure of the saturated desiccant is much higher than ambient air at normal pressures; thus the moisture leaves the desiccant for the surrounding air. An alternate desorption strategy uses a small portion of the dried air, returning it to the moist desiccant bed to reabsorb the moisture, then venting the air to the atmosphere at ambient pressures.

Table 1 shows the range of vapor pressures over which the desiccant must operate in space-conditioning applications. It converts the relative humidity at 21°C to dew point and the corresponding vapor pressure. The greater the difference between the air and desiccant surface vapor pressures, the greater the ability of the material to absorb moisture from the air at that moisture content.

The ideal desiccant for a particular application depends on the range of water vapor pressures likely to occur in the air, the temperature of the regeneration heat source, and the moisture sorption and desorption characteristics of the desiccant within those constraints. In commercial practice, however, most desiccants can be made to perform well in a wide variety of operating situations through careful engineering of the mechanical aspects of the dehumidification system. Some of these hardware issues are discussed in Chapter 22 of the 2000 *ASHRAE Handbook—Systems and Equipment*.

**TYPES OF DESICCANTS**

Desiccants can be liquids or solids and can hold moisture through absorption or adsorption, as described earlier. Most absorbents are liquids, and most adsorbents are solids.

**Liquid Absorbents**

Liquid absorption dehumidification can best be illustrated by comparison to the operation of an air washer. When air passes through an air washer, its dew point approaches the temperature of the water supplied to the machine. Air that is more humid is dehumidified and air that is less humid is humidified. In a similar manner, a liquid absorption dehumidifier brings air into contact with a liquid desiccant solution. The liquid has a vapor pressure lower than water at the same temperature, and the air passing over the solution approaches this reduced vapor pressure; it is dehumidified.

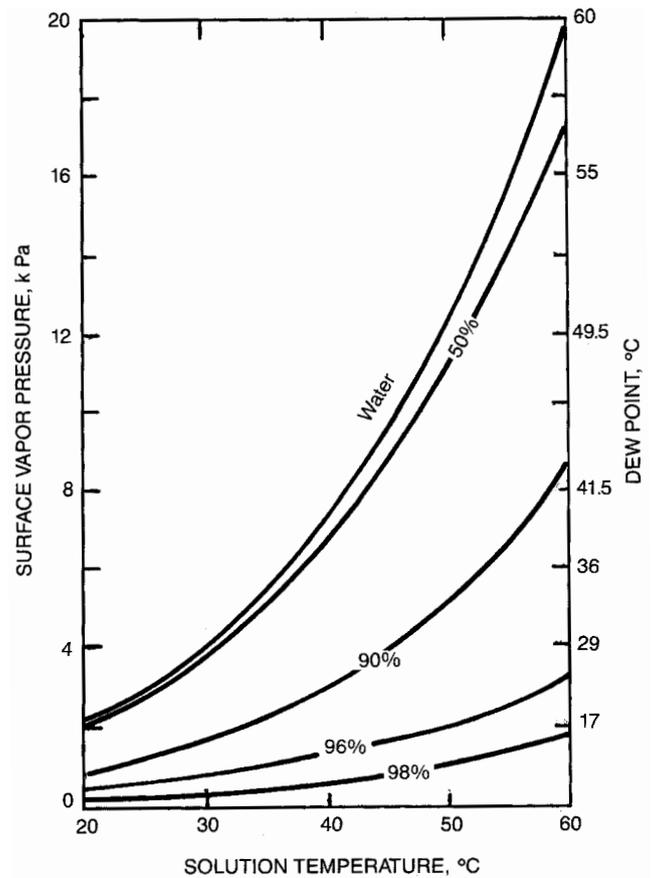

The vapor pressure of a liquid absorption solution is directly proportional to its temperature and inversely proportional to its concentration. Figure 4 illustrates the effect of increasing desiccant concentration on the water vapor pressure at its surface. The figure shows the vapor pressure of various solutions of water and triethylene glycol, a common commercial desiccant. As the glycol content of the mixture increases, the vapor pressure of the mixture decreases. This pressure difference allows the glycol solution to absorb moisture from the air whenever the vapor pressure of the air is greater than that of the solution.

From a slightly different perspective, the vapor pressure of a given concentration of absorbent solution approximates the vapor pressure values of a fixed relative humidity line on a psychrometric chart. Higher solution concentrations give lower equilibrium relative humidities, which allow the absorbent to dry air to lower levels.

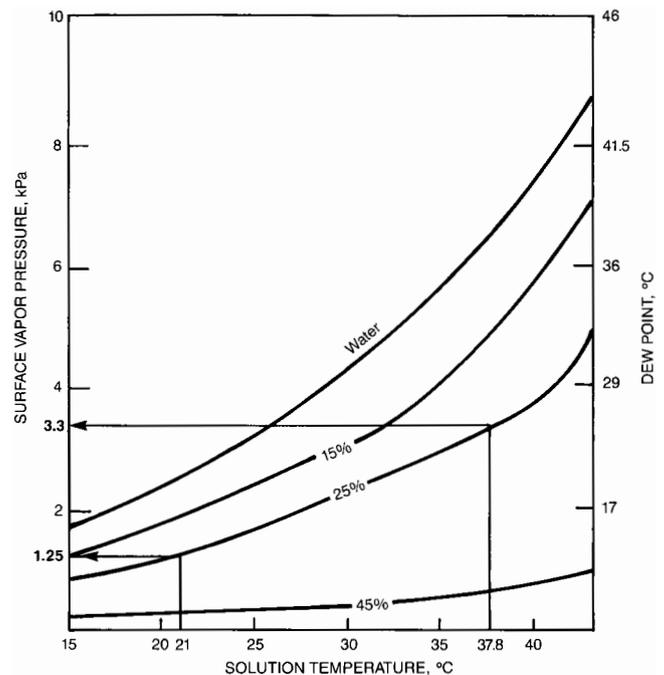

Figure 5 illustrates the effect of temperature on the vapor pressure of various solutions of water and lithium chloride (LiCl), another liquid desiccant in common use. A solution that is 25% lithium chloride has a vapor pressure of 1.25 kPa at a temperature of 21°C. If the same 25% solution is heated to 38°C, its vapor pressure more than doubles to 3.34 kPa. Expressed another way, the 21°C, 25% solution is in equilibrium with air at a 10.5°C dew point. The same 25% solution at 38°C is at equilibrium with an airstream at a 26°C dew point. The warmer the desiccant, the less moisture it can attract from the air.

In standard practice, the behavior of a liquid desiccant is controlled by adjusting its temperature, its concentration, or both. Desiccant temperature is controlled by simple heaters and coolers. Concentration is controlled by heating the desiccant to drive moisture out into a waste airstream or directly to the ambient.

Commercially available liquid desiccants have an especially high water-holding capacity. Each molecule of LiCl, for example, can hold two water molecules, even in the dry state. Above two water molecules per molecule of LiCl, the desiccant becomes a liquid and continues to absorb water. If the solution is in equilibrium with air at 90% rh, approximately 26 water molecules are attached to each molecule of LiCl. This represents a water absorption of more than 1000% on a dry mass basis.

**Fig. 4 Surface Vapor Pressure of Water-Triethylene Glycol Solutions**  
(Dow 1981)

**Fig. 5 Surface Vapor Pressure of Water-Lithium Chloride Solutions**  
(Foote Mineral 1988)

As a practical matter, however, the adsorption process is limited by the exposed surface area of the desiccant and by the contact time allowed for the reaction. More surface area and more contact time allow the desiccant to approach its theoretical capacity. Commercial desiccant systems stretch these limits by flowing the liquid desiccant onto an extended surface much like in a cooling tower.

### Solid Adsorbents

Adsorbents are solid materials with a tremendous internal surface area per unit of mass; a single gram can have more than 4600 m<sup>2</sup> of surface area. Structurally, adsorbents resemble a rigid sponge, and the surface of the sponge in turn resembles the ocean coastline of a fjord. This analogy indicates the scale of the different surfaces in an adsorbent. The fjords can be compared to the **capillaries** in the adsorbent. The spaces between the grains of sand on the fjord beaches can be compared to the spaces between the individual molecules of the adsorbent, all of which have the capacity to hold water molecules. The bulk of the adsorbed water is contained by condensation into the capillaries, and the majority of the surface area that attracts individual water molecules is in the crystalline structure of the material itself.

Adsorbents attract moisture because of the electrical field at the desiccant surface. The field is not uniform in either force or charge, so specific sites on the desiccant surface attract water molecules that have a net opposite charge. When the complete surface is covered, the adsorbent can hold still more moisture because vapor condenses into the first water layer and fills the capillaries throughout the material. As with liquid adsorbents, the ability of an adsorbent to attract moisture depends on the difference in vapor pressure between its surface and the air.

The capacity of solid adsorbents is generally less than the capacity of liquid adsorbents. For example, a typical molecular sieve adsorbent can hold 17% of its dry mass in water when the air is at 21°C and 20% rh. In contrast, LiCl can hold 130% of its mass at the same temperature and relative humidity. But solid adsorbents have several other favorable characteristics.

For example, molecular sieves continue to adsorb moisture even when they are quite hot, allowing dehumidification of very warm airstreams. Also, several solid adsorbents can be manufactured to precise tolerances, with pore diameters that can be closely controlled. This means they can be tailored to adsorb molecules of a specific diameter. Water, for example, has an effective molecular diameter of 3.2 nm. A molecular sieve adsorbent with an average pore diameter of 4.0 nm adsorbs water but has almost no capacity for larger molecules, such as organic solvents. This selective adsorption characteristic is useful in many applications. For example, several desiccants with different pore sizes can be combined in series to remove first water and then other specific contaminants from an airstream.

**Adsorption Behavior.** The adsorption behavior of solid adsorbents depends on (1) total surface area, (2) total volume of capillaries, and (3) range of capillary diameters. A large surface area gives the adsorbent a larger capacity at low relative humidities. Large capillaries provide a high capacity for condensed water, which gives the adsorbent a higher capacity at high relative humidities. A narrow range of capillary diameters makes an adsorbent more selective in the vapor molecules it can hold.

In designing a desiccant, some trade-offs are necessary. For example, materials with large capillaries necessarily have a smaller surface area per unit of volume than those with smaller capillaries. As a result, adsorbents are sometimes combined to provide a high adsorption capacity across a wide range of operating conditions. Figure 6 illustrates this point using three noncommercial silica gel adsorbents prepared for use in laboratory research. Each has a different internal structure, but since they are all silicas, they have similar surface adsorption characteristics. Gel 1 has large capillaries, making its total volume large but its total surface area small. It has

a large adsorption capacity at high relative humidities but adsorbs a small amount at low relative humidities.

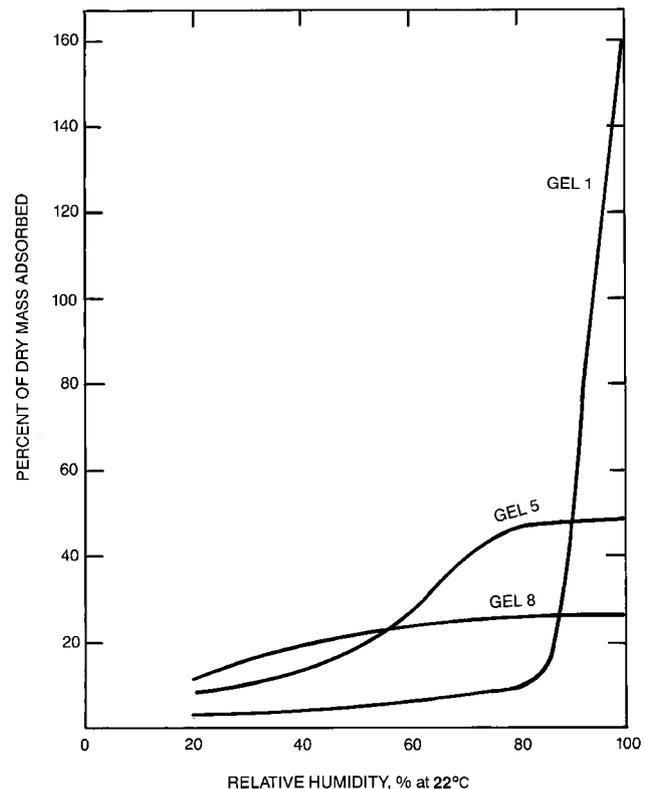

In contrast, Gel 8 has a capillary volume one-seventh the size of Gel 1, but a total surface area almost twice as large. This gives it a higher capacity at low relative humidities but a lower capacity to hold the moisture that condenses at high relative humidities.

Silica gels and most other adsorbents can be manufactured to provide optimum performance in a specific application, balancing capacity against strength, mass, and other favorable characteristics (Bry-Air 1986).

**Types of Solid Adsorbents.** General classes of solid adsorbents include

- Silica gels
- Zeolites
- Synthetic zeolites (molecular sieves)
- Activated aluminas
- Carbons
- Synthetic polymers

**Silica gels** are amorphous solid structures formed by condensing soluble silicates from solutions of water or other solvents. They have the advantages of relatively low cost and relative simplicity of structural customizing. They are available as large as spherical beads about 5 mm in diameter or as small as grains of a fine powder.

Gel Number	Total Surface Area, m <sup>2</sup> /g	Average Capillary Diameter, nm	Total Volume of Capillaries, mm <sup>3</sup> /g
1	315	21	1700
5	575	3.8	490
8	540	2.2	250

**Fig. 6 Adsorption and Structural Characteristics of Some Experimental Silica Gels**  
(Oscic and Cooper 1982)

**Zeolites** are aluminosilicate minerals. They occur in nature and are mined rather than synthesized. Zeolites have a very open crystalline lattice that allows molecules like water vapor to be held inside the crystal itself like an object in a cage. Particular atoms of an aluminosilicate determine the size of the openings between the "bars" of the cage, which in turn governs the maximum size of the molecule that can be adsorbed into the structure.

**Synthetic zeolites**, also called **molecular sieves**, are crystalline aluminosilicates manufactured in a thermal process. Controlling the temperature of the process and the composition of the ingredient materials allows close control of the structure and surface characteristics of the adsorbent. At a somewhat higher cost, this provides a much more uniform product than naturally occurring zeolites.

**Activated aluminas** are oxides and hydrides of aluminum that are manufactured in thermal processes. Their structural characteristics can be controlled by the gases used to produce them and by the temperature and duration of the thermal process.

**Carbons** are most frequently used for adsorption of gases other than water vapor because they have a greater affinity for the nonpolar molecules typical of organic solvents. Like other adsorbents, carbons have a large internal surface and especially large capillaries. This capillary volume gives them a high capacity to adsorb water vapor at relative humidities of 45 to 100%.

**Synthetic polymers** have potential for use as desiccants as well. Long molecules, like those found in polystyrenesulfonic acid sodium salt (PSSASS), are twisted together like the strands of string. Each of the many sodium ions in the long PSSASS molecules has the potential to bind several water molecules, and the spaces between the packed strings can also contain condensed water, giving the polymer a capacity exceeding that of many other solid adsorbents.

### DESICCANT ISOTHERMS

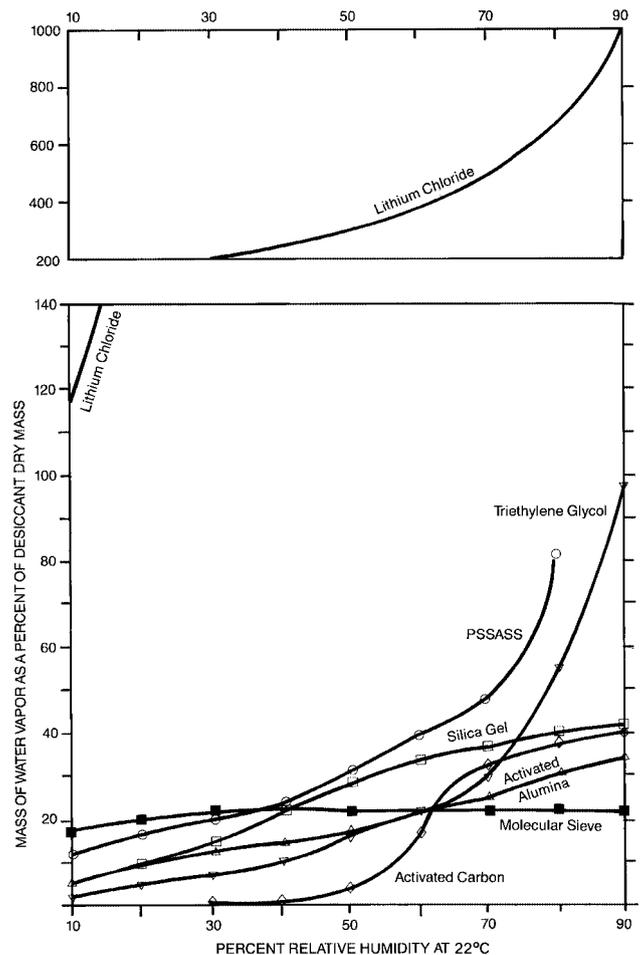

Figure 7 shows a rough comparison of the sorption characteristics of different desiccants. Large variations from these isotherms occur because manufacturers use different methods to optimize the materials for different applications. The suitability of a given desiccant to a particular application is generally governed as much by the engineering of the mechanical system that presents the material to the airstreams as by the characteristics of the material itself.

Several sources give details of desiccant equipment design and information about desiccant isotherm characteristics. Brunauer (1945) considers five basic isotherm shape types. Each isotherm shape is determined by the dominant sorption mechanisms of the desiccant, which give rise to its specific capacity characteristics at different vapor pressures. Isotherm shape can be important in designing the optimum desiccant for applications where a narrow range of operating conditions can be expected. Collier (1986, 1988) illustrates how an optimum isotherm shape can be used to ensure a maximum coefficient of performance in one particular air-conditioning desiccant application.

### DESICCANT LIFE

The useful life of desiccant materials depends largely on the quantity and type of contamination in the airstreams they dry. In commercial equipment, desiccants last from 10 000 to 100 000 h and longer before they need replacement. Normally, two mechanisms cause the loss of desiccant capacity: (1) change in desiccant sorption characteristics through **chemical reactions** with contaminants and (2) loss of effective surface area through clogging or **hydrothermal degradation**.

Liquid adsorbents are more susceptible to chemical reaction with airstream contaminants other than water vapor than are solid adsorbents. For example, certain sulfur compounds can react with LiCl to form lithium sulfate, which is not a desiccant. If the concentration of sulfur compounds in the airstream were below 10 mg/kg and the desiccant were in use 24 h a day, the capacity reduction would be approximately 10 to 20% after three years of operation. If

Fig. 7 Sorption Isotherms of Various Desiccants

the concentration were 30 mg/kg, this reduction would occur after one year.

Solid adsorbents tend to be less chemically reactive and more sensitive to clogging, a function of the type and quantity of particulate material in the airstream. In some situations, certain adsorbents are sensitive to hydrothermal stress due to the thermal expansion and contraction of the desiccant material on rapid changes in desiccant moisture content. For example, silica gel that must move between an airstream above 95% rh at low temperatures and a reactivating airstream at high temperatures six times per hour, 24 h a day can partly fracture; this may mean a 10% reduction in capacity over the course of one year. For applications where such capacity reduction is undesirable, thermally stabilized desiccants are used in place of more sensitive materials.

In air-conditioning applications, desiccant equipment is designed to minimize the need for desiccant replacement in much the same way that vapor compression cooling systems are designed to avoid the need for compressor replacement. Unlike filters, desiccants are seldom intended to be frequently replaced during normal service in an air-drying application.

## COSORPTION OF WATER VAPOR AND INDOOR AIR CONTAMINANTS

Hines et al. (1991) have confirmed that many desiccant materials can collect common indoor pollutants at the same time they collect water vapor from ambient air. This characteristic promises to become useful in future air-conditioning systems where the quality of indoor air is especially important.

The behavior of different desiccant and vapor mixtures is complex, but in general, pollutant sorption reactions can be classified into five categories:

- Humidity-neutral sorption
- Humidity-reduced sorption
- Humidity-enhanced sorption
- Humidity-pollutant displacement
- Desiccant-catalyzed pollutant conversion

Humidity-reduced sorption is illustrated by the behavior of water vapor and chloroform on activated carbon. Sorption is humidity-neutral until relative humidity exceeds 45%, when the uptake of chloroform is reduced. The adsorbed water blocks sites that would otherwise attract and hold chloroform. In contrast, water and carbonyl chloride mixtures on activated carbon demonstrate humidity-enhanced sorption. Here, sorption of the pollutant increases at high relative humidities. Hines et al. (1991) attribute this phenomenon to the high water solubility of carbonyl chloride.

**P**ROPER DESIGN of space heating, air-conditioning, refrigeration, and other industrial systems requires knowledge of thermal insulations and thermal-moisture behavior of building structures. This chapter deals with heat and moisture transfer definitions, fundamentals and properties of thermal insulation materials, heat flow calculations, economic thickness of insulation, and the fundamentals of moisture as it relates to building components and systems.

## TERMINOLOGY AND SYMBOLS

The following heat and moisture transfer definitions and symbols are commonly used in the building industry.

**Thermal transmission, heat transfer, or rate of heat flow.** The flow of heat energy induced by a temperature difference. Heat may be transferred by conduction, convection, radiation, and mass transfer. These can occur separately or in combinations, depending on specific circumstances.

**Thermal conductivity,  $k$ .** The time rate of heat flow through a unit area of 1 m thick homogeneous material in a direction perpendicular to isothermal planes, induced by a unit temperature gradient. (ASTM Standard C 168 defines homogeneity.) Units are W/(m·K). Thermal conductivity must be evaluated for a specific mean temperature and moisture content, because in most materials it varies with temperature and moisture content.

For porous materials, heat flows by a combination of modes and may depend on orientation, direction, or both. The measured property of such materials may be called **effective** or **apparent thermal conductivity**. The specific test conditions (i.e., sample thickness, orientation, environment, environmental pressure, surface temperature, mean temperature, temperature difference, and moisture content) should be reported with the values. With thermal conductivity, the symbol  $k_{app}$  is used to denote the lack of pure conduction or to indicate that all values reported are apparent.

**Thermal resistivity,  $R_u$ .** The reciprocal of thermal conductivity. Units are m·K/W.

**Thermal conductance, C-factor,  $C$ .** The time rate of heat flow through a unit area of a body induced by a unit temperature difference between the body surfaces. Units are W/(m<sup>2</sup>·K).

When the two defined surfaces of mass-type (i.e., nonreflective) thermal insulation have unequal areas, as in the case of radial heat flow through a curved block or through a pipe covering (see Table 2 in Chapter 3), or through materials of nonuniform thickness, an appropriate mean area and mean thickness must be given. Heat flow formulas involving materials that are not uniform slabs must contain *shape factors* to account for the area variation involved.

When heat flow occurs by conduction alone, the thermal conductance of a material may be obtained by dividing the thermal conductivity of the material by its thickness. When several modes of heat transfer are involved, the **apparent** or **effective thermal conductance** may be obtained by dividing the apparent thermal conductivity by the thickness.

Where air circulates within or passes through insulation, as it may with low-density fibrous materials, the effective thermal conductance is affected.

Thermal conductances and resistances of the more common building materials and industrial insulations are tabulated in Table 4 in Chapter 25.

**Heat transfer film coefficient** (or surface coefficient of heat transfer or surface film conductance),  $h$  or  $f$ . Heat transferred between a surface and a fluid per unit time per unit area driven by a unit temperature difference between the surface and the fluid in contact with it, in W/(m<sup>2</sup>·K).

**Surface film resistance.** The reciprocal of the heat transfer film coefficient, in m<sup>2</sup>·K/W. Subscripts  $i$  and  $o$  often denote inside and outside surface resistances and conductances, respectively.

The surrounding space must be air or other fluids for convection to take place. If the space is evacuated, the heat flow only occurs by radiation.

**Thermal resistance R-value,  $R$ .** Under steady-state conditions, the mean temperature difference between two defined surfaces of material or construction that induces unit heat flow through a unit area, in m<sup>2</sup>·K/W.

**Thermal transmittance, U-factor,  $U$ .** The rate of heat flow per unit area under steady-state conditions from the fluid on the warm side of a barrier to the fluid on the cold side, per unit temperature difference between the two fluids. It is determined by first evaluating the R-value, including the surface film resistances, and then computing its reciprocal,  $U$ , in W/(m<sup>2</sup>·K). The U-factor is sometimes called the **overall coefficient of heat transfer**. In building

The preparation of this chapter is assigned to TC 4.4, Building Materials and Building Envelope Performance.

practice, the heat transfer fluid is air. The temperature of the fluid is obtained by averaging its temperature over a finite region near the surface involved.

**Thermal emittance,  $\epsilon$ .** The ratio of the radiant flux emitted by a body to that emitted by a blackbody at the same temperature and under the same conditions.

**Effective emittance of an air space,  $E$ .** The combined effect of emittances from the boundary surfaces of an air space, where the boundaries are parallel and of a dimension much larger than the distance between them. Table 2 in Chapter 25 lists values of  $E$  for various air spaces.

**Surface reflectance,  $\rho$ .** The fraction of the radiant flux falling on a surface that is reflected by it.

**Water vapor permeance,  $M$ .** The rate of water vapor transmission by diffusion per unit area of a body between two specified parallel surfaces, induced by unit vapor pressure difference between the two surfaces,  $\text{ng}/(\text{s} \cdot \text{m}^2 \cdot \text{Pa})$ .

**Water vapor permeability,  $\mu$ .** The rate of water vapor transmission by diffusion per unit area of flat material of unit thickness induced by unit vapor pressure difference between two surfaces, under specified temperature and humidity conditions. When permeability varies with psychrometric conditions, the spot or specific permeability defines the property at a specific condition in  $\text{ng}/(\text{s} \cdot \text{m} \cdot \text{Pa})$ , where the vapor pressure difference is in pascals.

**Water vapor resistance,  $Z$ .** The reciprocal of permeance—signifies a resistance to moisture flow,  $\text{TPa} \cdot \text{m}^2 \cdot \text{s}/\text{kg}$ .

## THERMAL INSULATION

Thermal insulations are materials or combinations of materials that, when properly applied, retard the rate of heat by conductive, convective, and/or radiative transfer modes. Thermal insulations can be fibrous, particulate, film or sheet, block or monolithic, open-cell or closed-cell, or composites of these materials that can be chemically or mechanically bound or supported.

By retarding heat flow, thermal insulations can serve one or more of the following functions:

- Conserve energy by reducing heat loss or gain of piping, ducts, vessels, equipment, and structures
- Control surface temperatures of equipment and structures for personnel protection and comfort
- Help control the temperature of a chemical process, a piece of equipment, or a structure
- Prevent vapor condensation on surfaces. However, thermal insulation may promote moisture condensation and subsequent damage in a building envelope, if the insulation application is improperly installed or poorly designed
- Reduce temperature fluctuations within an enclosure when heating or cooling is not needed or available
- Reduce temperature variations within a conditioned space for increased personal comfort
- Provide fire protection

Thermal insulation can serve additional functions, although such secondary functions should be consistent with its capabilities and primary purpose. Under certain conditions, insulations may

- Add structural strength to a wall, ceiling, or floor section
- Provide support for a surface finish
- Impede water vapor transmission and air infiltration
- Prevent or reduce damage to equipment and structures from exposure to fire and freezing conditions
- Reduce noise and vibration
- Reduce growth of mold and mildew

Thermal insulation is used to control heat flow at all temperatures, the limiting value being its survival temperature.

## BASIC MATERIALS

Thermal insulations normally consist of the following basic materials and composites:

- Inorganic, fibrous, or cellular materials such as glass, rock, or slag wool; and calcium silicate, bonded perlite, vermiculite, and ceramic products. In the past, asbestos insulations was applied. But, because asbestos has been shown to be a carcinogen, extreme caution must be used if it is encountered.
- Organic fibrous materials such as cellulose, cotton, animal hair, wood, pulp, cane, or synthetic fibers; and organic cellular materials such as cork, foamed rubber, polystyrene, polyurethane, and other polymers.
- Metallic or metallized organic reflective membranes. These surfaces must face an air-filled, gas-filled, or evacuated space to be effective.

## PHYSICAL STRUCTURE AND FORM

Mass-type insulation can be cellular, granular, or fibrous solid material. Reflective insulation consists of smooth-surfaced sheets of metal foil or foil-surfaced material separated by air spaces.

The physical forms of industrial and building insulations include the following:

**Loose-fill insulations** consist of fibers, powders, granules, or nodules. They are usually poured or blown into walls or other spaces.

**Insulating cement** is a loose material that is mixed with water or a suitable binder to obtain plasticity and adhesion. It is troweled or blown wet on a surface and dried in place. Both loose-fill and insulating cement are suited for covering irregular spaces.

**Flexible and semirigid insulations** consist of organic and inorganic materials with and without binders and with varying degrees of compressibility and flexibility. These insulations are generally available as blanket, batt, or felt insulation, and in either sheets or rolls. Coverings and facings may be fastened to one or both sides and serve as reinforcing, air or vapor retarders or both, reflective surfaces, or surface finishes. These coverings include combinations of laminated foil, glass, cloth or plastics and paper, wire mesh, or metal lath. Although standard sizes are generally used, thickness and shape of insulation can be any dimension handled conveniently.

**Rigid materials** are available in rectangular blocks, boards, or sheets, which are preformed during manufacture to standard lengths, widths, and thicknesses. Insulation for pipes and curved surfaces is supplied in sections or segments, with radii of curvature available to suit all standard sizes of pipe and tubing.

**Reflective materials** are available in sheets and rolls of single layer or multilayer construction and in preformed shapes with integral air spaces.

**Formed-in-place insulations** are available as liquid components or expandable pellets that can be poured, frothed, or sprayed in place to form rigid or semirigid foam insulation. Fibrous materials mixed with liquid binders can also be sprayed in place, and in some products, the binder is also a foam.

**Accessory materials** for thermal insulation include mechanical and adhesive fasteners, exterior and interior finishes, vapor and air retarder coatings, jackets and weather coatings, sealants, lagging adhesives, membranes, and flashing compounds. ASTM *Standard C 168* defines terms related to thermal insulating materials.

## PROPERTIES

In addition to low thermal conductivity, the selection of thermal insulation may involve secondary criteria. Characteristics such as

resiliency or rigidity, acoustical energy absorption, water vapor permeability, airflow resistance, fire hazard and fire resistance, ease of application, applied cost, health and safety aspects, or other parameters may influence the choice among materials that have almost equal thermal performance values.

### Thermal Properties

Thermal resistance is a measure of the effectiveness of thermal insulation to retard heat flow. A material with a high thermal resistance (low thermal conductance) is an effective insulator.

Heat flows through most thermal insulations by a combination of gas and solid conduction, radiation, and convection. Heat transfer through materials or systems is controlled by factors such as length of heat flow paths, temperature, temperature difference characteristics of the system, and environmental conditions.

Although heat transmission characteristics are usually determined by measuring thermal conductivity, this property does not strictly apply to thermal insulation. A particular sample of a material has a unique value of thermal conductivity for a particular set of conditions. This value may not be representative of the material at other conditions and should be called **apparent thermal conductivity**. For details, refer to ASTM *Standards* C 168, C 177, C 236, C 335, C 518, C 976, and C 1045.

Reflective insulations impede radiant heat transfer because the surfaces have high reflectance and low emittance values. (Table 1 and Table 2 in Chapter 25 give typical design values.) To be effective, the reflective face of both single and multiple layer reflective insulations must face an air or evacuated space. Multiple layers of reflective materials and smooth and parallel sealed air spaces increase overall thermal resistance. Air exchange and movement must be inhibited.

Mass-type insulation can be combined with reflective surfaces and air spaces to obtain a higher thermal resistance. However, each design must be evaluated because maximum thermal performance depends on such factors as condition of the insulation, shape and form of the construction, the means to avoid air leakage and movement, and the condition of the installed reflective surfaces and their aging characteristics.

Design values of effective or apparent thermal conductivity, thermal conductance, and thermal resistance for the most common insulations are listed in Table 4 in Chapter 25. These values have been selected as typical and useful for engineering calculations. The manufacturer or test results of the insulation under appropriate conditions can give values for a particular insulation.

Other thermal properties that can be important are specific heat, heat capacity, thermal diffusivity, the coefficient of thermal expansion, and the maximum temperature limit. **Heat capacity** is the product of specific heat and mass. Because the rate of temperature change within an insulation is proportional to its thermal diffusivity for a given thickness, **thermal diffusivity** becomes important for applications where temperature varies with time. Chapter 3 covers symbols, definitions, and methods of calculation in steady-state heat transfer.

### Mechanical Properties

Some insulations have sufficient structural strength for load bearing. They are used occasionally to support load-bearing roofs and floors, form self-supporting partitions, or stiffen structural panels. For such applications, one or more of the following properties of an insulation may be important: strength in compression, tension, shear, impact, flexure, and resistance to vibration. These mechanical properties vary with basic composition, density, cell size, fiber diameter and orientation, type and amount of binder (if any), and temperature and environmental conditioning.

### Health and Safety

Most thermal insulations have good resistance to fire, vermin, rot, objectionable odors, and vapors; some are a potential risk to health and safety. These risks can result from direct exposure to these materials and accessories while they are being stored or transported, during or after installation, or as a result of intervening or indirect actions or events, such as aging, fire, or physical disturbance. The potential health and safety effects of thermal insulation can be considered in two categories: (1) those related to storage, handling, and installation operations and (2) those that occur after installation (such as aging). Potential hazards during manufacture are not discussed here. Correct handling, installation, and precautionary measures can reduce or eliminate these problems.

Potential health effects range from temporary irritation to serious changes in body functions. The principal concerns are with insulation containing asbestos. Questions have also been raised about man-made fibers. To date, research is inconclusive as to their potential hazard; however, they can be very annoying in installation, and the use of proper safeguards is desirable. Potential traumatic injury can occur from direct contact with materials that are sharp, rough, have protrusions or abrasive surfaces, permit overheating, or transmit electrical energy.

Combustion of insulation materials and accessories may release heat, hazardous gases, fibers, and particulates. Manufacturers' recommendations and applicable government codes and standards (ASTM *Standard* C 930) have more details.

### Acoustics

Some thermal insulations are used as acoustical control materials, whether or not thermal performance is a design requirement. Acoustical efficiency depends on the physical structure of the material. Materials with open, porous surfaces have sound absorption capability. Those with high density and resilient characteristics can act as vibration insulators; either alone or in combination with other materials, some are effective barriers to sound transmission. Insulations for sound conditioning include flexible and semirigid, formed-in-place fibrous materials, and rigid fibrous insulation.

Sound absorption insulations are normally installed on interior surfaces or used as interior surfacing materials. Rigid insulations are fabricated into tile or blocks, edge-treated to facilitate mechanical or adhesive application, and prefinished during manufacture. Some insulation units have a natural porous surface, and others include mechanical perforations to facilitate the entry of sound waves. Still others have a diaphragm or decorative film surfacing attached only to the edges of the units, which allows the sound waves to reach the fibrous backing by diaphragm action.

Flexible, semirigid, and formed-in-place fibrous materials used for sound absorption are available in a variety of thicknesses and densities that determine their sound absorption characteristics.

When density is increased by reducing the thickness of the material, sound absorption is generally reduced; however, as thickness increases, the influence of density decreases.

Thermal insulations improve sound transmission loss when installed in **discontinuous construction**. A wall of staggered-stud construction that uses resilient clips or channels on one side of the stud or resilient insulation boards of special manufacture to prevent acoustical coupling mechanically between the surfaces reduces sound transmission. A sound absorption thermal insulation blanket in a wall cavity reduces sound transmission, depending on the type of construction.

In floor construction, resilient channels or separate floor and ceiling joists form a discontinuous construction. Sound-absorbing thermal insulation placed within this construction further reduces sound transmission. Sound-deadening boards underlying finish

flooring absorb impact sounds and improve the airtightness of the construction, thus reducing airborne sound transmission.

Thermal insulation boards can be placed under mechanical equipment to isolate vibration. The imposed loading and natural resonant frequency of materials are critical for proper design. Because material must deflect properly under load to provide isolation, the system should be neither overloaded nor underloaded.

For further information on sound and vibration control, refer to Chapter 46 of the 1999 ASHRAE Handbook—Applications.

**Other Properties**

Other properties of insulating materials that can be important, depending on the application, include density, resilience, resistance to settling, permanence, reuse or salvage value, ease of handling, dimensional uniformity and stability, resistance to chemical action and chemical change, resistance to moisture penetration, ease in fabrication, application of finishes, and sizes and thicknesses obtainable.

**HEAT FLOW**

**FACTORS AFFECTING THERMAL PERFORMANCE**

A wide variety of physical, environmental, application, and, in some cases, aging factors affect the thermal performance of insulations.

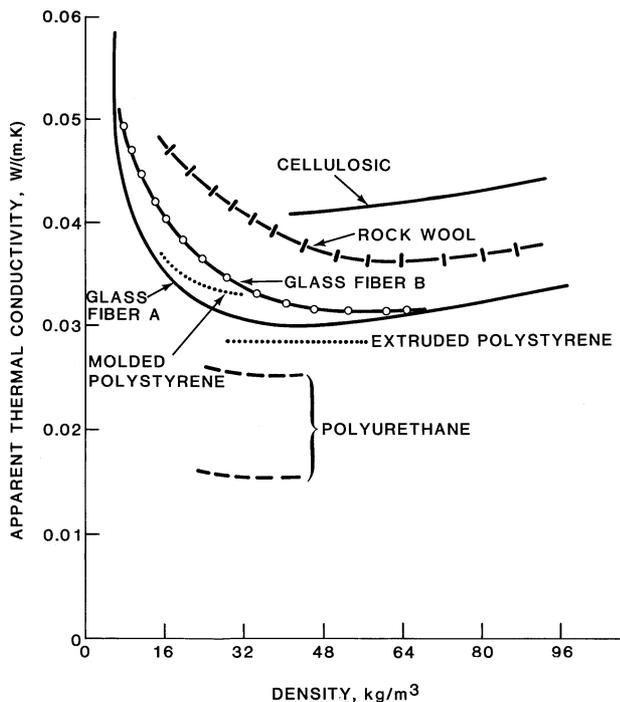

Thermal conductivity  $k$  is a property of a homogeneous material. Building materials, such as lumber, brick, and stone, are usually considered homogeneous. Most thermal insulation and many other building materials are porous and consist of combinations of solid matter with small voids.

For many materials, conduction is not the only mode of heat transfer. Consequently, the term **apparent thermal conductivity** describes the heat flow properties of materials. Some materials with low thermal conductivities are almost purely conductive (silica opacified aerogel, corkboard, etc.).

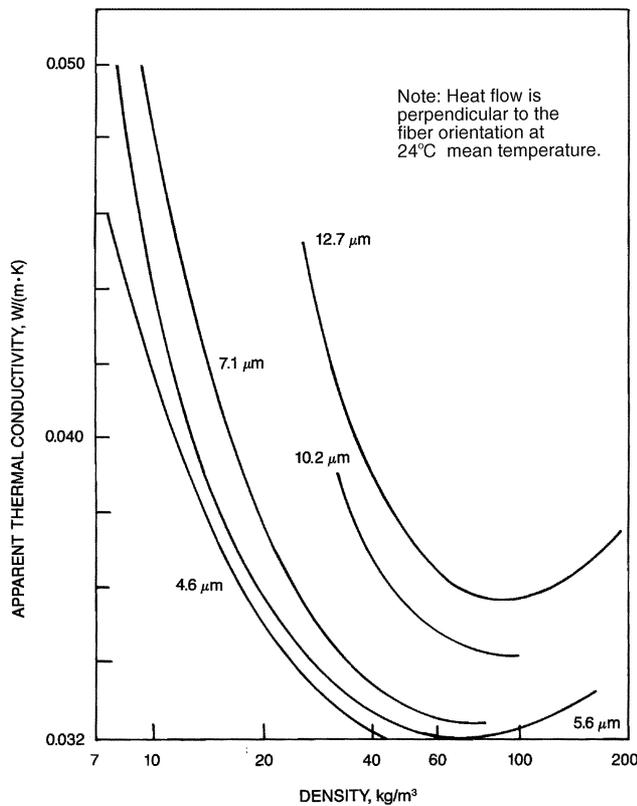

The apparent thermal conductivity of insulation varies with form and physical structure, environment, and application conditions. Form and physical structure vary with the basic material and manufacturing process. Typical variations include density, cell size, diameter and arrangement of fibers or particles, degree and extent of bonding materials, transparency to thermal radiation, and the type and pressure of gas within the insulation.

Environment and application conditions include mean temperature, temperature gradient, moisture content, air infiltration, orientation, and direction of heat flow. Thermal performance values for insulation materials and systems are usually obtained by standard methods listed in Volume 04.06 of the *Annual Book of ASTM Standards*. The methods apply mainly to laboratory measurements on dried or conditioned samples at specific mean temperatures and temperature gradient conditions. Although the fundamental heat transmission characteristics of a material or system can be determined accurately, actual performance in a structure may vary from that indicated in the laboratory. The design of the envelope, its construction, and the materials used may all affect the test procedure. These factors are detailed in ASTM STP 544, STP 660, STP 718, STP 789, STP 879, STP 885, STP 922, STP 1030, and STP 1116.

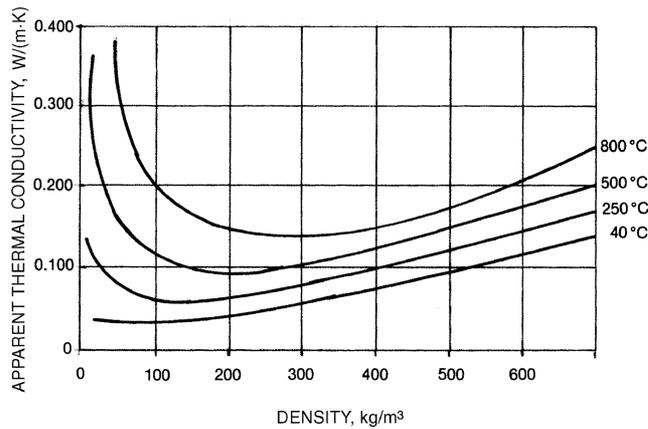

The effective thermal conductivity of some thermal insulation materials varies with density. Figure 1 illustrates this variation at one mean temperature for a number of materials currently used to insulate building envelopes. For most mass-type insulations, there is a minimum in the respective apparent thermal conductivity versus density. This minimum depends on the type and form of material, temperature, and direction of heat flow. For fibrous materials, the values of density at which the minimum value occurs increase as both the fiber diameter or cell size and the mean temperature

**Fig. 1 Apparent Thermal Conductivity Versus Density of Several Thermal Insulations Used as Building Insulations**

**Fig. 2 Typical Variation of Apparent Thermal Conductivity with Fiber Diameter and Density**

**Fig. 3 Typical Variation of Apparent Thermal Conductivity with Mean Temperature and Density for Fibrous Insulations**

increase. These effects are shown in Figure 2 (Lotz 1969) and Figure 3, respectively.

Other factors that affect thermal performance include compaction and settling of insulation, air permeability, type and amount of binder used, additives that may influence the bond or contact between fibers or particles, and the type and form of radiation transfer inhibitor, if used. In cellular materials, the factors that influence thermal performance and strength properties are the same as those that control the thermal conductivity of the basic structured material: size and shape of the cells, thickness of the cell walls, gas contained in the cells, orientation of the cells, and radiation characteristics of the cell surfaces.

A change in density caused by the degree of compaction of insulation powders affects their effective thermal conductivity. Insulating concretes made from lightweight aggregates can be produced in a wide range of densities, with corresponding thermal conductances.

Fibrous insulations reach a minimum conductivity when fibers are uniformly spaced and perpendicular to the direction of heat flow. Generally, a decrease in the diameter of the fiber lowers the conductivity for the same density (Figure 2). For cellular insulation, a specific combination of cell size, density, and gas composition produces optimum thermal conductivity.

At temperatures below 200 to 300°C, a large portion of heat transfer across most insulations occurs by conduction through the air or other gas in the insulations (Rowley et al. 1952, Lander 1955, Simons 1955, Verschoor and Greebler 1952). The overall heat transfer can be closely approximated by supposition of gas conduction with other mechanisms of heat transfer, each determined separately. If the gas in the insulation is replaced by another gas with a different thermal conductivity, the apparent thermal conductivity of the insulation is changed by an amount approximately equal to the difference in conductivity of the two gases. For example, replacing air with a fluorinated hydrocarbon gas can lower the apparent thermal conductivity of the insulation by as much as 50%.

Fluorocarbon-expanded cellular plastic foams with a high proportion (greater than 90%) of closed cells retain the fluorocarbon within the cells for extended periods. As these products are initially produced, they have apparent thermal conductivities of approximately 0.016 W/(m·K) at 24°C when the gas contained has a mean-free-path greater than the dimensions within the cells. However, this value increases with time as atmospheric gases diffuse into the cells and, over a long period of time, the fluorocarbon gas dissolves in the polymer or diffuses out.

The rates of diffusion and increase in apparent thermal conductivity depend on several factors, including permeance of the cell

walls to the gases involved, age of the foam, temperature, geometry of the insulation (thickness), and integrity of the surface protection provided. The significance of the surface protection is apparent when foams are encased in gas-impermeable membranes or some water vapor retarders (Brandreth 1986, Tye 1987). For estimating the long-term change in thermal resistance of unfaced rigid closed-cell plastic foams, a test method (ASTM *Standard C 1303*) has been developed that involves slicing and scaling under controlled laboratory conditions. Christian et al. (1995) provides an example of an application of this accelerated aging test method.

Brandreth (1986) and Tye (1988) show that the aging process of polyurethane and polyisocyanurate materials is reasonably well understood analytically and confirmed experimentally. The dominant parameters for minimum aging are as follows:

- Closed-cell content > 90%, preferably > 95%
- Small uniform cell diameter << 1 mm, with a larger proportion of polymer in windows
- Small anisotropy in cell structure
- High density
- Increased thickness
- High initial pressure of fluorocarbon blowing agent in cell
- Polymer highly resistant to gas diffusion and solubility
- Polymer distributed evenly in struts and windows of cells
- Low aging temperature

Aging may be further reduced, particularly for laminated and spray-applied products, with higher density polymer skins, or by well-adhered facings and coverings with low gas and moisture permeance characteristics. An oxygen diffusion rate of less than 3.5 mm<sup>3</sup>/(m<sup>2</sup>·day) for 25 μm thickness of barrier is one criterion used by some industry organizations manufacturing laminated products. The adhesion of any facing must be continuous, and every effort must be made in the manufacturing process to eliminate or minimize the shear plane layer at the foam/substrate interface (Ostrogorsky and Glicksman 1986).

Closed-cell phenolic-type materials and products, which are blown with similar gases, age differently and much more slowly. The reasons for this are believed to be higher material density, smaller more uniform cell size with a larger proportion of polymer in windows, and a basic polymer more resistant to gas diffusion.

The average distance, or **mean free path**, that an enclosed gas molecule travels before striking another gas molecule increases as pressure within an insulation decreases. When the mean free path equals the average distance a gas molecule travels before striking a solid part of the insulation, the apparent thermal conductivity of the insulation decreases with decreasing pressure. Correspondingly, for materials such as silica gel and fine carbon black, which have an average pore size smaller than the mean free path of air at atmospheric pressure, it is possible to attain thermal conductivity values lower than those for still air (Verschoor and Greebler 1952).

For homogeneous, dense materials, the primary mode of heat transfer is conduction. However, as the temperature increases, the heat transmission by thermal radiation and possible convection becomes a greater part of the total heat transferred. The magnitude of radiation and convection transfer depends on temperature difference, direction of heat flow, the nature of materials involved, and geometric considerations.

Because heat is transferred partly by radiation in low-density insulation, measured apparent thermal conductivity depends on test thickness. The thickness effect increases the apparent thermal conductivity measured at installed thickness over that commonly determined at 25 mm (Pelanne 1979). From a thermal resistance standpoint, the effect is small, typically less than 10% even for thin (e.g., 25 mm) low-density (e.g., 5.5 kg/m<sup>3</sup>) insulation. The effect becomes negligible for typical building applications (e.g., 150 mm insulation with a density of 11 kg/m<sup>3</sup>).

**Environmental and Application Conditions**

The apparent conductivity of insulating materials generally increases with increasing temperature. Figure 4 shows typical variations with mean temperature. However, some materials, such as fluorocarbon-expanded, closed-cell urethanes, have an inflection in the curve over the temperature range where there is a change of phase of the fluorocarbon from gas to liquid (see Table 10 in Chapter 25).

The apparent thermal conductivity of a sample at one mean temperature (average of the two surface temperatures) only applies to the material at the particular thickness tested. Further testing is required to obtain values suitable for all thicknesses. The rate of change of apparent thermal conductivity with temperature and environmental conditions varies with the type and density of material.

Insulating materials that permit a large percentage of heat transfer by radiation, such as low-density fibrous and cellular products, show the greatest change in apparent thermal conductivity with changes of temperature and surrounding surface emittance. The ASTM Standard Test Methods recognize the importance of radiation in heat transmission and require that the surfaces of all test apparatus plates be painted or otherwise treated to have a total emittance greater than 0.8 at operating temperature.

The effect of temperature alone on structural integrity is not ordinarily important for most materials in low-temperature insulation applications. Decomposition, excessive linear shrinkage, softening, or some other effects of temperature alone limit the maximum temperature for which a material is suited. At extreme temperatures, selecting materials for a specific service becomes more critical and

must be based on experience and actual performance data (see Table 4 and Table 10 in Chapter 25).

Convection and air infiltration in or through some insulation systems may increase heat transfer across them. Low-density, loose-fill, large open-cell and fibrous insulations, and poorly designed or installed reflective systems are most susceptible to increased heat transfer by air filtration and convection. The temperature difference across an insulation, as well as the height, thickness, or width of the insulated space, influences the amount of convection. In some cases, natural convection may be inherent in the systems (Wilkes and Rucker 1983, Wilkes and Childs 1992). However, in many cases, the effect of convection in or through insulation can be minimized by careful design of an insulated structure (Donnelly et al. 1976).

Gaps between both board- and batt-type insulation can lower the effectiveness. Board-type insulation may not be perfectly square, may be installed improperly, and may be applied to uneven surfaces. For example, a 4% void area around batt insulation can produce a 50% loss in effective thermal resistance of ceiling application with  $R = 3.4 \text{ m}^2 \cdot \text{K/W}$  (Verschoor 1977). Similar results have been obtained with different test conditions and for wall configurations (Lewis 1979, Hedlin 1985, Tye et al. 1981). Preformed joints in board-type insulation allow it to fit together without air gaps. Boards and batts can be installed in two layers, with joints between layers offset and staggered to eliminate gaps. Chapter 24 has further details on these effects.

The presence of moisture may decrease the thermal performance of the installed insulation. The apparent thermal conductivity of construction materials increases with moisture content. If moisture condenses in the insulation, it may further reduce thermal resistance, and, perhaps physically damage the system. The reduction in thermal resistance depends on the material, the moisture content, and its distribution.

More information on the effects of moisture is provided in the section on Effect of Moisture on Heat Flow. Section A3 of the *CIBSE Guide* (1986) and Chapter 24 cover the thermal properties of building structures affected by moisture.

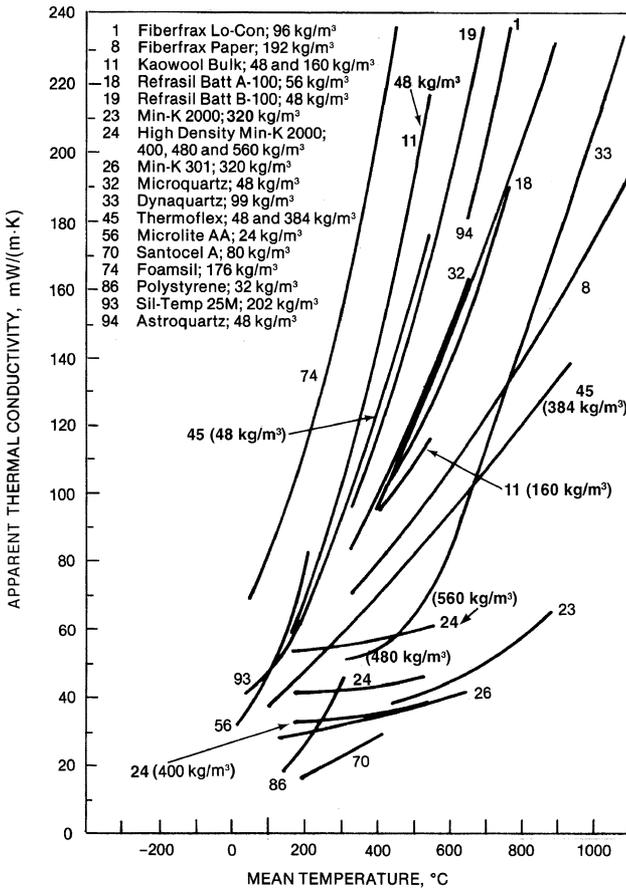

**THERMAL TRANSMITTANCE**

The method of calculating an overall coefficient of heat transmission requires knowledge of (1) the apparent thermal conductivity and thickness of homogeneous components, (2) thermal conductance of nonhomogeneous components, (3) surface conductances of both sides of the construction, and (4) conductance of air spaces in the construction. Procedures for calculating thermal conductance and resistance, and definitions of heat transfer terms and symbols are included in this chapter and in Chapter 3. In some construction, multidimensional heat flow effects are significant. Parallel heat flow paths of different resistances occur in wood frame house construction, for example. In such cases, the hot box method (ASTM *Standard C 1363*) or a multi-dimensional computer model may be used to determine overall thermal transmittance.

**Surface Conductance**

Surface conductance is the heat transfer to or from the surface by the combined effects of radiation, convection, and conduction. Each of these transport modes can vary independently. Heat transfer by radiation between two surfaces is controlled by the character of the surfaces (emittance and reflectivity), the temperature difference between them, and the solid angle through which they see each other. Heat transfer by convection and conduction is controlled by surface roughness, air movement, and temperature difference between the air and surface. Table 1 illustrates the importance of the effect of temperature of surrounding surfaces on surface heat flux caused by radiation.

In many cases, because the thermal resistance (reciprocal of conductance) of the internal parts of the wall is high compared

**Fig. 4 Apparent Thermal Conductivity Versus Mean Temperature for Various Materials (in Air at Atmospheric Pressure)**  
(Glaser et al. 1967, Pelanne 1977)

**Table 1** Variation in Surface Heat Flux for Vertical Surfaces at 26.7°C with Different Temperatures of Surrounding Surface (21.1°C Ambient Still Air; 0.83 Emittance)

Surrounding Surface Temperature, °C	Surface Heat Flux, W/m <sup>2</sup>				
	23.9	21.1	18.3	15.6	10
Convection	20.8	20.8	20.8	20.8	20.8
Radiation	13.9	27.1	40.4	53.6	78.6
Total	34.7	47.9	61.2	74.4	99.4

with the surface resistance, the surface factors are of minor importance. However, surface resistances on a window with a single pane of glass constitute almost the entire resistance and are very important. Raber and Hutchinson (1945) analyzed the factors affecting surface conductance and the difference between surface and air temperatures.

The convective part of the surface conductance is markedly affected by the nature of the air movement on the surface, illustrated by Figure 1 in Chapter 25. On smooth surfaces, surface length (Parmelee and Huebscher 1947) also affects the convection part of conductance; the average value decreases as the surface length increases. Moreover, Parmelee and Aubele (1950) observed that only under certain conditions can outdoors be treated as a blackbody radiating at an effective air temperature. Therefore, selection of surface conductance coefficients for a building becomes a matter of judgment. Surface conductances in Table 1 in Chapter 25 are applicable to ordinary building materials. In special cases, where surface conductances become important factors in the overall rates of heat transfer, more accurate coefficients may be required. Principles and data given in Chapter 3 can be applied in such cases.

### FACTORS AFFECTING HEAT TRANSFER ACROSS AIR SPACES

Heat transfer across an air space is affected by the nature of the boundary surfaces, the intervening air space, the orientation of the air space, the distance between boundary surfaces, and the direction of heat flow. Air space conductance coefficients represent the total conductance from one surface bounding the air space to the other. The total conductance is the sum of a radiation component and a convection and conduction component. In all cases, the spaces are considered airtight with no through air leakage.

The radiation portion of the coefficient is affected by the temperature of the two boundary surfaces and by their respective surface properties. For surfaces that can be considered ideal graybodies, the surface properties can be characterized by emissivity. The combined effect of the emittances of the boundary surfaces of an air space is expressed by the effective emittance *E* of the air space. The radiation component is practically not affected by the thickness of the space, its orientation, the direction of heat flow, or the order of emittance (hot or cold surface). In contrast the heat transfer by convection and conduction combined is affected markedly by orientation of the air space and the direction of heat flow, by the temperature difference across the space, and, in some cases, by the thickness of the space. It is also slightly affected by the mean temperature of its surfaces. For air spaces in building construction, the radiation and convection-conduction components can vary independently of each other.

Table 3 in Chapter 25 lists the thermal resistance values of sealed air spaces of uniform thickness and moderately smooth, plane, parallel surfaces. These data are based on experimental measurements (Robinson et al. 1954). Resistance values for systems with air spaces can be estimated from these results if emis-

sivity values are corrected for field conditions. However, the resistance value of some common composite building insulation systems involving mass-type insulation with a reflective surface in conjunction with an air space may be appreciably lower than the estimated value (Palfey 1980). This is true particularly if the air space is not sealed or of uniform thickness. The thermal resistance values for plane air spaces in Table 3 in Chapter 25 represent typical values; for critical applications, the effectiveness of a particular design should be confirmed by actual test data undertaken by using ASTM hot box methods (ASTM *Standards* C 236 and C 976). This test is especially necessary for constructions combining reflective and nonreflective thermal insulation.

For narrow air spaces, defined as those for which the product of the temperature difference (in kelvins) and the cube of the space thickness (in millimetres) is less than 27 000 for heat flow horizontally or downward, or less than 9000 for heat flow upward, convection is practically suppressed. The conductance for these spaces is the sum of the radiative heat transfer coefficient and that for heat conduction alone through air. The radiation and conduction component can be computed by the method shown in the footnote to Table 3 in Chapter 25. Effects of different mean temperatures, temperature differences, and effective emittances may be found in this table.

To obtain high thermal resistance with reflective insulation, a series of multiple air layers bounded by reflective surfaces is needed. The total resistance equals the sum of the resistance values across each air space. All air layers or spaces must be sealed because air moving between the layers can increase the heat flow. Depending on the type of reflective insulation, one or both sides may have highly reflective surfaces. Except for thick horizontal air spaces with heat flow down, little is gained thermally by the addition of a second highly reflective surface to the same air space. If an air space has only one reflective surface, and conditions are completely dry, the side on which the reflective surface is placed makes no appreciable difference in the rate of heat transfer. In typical building situations moisture is present and the reflective facing should always be placed on the warm side of the air space, else trace condensation will at times increase the emittance and reduce the insulation value (see Chapter 25, Table 2). A reflective surface placed on the warm side of an air space may also act as a water vapor retarder if the material and its joints have sufficiently low permeance (see the section on Vapor Retarder Functions and Properties).

The emittance of a surface is the measure of its ability to emit radiant energy and, for the same temperature and wavelength, is equal to its absorptance (ratio of the radiant energy absorbed by a surface to the total radiant energy falling on it). The ratio of the energy reflected by the surface to that falling on it is the reflectance. For an opaque surface, reflectance is equal to one minus the emittance. This emittance varies with surface type and condition and radiation wavelength.

For reflective insulation used with heating, air-conditioning, and refrigeration applications, the emittance value for long-wavelength (infrared) radiation is important, not the value for the shorter wavelengths of the visible spectrum. Visible brightness is not a true measure of the reflectance for thermal radiation because the reflectance for light and for long-wavelength radiation is unrelated. Table 2 in Chapter 25 lists typical emittance values for reflective surfaces and building materials, and the corresponding emittance factors for air spaces.

Chemical action, dust or oil accumulation, or the presence of condensation or frost can change a reflective surface enough to reduce its reflectance and increase its emittance. Chemical changes include oxidation, corrosion, or tarnishing caused by air, moisture, wet plaster, or the chemical treatment of wood spacing strips or other adjoining structural members. Surface emittance values should be obtained by tests.

### CALCULATING OVERALL THERMAL RESISTANCE

Using the principles of heat flow presented in Chapter 3, calculating heat flow by the overall thermal resistance method is preferred.

The total resistance to heat flow through a flat building construction composed of parallel layers such as a flat ceiling, floor, or wall (or curved surface if the curvature is small) is the numerical sum of the resistances (R-values) of all layers of the construction in series:

$$R = R_1 + R_2 + R_3 + R_4 + \dots + R_n \quad (1)$$

where

$R_1, R_2, \dots, R_n$  = individual resistances of the layers  
 $R$  = resistance of construction from inside surface to outside surface

However, in buildings, to obtain the overall resistance  $R_T$ , the film resistances  $R_i$  and  $R_o$  from Table 1 in Chapter 25 must be added to  $R$ :

$$R_T = R_i + R + R_o \quad (2)$$

The U-factor (thermal transmittance) is the reciprocal of  $R_T$ , or

$$U = \frac{1}{R_T} \quad (3)$$

Thus, for a wall with air space construction, consisting of two homogeneous materials of conductivities  $k_1$  and  $k_2$  and thickness  $x_1$  and  $x_2$ , respectively, and separated by an air space of conductance  $C$ , the overall resistance is

$$R_T = \frac{1}{h_i} + \frac{x_1}{k_1} + \frac{1}{C} + \frac{x_2}{k_2} + \frac{1}{h_o} \quad (4)$$

where  $h_i$  and  $h_o$  are the heat transfer film coefficients.

### Series and Parallel Heat Flow Paths

In many installations, components are arranged so that heat flows in parallel paths of different conductances. If no heat flows between lateral paths, heat flow in each path may be calculated using Equations (1) and (2). The average transmittance is then

$$U_{av} = aU_a + bU_b + \dots + nU_n \quad (5)$$

where  $a, b, \dots, n$  are respective fractions of a typical basic area composed of several different paths with transmittances  $U_a, U_b, \dots, U_n$ .

If heat can flow laterally with little resistance in any continuous layer so that transverse isothermal planes result, total average resistance  $R_{T(av)}$  is the sum of the resistance of the layers between such planes. Each layer is calculated by the appropriate Equation (1) or modification of Equation (4), using the resistance values. This is a series combination of layers, of which one (or more) provides parallel paths.

The calculated heat flow, assuming parallel heat flow only, is usually considerably lower than that calculated with the assumption of combined series-parallel heat flow. The actual heat flow is some value between the two calculated values. In the absence of test values for the combination, an intermediate value should be used. Examination of the construction usually reveals whether a value closer to the higher or lower calculated value should be used. Generally, if the construction contains any highly conductive layer in which lateral conduction is very high compared to heat flow through the wall, a value closer to the series-parallel calculation should be used. If, however, no layer has a high lateral conductance, a value closer to the parallel heat flow calculation should be used. In the case where the presence or absence of high lateral conductance is

unclear, use the arithmetic mean of the isothermal-planes and parallel-path methods. A more precise value of the thermal transmittance may be obtained by using an appropriate computer program for two- or three-dimensional heat flow.

### CALCULATING INTERFACE TEMPERATURES

The temperature at any interface can be calculated, since the temperature drop through any component of the wall is proportional to its resistance. Thus, the temperature drop  $\Delta t_n$  through  $R_n$  in Equation (1) is

$$\Delta t_n = \frac{R_n(t_i - t_o)}{R_T} \quad (6)$$

where  $t_i$  and  $t_o$  are the indoor and outdoor temperatures, respectively. Hence, the temperature at the interface between  $R_n$  and  $R_{n+1}$  is

$$t_{n-n+1} = t_i - \sum_{m=1}^n \Delta t_m \quad (7)$$

For building materials having nonuniform or irregular sections such as hollow clay tile or concrete blocks, the R-value of the unit as manufactured should be used.

If the resistances of materials in a wall are highly dependent on temperature, the mean temperature must be known to assign the correct value. In such cases, it is perhaps most convenient to use a trial-and-error procedure for the calculation of the total resistance  $R_T$ . First, the mean operating temperature for each layer is estimated, and R-values for the particular materials are selected. The total resistance  $R_T$  is then calculated as in Equation (4), and the temperature at each interface is calculated using Equations (6) and (7). The mean temperature of each component (arithmetic mean of its surface temperatures) can then be used to obtain second generation R-values. This procedure can then be repeated until the R-values have been correctly selected for the resulting mean temperatures. Generally, this can be done in two or three trial calculations.

### HEAT FLOW CALCULATIONS

Equation (8) is used to calculate heat flow through flat surfaces; Equation (9) is used for cylindrical surfaces (Figure 5).

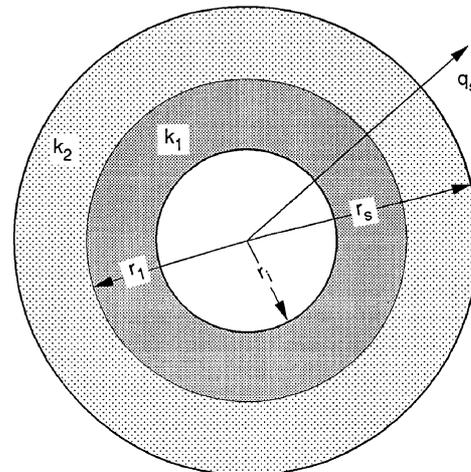

Fig. 5 Heat Flow Through Cylindrical Surfaces

$$q_s = \frac{t_{is} - t_{os}}{R} \tag{8}$$

$$q_s = \frac{t_{is} - t_{os}}{r_s \sum_{m=1}^N \ln(r_{o,n}/r_{i,n})/k_n} \tag{9}$$

where

- $q_s$  = rate of heat transfer per unit area of outer surface of insulation
- $R$  = surface-to-surface thermal resistance from Equation (1)
- $k_n$  = thermal conductivity of insulation layer  $n$  at calculated mean temperature
- $t_{is}$  = temperature of inner surface
- $t_{os}$  = temperature of outer surface
- $r_{i,n}$  = inner radius of insulation layer  $n$
- $r_{o,n}$  = outer radius of insulation layer  $n$
- $r_s$  = outer radius of outer insulation layer
- $N$  = total number of insulation layers
- $\ln$  = natural or Naperian logarithm

Heat flow per unit length of pipe is the preferred unit. The terms that appear in the denominator of Equation (9) represent the resistances to heat flow based on logarithmic mean thickness. The thermal resistances for flat surfaces should not be confused with the thermal resistance of a cylindrical insulation where the surface areas involved are never equal.

## INSULATION THICKNESS

### ECONOMIC THICKNESS

Economics can be used (1) to select the optimum insulation thickness for a specific insulation, or (2) to evaluate two or more insulation materials for least cost for a given thermal performance. In either case, economics determine the most cost-effective solution for insulating over a specific period (FEA 1976). This solution can be reached by different techniques, but only one solution exists for a given set of economic variables.

Greater than optimum insulation thickness may also require a greater capital investment for the structure and piping. However, other concerns such as limited energy availability, sustainability, or comfort may alter the results of an economic analysis alone.

Life-cycle costing spreads the initial cost of the insulation over the number of years the insulation is expected to be in service. The life cycle selected affects the economic thickness of the insulation. Thinner insulation pays back on a short life cycle, and thicker insulation pays back over a longer cycle. An insulation system designed to pay for itself with energy savings in a short time, and that stays in service longer, does not necessarily produce the lowest total cost over the service period.

The annualized cost of the installed insulation must also be adjusted for the cost of money, which can be based on a desired rate of return on the insulation investment. Insulation system maintenance costs should also be included in the annual cost.

Because fuel cost is likely to change during the depreciation period (the life of the facility or payback period), the average cost should be estimated and this value used rather than current cost.

The total annual cost is the sum of the annual cost of insulation and the annual cost of lost energy. For each incremental increase in insulation thickness, the corresponding change in the total cost is  $m_t = m_c + m_s$  where  $m_t$  is the incremental change in total annual costs,  $m_c$  is the incremental change in cost of insulation, and  $m_s$  is the incremental change in cost of lost energy plus any change in the cost of the mechanical equipment needed.

Initially, as insulation is applied, the total cost decreases because the incremental energy savings is greater than the incremental cost

of insulation. Additional insulation reduces this cost up to a thickness where the change in the total cost is equal to zero. At this point,  $m_t = m_c + m_s = 0$ , and no further reduction can be obtained. Beyond this thickness, the incremental insulation costs become greater than the additional energy savings derived by adding another increment of insulation. However, if total insulation costs then exceed total insulation benefits, the optimal level of insulation for a given component from a purely economics viewpoint is no insulation at all. This may occur if the startup costs are extremely high, as for installation of insulation in a sealed wall cavity.

### ECONOMIC THICKNESS: MECHANICAL SYSTEMS

Determining the most profitable thickness of insulation for mechanical systems is difficult. The economics of each plant (including cost of producing energy, cost of insulating, discount rate or cost of capital, and potential for energy loss) indicate the preferred amount of insulation. Various types of equipment and piping also require different economic thicknesses. This analysis is further complicated because future energy cost and the life of the facility and insulation must also be considered. For every plant, these factors dictate different solutions to the economic analysis. Furthermore, additional insulation may lower heat loss or gain, possibly allowing for lower capacity equipment and thus for lower first costs.

#### Economic Analysis

The cost of installed insulation increases with thickness. This incremental cost is for both labor and material. Insulation is often applied in multiple layers (1) because materials are not manufactured in single layers of sufficient thickness and, (2) in many cases, to compensate for expansion and contraction. Figure 6 shows installed costs for a multilayer application. The average slope of the curves increases with the number of layers because labor and material costs increase at a more rapid rate as thickness increases.

Because the optimal economic thickness is the lowest total cost of lost energy and installed insulation over the life of the insulation,

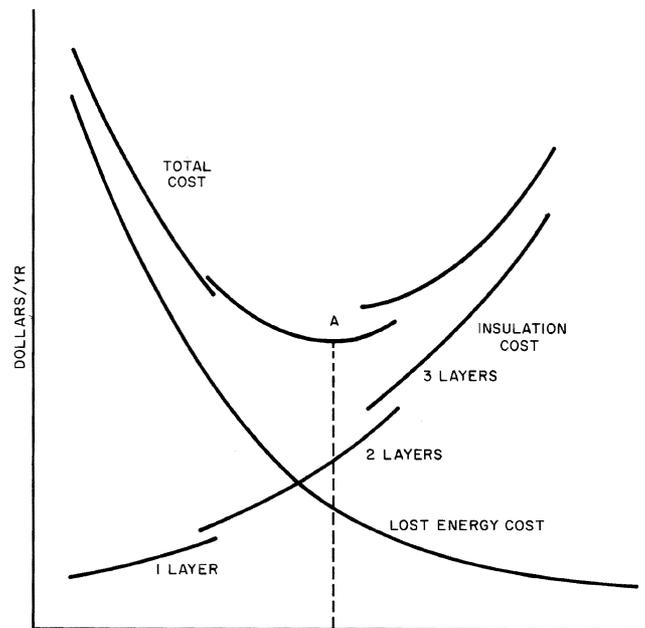

Fig. 6 Determination of Economic Thickness of Installed Insulation of Mechanical Equipment

these two costs must be compared in similar terms. Either the annual cost of the insulation must be compared to the average annual cost of lost energy, or the cost of the energy lost each year must be expressed in present dollars and compared with the total cost of the insulation investment. The former method, annualizing the insulation cost and comparing this with the average annual cost of lost energy, is easier to compute.

Insulation reduces the size and capital costs of the heating and cooling equipment required for an installation because it lowers energy demand. This capital cost may be annualized by considering the plant depreciation period, cost of money, annual energy output for the plant, and operational expenses.

Figure 6 shows curves of total annual costs of operation, insulation costs, and lost energy costs. Point A on the total cost curve corresponds to the economic insulation thickness, which, in this example, is in the double-layer range. Viewing the calculated economic thickness as a minimum thickness provides a hedge against unforeseen fuel price increases and conserves energy.

### ECONOMIC THICKNESS: BUILDING ENVELOPES

In buildings such as residences and warehouses, the internal energy gains are insignificant compared with the heat losses and gains through the envelope. For these buildings, the heating and cooling requirements are roughly proportional to the difference between the indoor and outdoor temperature. For commercial, industrial, and institutional buildings, internal heat loads can be significant, and the heating and cooling requirements are not as directly related to the indoor/outdoor temperature difference. In both types of buildings, solar heat can be an important factor and should be evaluated.

### Dominant Heat Loss and Gain Through Envelope

Thermal insulation is generally installed in building envelope components (e.g., ceilings, walls, and floors) to reduce space heating and cooling costs on a long-term basis. Additional benefits may include increased occupant comfort, reduced heating and cooling system capacity, and elimination of condensation on wall surfaces in cold climates. When possible these benefits should be considered. The economically optimal insulation thickness (best measured in terms of thermal resistance) in an envelope component minimizes total life-cycle space heating and cooling costs attributable to it. Total life-cycle costs are the sum of present-value heating and cooling costs over the useful lifetime of the insulation plus the installed cost of the insulation and the installed cost of the heating and cooling equipment.

If the R-value of the insulation used is continuously variable (e.g., loose-fill insulation in attics), uniformly small increments of insulation can be used to determine appropriate optimal thicknesses; or calculus can be used to determine an exact optimum. If the insulation materials used are available only in discrete levels of thermal resistance ( $R = 2$ ,  $R = 3$ ,  $R = 5$ ), the increment used in determining optimal thickness should be based on differences between those levels ( $R = 2$  over  $R = 0$ ,  $R = 3$  over  $R = 2$ ,  $R = 5$  over  $R = 3$ ). Where discrete increments of resistance are used, determining the resistance level for which incremental savings equal incremental costs may not be feasible. In such cases, the selection should be left to the judgment of the analyst based on the level of conservation desired. In addition, an increase in insulation may make it possible to reduce the size of the heating and cooling equipment, which becomes a discrete reduction in equipment cost.

If a building envelope component requires structural modifications to accommodate increased insulation thickness, this cost must be included in the installed cost of the additional insulation. Generally, such modifications should only be considered when they are less costly than the use of more efficient (i.e., lower thermal

conductivity) but more expensive insulation materials than those ordinarily used.

Typically, the incremental energy savings and insulation costs differ for each building envelope component; therefore, the optimal insulation level differs for each component in the same building. Less efficient heating plants and higher costs of heating energy necessitate higher optimal insulation levels in each building envelope component. Conversely, more efficient heating equipment reduces the optimal insulation level. The effects of climate, cooling energy costs, and cooling equipment efficiency on optimal insulation levels are less clear and differ widely, depending on overall building design and operational profile.

### Dominant Internal Heat Loads

In buildings with dominant internal loads, the energy requirements vary so widely that no generalizations can be made regarding insulation. This contrasts with envelope-dominated structures, in which more insulation reduces energy consumption (Hart 1981).

In internal-load-dominated buildings with both annual heating and cooling loads, higher thermal resistance increases cooling energy consumption while reducing heating energy consumption. Therefore, the calculation of economically optimum resistance becomes quite complex and involves multiple measure or hourly methods described in Chapter 31. Spielvogel (1974), Burch and Hunt (1978), and Rudoy (1975) give more details.

Figure 7 shows the results of these calculations for a building in Columbus, Ohio, with  $26 \text{ W/m}^2$  of internal heat gains that operates 24 h per day (Spielvogel 1974). This solution is not the only one possible, but illustrates problems faced by the designer. In this case, thermal resistance increases, the U-factor decreases, annual heating energy decreases, and annual cooling energy increases. The energy optimum exists at Point Y in Figure 7, where the total heating and cooling energy is at a minimum. Because the cost of cooling energy differs from the cost of heating energy, the economic optimum will not be the same as the energy optimum.

These results occur in some localities where there are far more hours per year with outdoor temperatures between  $10$  and  $24^\circ\text{C}$  than

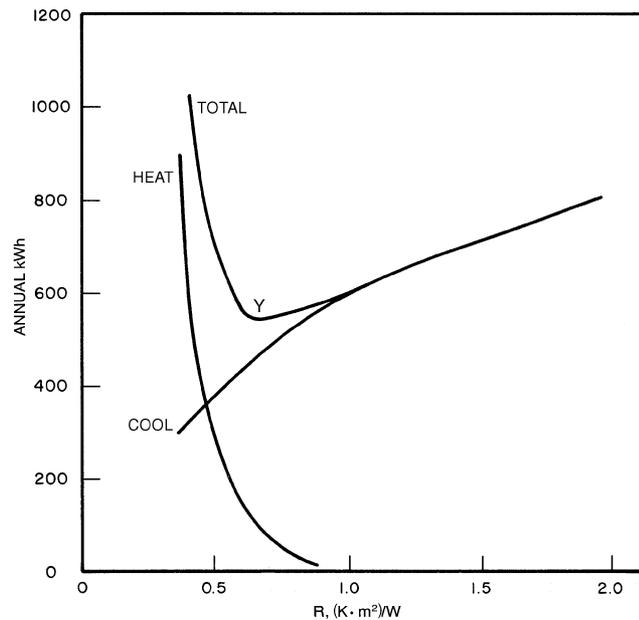

Fig. 7 Example of Optimal Thermal Resistance for Building with Internal Heat Gains  
(Adapted from Spielvogel 1974)

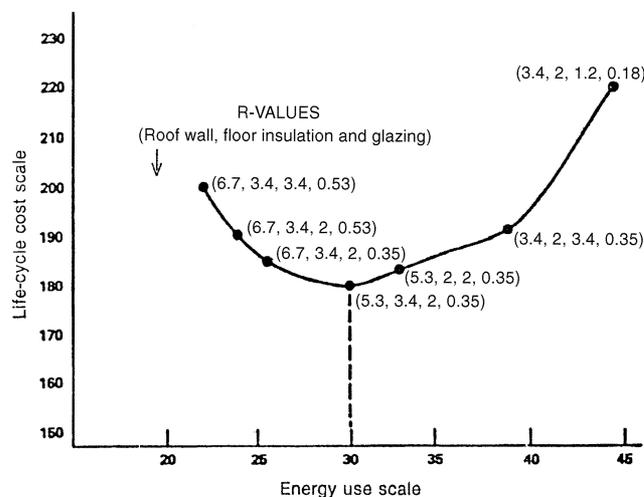

between 24 and 38°C. At temperatures between 24 and 38°C, low U-factors result in less energy consumption for cooling. However, for temperatures between 10 and 24°C, low U-factors inhibit the flow of internal heat from the building, thereby creating higher cooling loads and higher energy requirements than those in buildings with higher U-factors. What might be saved at outdoor temperatures over 24°C can be more than spent in additional cooling energy at temperatures below 24°C. Economizer cycles could offset these excess internal gains with ventilation air, however.

Where the hours of use or the quantity of internal heat gains vary from room to room, the optimum thermal resistance also varies. For example, in a cold climate, a hotel kitchen requires little or no insulation, because the internal heat is sufficient to heat the space almost all year. In a meeting room adjacent to the kitchen, substantially more insulation is justified. Thus, the economic thermal resistance of any envelope element, such as a roof, will not be the same throughout the entire building.

This type of analysis must include the level and duration of internal gains and the nature of the energy consumption of the heating and cooling systems. Most buildings need evaluation of walls, roofs, and floors on a room-by-room basis. Computer programs make these more complex analyses possible. Due to the wide diversity of building types, internal gains, system types, and operating conditions, no simple rules can establish U-factors for minimum energy consumption.

**Effectiveness of Added Insulation**

The effectiveness of added insulation varies with many factors, including climate, original insulation level, preparation costs, and predicted life, based on payback calculations. Building codes generally balance life-cycle costs between construction, financing, and energy expenditures. Figure 8 shows typical relationships between life-cycle costs and energy consumption. Individual points on the curve represent different combinations of ceiling, wall, and floor insulation in R-values and glazing types (single, double, or triple). Because life-cycle costs vary not only with construction and energy costs but also with climatic factors, the profiles of this curve vary according to locality. In Figure 8, the optimal condition for this example is attained with  $R = 5.3 \text{ m}^2 \cdot \text{K/W}$  attic insulation,  $R = 3.4$  wall insulation,  $R = 2$  floor insulation, and double glazing. However, the effectiveness of added insulation can be determined only by analyzing actual conditions.

**Fig. 8 Typical Relationship of Life-Cycle Cost to Energy Use**

**MOISTURE IN BUILDINGS**

**MOISTURE PROBLEMS IN BUILDINGS**

Moisture control is necessary to avoid moisture-related problems with building energy performance, building maintenance and durability, and human comfort and health. Moisture degradation is the largest factor limiting the useful life of a building and can be visible or invisible. Invisible degradation includes degradation of the thermal resistance of building materials and decrease in the strength and stiffness of some materials. Visible moisture degradation may be in the form of (1) mold and mildew, (2) the decay of wood-based materials, (3) spalling of masonry and concrete caused by freeze-thaw cycles, (4) hydration of plastic materials, (5) corrosion of metals, (6) damage due to expansion of materials (e.g., buckling of wood floors), and (7) a decline in visual appearance (e.g., buckling of wood siding or efflorescence of masonry materials, which is the formation of a salt crust from the leaching of free alkalies). In addition, high moisture levels can lead to odors and mold spores in indoor air, which can seriously affect occupant health and comfort. Short summaries of such moisture conditions and related performance and health issues follow.

**Mold, Mildew, Dust Mites, and Human Health**

Mold and mildew in buildings are offensive, and the spores can cause respiratory problems and other allergic reactions in humans. Mold and mildew will grow on most surfaces if the relative humidity at the surface is above a critical value and the surface temperature is conducive to growth. The longer the relative humidity remains above the critical value, the more likely is visible mold growth; and the higher the humidity or temperature, the shorter is the time needed for germination. The surface relative humidity is a complex function of material moisture content, material properties, and local temperature and humidity conditions. In addition, mold growth depends on the type of surface. Fully recognizing the complexity of the issue, the International Energy Agency Annex 14 (1990) nevertheless established a surface humidity criterion for design purposes: The monthly average surface relative humidity should remain below 80%. Others have proposed more stringent criteria, the most stringent requiring that surface relative humidity remain below 70% at all times. Although there still is no agreement on which criterion is most appropriate, mold and mildew can usually be avoided by limiting surface moisture conditions over 80% to short time periods. These criteria should only be relaxed for nonporous surfaces that are regularly cleaned. Hukka and Viitanen (1999) developed a mathematical model for the prediction of the mold growth index. This model was successfully implemented and linked to a hygrothermal model by Karagiozis and Salonvaara (1998). Most molds grow at temperatures above approximately 5°C. Moisture accumulation below 5°C may not cause mold and mildew if the material is allowed to dry below the critical moisture content before the temperature rises above 5°C.

Dust mites can trigger allergies and asthma (Burge et al. 1994). Dust mites thrive at high relative humidities (over 70%) at room temperature, but will not survive sustained relative humidities below 50% (Burge et al. 1994). These relative humidities relate to local conditions in typical places that mites tend to inhabit such as mattresses, carpets, soft furniture, etc.

**Paint Failure and Other Appearance Problems**

Moisture trapped behind paint films may cause failure of the paint. Water or condensation may also cause streaking or staining. Excessive swings in the moisture content of wood-based panels or boards may cause buckling or warping. Excessive moisture in masonry and concrete may cause efflorescence, a white powdery area or lines, or, when combined with low temperatures, may cause freeze-thaw damage and spalling (chipping).

## Structural Failures

Structural failures due to decay of wood are rare but have occurred (e.g., Merrill and TenWolde 1989). Decay generally requires wood moisture content at fiber saturation (usually about 30%) or higher and temperatures between 10 and 40°C. Wood moisture contents above fiber saturation are only possible in green lumber or by absorption of liquid water from condensation, leaks, ground water, or other saturated materials in contact with the wood. To maintain a safety margin, 20% moisture content is sometimes used during field inspections as the maximum allowable moisture level. Because wood moisture content can vary widely with sample location, a local moisture content of 20% or higher may indicate fiber saturation elsewhere. Once established, decay fungi produce water that enables them to maintain moisture conditions conducive to their own growth.

Rusting or corrosion of nails, nail plates, or other metal building components is also a potential cause of structural failure. Corrosion may occur at high relative humidities near the metal surface or as a result of liquid water from elsewhere. Wood moisture content over 20% encourages corrosion of steel fasteners in wood, especially if the wood is treated with preservatives. In buildings, metal fasteners are often the coldest surfaces, encouraging condensation on and corrosion of the fasteners.

## Effect of Moisture on Heat Flow

Moisture in the building envelope can significantly degrade the thermal performance of most insulation materials. Bomberg and Shirtliffe (1978), Epstein and Putnam (1977), Hedlin (1977, 1983, 1987, 1988a, 1988b), Jespersen (1960), Joy (1957), Knab et al. (1980), Kumaran (1989), Kyle and Desjarlais (1994), Langlais et al. (1983), Paljack (1973), Pedersen (1990), Pedersen et al. (1991), Shapiro and Motakef (1990), Thomas et al. (1983), Tobiasson and Richard (1979), Tobiasson (1987, 1991), and Tye (1987) investigated the effect of moisture content on heat flow and showed that the effect depends on the type of insulation material, the moisture content, the temperature of the insulation material, the insulation material's thermal history, and the building envelope's interior and exterior environments. The reported relationships between the thermal performance of the insulation material and heat flow can vary significantly; the variations are more pronounced in open-cell and fibrous insulations. Rapid vapor transfer through vapor-permeable insulations during testing accounts for these variations. Variations can also be due to the location of water in the insulation layer. Kyle and Desjarlais (1994) estimated that water distribution can account for a difference of up to 25% in heat flow in certain cases.

Moisture can contribute to both sensible and latent heat flow, as well as through mass transfer by diffusion or convection. Evaporation on the warm side of the insulation and condensation or adsorption on the cold side add a latent heat component to the heat flow.

Under steady-state conditions, the effect of moisture on thermal resistance may be small. Verschoor (1985) showed that an insulated residential-type stud wall panel with a poor vapor retarder on the warm side accumulated 1.5 kg of moisture per square metre when exposed to conditions continuously below freezing (steady-state) for 31 days. All of the accumulated moisture was located in the 13 mm layer of mineral fiber insulation immediately adjacent to the cold-side sheathing and at the interface between the insulation and the sheathing. In a continuation of the test program, to a total exposure period of 60 days, the rate of moisture gain remained constant during the entire period. Subsequently, the same test wall was subjected to diurnal outside temperature cycles through the freezing point. With this exposure, most of the accumulated moisture was found in the sheathing and the bottom of the test wall rather than in the coldest insulation layer. Except for the sheathing, there was negligible change in the overall thermal performance of the wall.

The behavior may be different for closed-cell plastic foam insulations. Field observations of low-temperature insulated tanks have

shown that when no air space exists between the cold surface and the insulation, the expected accumulation of condensed moisture did not occur.

Degradation of thermal resistance is more pronounced when daily reversals in temperature across the insulation drive moisture back and forth through the insulation layer and is exacerbated when the insulation material has a high water vapor permeance. A wetted compact low-slope roof is a good example of these phenomena. During the nighttime, moisture migrates upward through the insulation layer and can condense in the upper part of the insulation layer on the underside of the membrane. The following day, the increase in ambient temperature coupled with solar radiation heats the membrane and reverses the vapor pressure difference, evaporating some or all of the condensed water and driving it downward into the roofing system, transporting heat in the process. If sufficient water vapor can be driven downward, it may condense somewhere in the lower portion of the insulation layer, releasing its heat of condensation.

Hedlin (1988b) and Shuman (1980) experimentally showed that, for building envelopes containing permeable fibrous insulations that underwent temperature reversals, the rate of energy transfer increased sharply as the moisture content (MC) increased to approximately 1% by volume. The rate of increase in energy transfer diminished rapidly with further increases in moisture content. Energy transfer for permeable insulation with 1% MC by volume was roughly double that of dry insulation. Pedersen et al. (1991) analytically reproduced Hedlin's results; he demonstrated the high mobility of moisture in a permeable insulation and showed that latent effects are appreciable for a wide variety of North American climates. The latent effects typically add to the energy load and can increase peak energy demand. The extra load is added to the building load in the warm afternoon, and nearly the same amount of heat is removed in the cool evening.

Certain organic insulations such as wood fiberboard and perlite are hygroscopic and can contain 1% MC by volume if installed at equilibrium conditions; water leakage into the building envelope component is *not* a prerequisite for significant increases in heat flow.

In studies of hourly temperature and moisture content variations in wood frame wall cavities, Duff (1971) showed measurable levels of daily moisture migration across the cavity. Pedersen et al. (1991) demonstrated the same phenomenon in compact low-slope roofs.

The building envelope is exposed to ever-changing exterior conditions; fluctuations in the outdoor air temperature and the amount of solar radiation affect the temperature profile through the building envelope. These temperature changes affect the magnitude and the direction of the vapor pressure gradients. Water vapor transfer rates and direction are constantly changing, adjusting not only to the thermal changes but to changes in moisture concentration. However, conditions may exist where the *average* vapor pressure drive is in one direction, for example, upward in a low-slope roof during winter. In this situation, moisture accumulates in the insulation just below the impermeable roof membrane, and, assuming these conditions can be maintained for a reasonable length of time, water accumulates or frost forms unless the top layer of the insulation has adequate moisture absorption capacity (e.g., perlite or wood fiberboard). Under similar conditions in the summer, moisture is driven down to the vapor retarder or deck (if the deck is less permeable than the insulation layer). If there are no layers in the system that are less permeable than the insulation, the water vapor simply diffuses into the building interior.

Under conditions where the vapor pressure changes slowly or where the insulation layer has an extremely low water vapor permeance, little water vapor is transported. Moisture still affects the sensible heat transfer in the building envelope component. Epstein and Putnam (1977) and Larsson et al. (1977) showed a nearly linear increase in sensible energy transfer of approximately 3 to 5% for each volume percent increase in moisture content in cellular plastic insulations. For example, an insulation material with a 5% MC by

volume has 15 to 25% greater energy transfer than the dry insulation material. Other field studies by Dechow and Epstein (1978) and Ovstaas et al. (1983) have shown similar results for insulations installed in below-grade applications such as foundation walls.

**Moisture Effect on Heat Storage**

Moisture also affects the thermal storage capacity of certain hygroscopic building materials. At 10% MC, nearly 30% of the heat storage capacity of wood is in the water held in the cell walls. Since the specific heat of wood is a function of its temperature and moisture content (but almost independent of density and species), heat storage calculations must include an estimate of the equilibrium in-service moisture content of wood building components.

**PROPERTIES OF WATER VAPOR IN AIR**

Chapter 6 describes the properties of moist air and defines the various terms associated with water vapor in air, such as dew-point temperature, dry-bulb and wet-bulb temperatures, and relative humidity. Chapter 6 also explains the use of the psychrometric chart, as well as the physics of heating and cooling moist air.

**MOISTURE IN BUILDING MATERIALS**

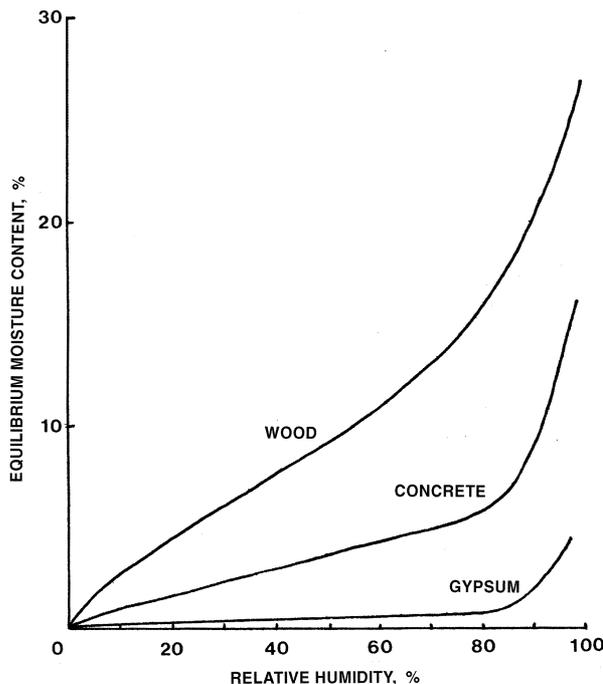

Many common building materials are porous. The pores provide a large internal surface area, which generally has an affinity for water. In some materials, such as wood, moisture may also be adsorbed in the cell wall itself. The amount of water in these **hygroscopic** (water-attracting) materials is related to the relative humidity (rh) of the surrounding atmosphere. When relative humidity of the surrounding air rises, hygroscopic materials gain moisture (**adsorption**), and when the relative humidity drops these materials lose moisture (**desorption**). The relationship between relative humidity and the moisture content (MC) at a particular temperature can be represented in a graph called a sorption isotherm. Often isotherms obtained by adsorption are not identical to isotherms obtained by desorption, because the material tends to retain moisture when it is

drying. This difference between desorption and adsorption isotherms is called **hysteresis**. At high relative humidity, small pores become entirely filled with water. The maximum moisture content is reached when all pores are filled with water. But experimentally this can only be achieved in a vacuum, by boiling the material or by keeping the material in contact with water for an extremely long time (i.e., many years). In practice, the maximum moisture content of porous materials is lower. This lower maximum moisture content is sometimes referred to as the **capillary saturation moisture content**. Figure 9 shows typical sorption curves, giving the **equilibrium moisture content (EMC)** as a function of relative humidity. The EMC increases with relative humidity, especially above 80% rh. The EMC decreases slightly with increasing temperature.

Chapter 22 describes hygroscopic substances and their use as dehumidifying agents. Table 2 in Chapter 11 of the 1999 *ASHRAE Handbook—Applications* has data on the moisture content of various common materials in equilibrium with the atmosphere at various relative humidities.

Wood and many other hygroscopic materials change dimensions with variations in moisture content. The moisture content at which cell walls of wood are saturated but no free water exists in cell cavities is the **fiber saturation point**. It represents the upper limit for moisture gain from the air as water vapor. It is also the upper limit of swelling; although more water can be absorbed in cell cavities, additional swelling does not occur. Wood moisture content is expressed as a percentage of its oven-dry mass. The average fiber saturation point for most species is about 30%. The average EMC at 20°C and 45% rh (heating season indoor conditions) is about 8.5%. At 24°C and 70% rh (summer conditions), the EMC is about 13%.

The resulting dimensional changes in wood are proportional to the change in moisture content, but vary with species and direction of grain. For white oak, which is representative of interior trim material, 4.5% MC variation causes 2.5% volumetric shrinkage or swelling. Longitudinal dimensional change in straight-grained wood is insignificant, but it increases with crossgrain and other irregularities.

**Fig. 9 Typical Sorption Isotherms for Wood, Concrete, and Gypsum (Hysteresis Is Ignored)**

**Table 2 Linear and Volumetric Shrinkage Values of Wood, from Green to Oven Dry Moisture Content**

Wood Species	Radial %	Tangential %	Volumetric %
<i>Hardwoods</i>			
Birch			
Yellow	7.3	9.5	16.8
Oak			
Northern red	4.0	8.6	13.7
Southern red	4.7	11.3	16.1
White	5.6	10.5	16.3
<i>Softwoods</i>			
Cedar			
Northern white	2.2	4.9	7.2
Western red cedar	2.4	5.0	6.8
Douglas fir			
Coast	4.8	7.6	12.4
Fir			
White	3.3	7.0	9.8
Hemlock			
Western	4.2	7.8	12.4
Pine			
Eastern white	2.1	6.1	8.2
Longleaf	5.1	7.5	12.2
Ponderosa	3.9	6.2	9.7
Redwood			
Young growth	2.2	4.9	7.0
<i>Imported wood</i>			
Lauan	3.8	8.0	—

*Note:* Values expressed as a percentage of the green dimension (FPL 1999).

Accordingly, residential wood trusses with top and bottom chords exposed to different temperature and moisture regimes can show measurable seasonal vertical movements (Plewes 1976).

Thermal expansion of wood is usually outweighed by shrinkage or swelling due to moisture content changes. The linear thermal expansion coefficient for wood across the grain ranges from about  $12.6 \times 10^{-6}$  per kelvin for light wood species to about  $45 \times 10^{-6}$  per kelvin for dense wood species, which is small compared to that of many other materials. The thermal expansion coefficient parallel to the grain is between  $3.1 \times 10^{-6}$  and  $4.5 \times 10^{-6}$  per kelvin.

Most plant and animal fibers undergo dimensional changes similar to those noted in wood. Typical values for wood can be found in Table 2; the *Wood Handbook* (FPL 1999) gives more detailed information. Related changes in other materials are not as well documented. However, different expansion rates caused by temperature and moisture changes in different materials used in composite constructions should be considered (Baker 1964, BRS 1974).

Porous materials also absorb water in liquid form when in contact with it. Liquid water may be present because of leaks, rain penetration, flooding, or surface condensation. Wetting may be so complete that the material reaches the capillary saturation moisture content.

## MOISTURE MIGRATION

Liquid water and water vapor migrate by a variety of moisture transport mechanisms. The following are some of the most important mechanisms:

- Liquid flow by gravity or air pressure differences
- Capillary suction of liquid water in porous building materials
- Movement of water vapor by air movement
- Water vapor diffusion by vapor pressure differences

Although in the past many moisture control strategies focused on control of vapor diffusion through the installation of vapor (diffusion) retarders, the other mechanisms, when present, can move far greater amounts of moisture. Therefore, liquid flow, capillary suction, and air movement should be controlled first.

Liquid flow by gravity and air pressure difference is not discussed here, but a short description of the other mechanisms follows. A more comprehensive treatment of moisture transport and storage may be found in Kumaran et al. (1994) and Kuenzel (1998).

### Capillary Suction

Within small pores of diameter less than approximately  $0.1 \mu\text{m}$ , molecular attraction between the surface of the capillary and the water molecules causes a capillary suction defined by

$$s = \frac{2\sigma\cos\theta}{r} \quad (10)$$

where

- $s$  = capillary suction
- $\sigma$  = surface tension of water
- $r$  = radius of the capillary
- $\theta$  = contact wetting angle

The **contact wetting angle** is the angle between the water meniscus and the capillary surface. The smaller this angle is, the larger the capillary suction. In **hydrophilic** (water-attracting) materials, the contact wetting angle is less than  $90^\circ$ , and in **hydrophobic** (water-repelling) materials, the angle is between  $90^\circ$  and  $180^\circ$ . Capillary suction is greater in smaller capillaries, so capillary suction moves moisture from larger to smaller capillaries. Although surface tension is a function of temperature (the higher the temperature, the lower the surface tension), this effect is very small.

Isothermal and nonisothermal movement may occur in the liquid phase, or in the vapor phase if the capillaries are not completely

filled. The transfer in the vapor phase is by vapor diffusion and is caused by a difference in vapor saturation pressure in the capillaries. **Thompson's law** states that the saturation vapor pressure in equilibrium with the water in a capillary is given by

$$p'' = p' \exp\left(\frac{s}{\rho RT}\right) = p' \exp\left(\frac{2\sigma\cos\theta}{r\rho RT}\right) \quad (11)$$

where

- $p''$  = saturation vapor pressure in capillary
- $p'$  = saturation vapor pressure in ambient air at same temperature as  $p''$
- $\rho$  = density of water
- $R$  = gas constant
- $T$  = absolute temperature

Equation (11) shows that the saturation vapor pressure is lower in smaller capillaries than in larger capillaries, which causes vapor diffusion from larger water-filled capillaries to smaller capillaries. Saturation vapor pressure in the capillaries is lower at lower temperatures, which causes diffusion from higher to lower temperatures.

If the vapor pressure in the ambient air is in equilibrium with the saturation vapor pressure in the capillaries, Equation (11) can be rewritten as

$$s = \rho RT \ln\phi \quad (12)$$

where  $\phi$  is the relative humidity of the ambient air.

Capillary flow of water can be expressed as a function of suction pressure gradients follows:

$$w_m = -k_m \frac{ds}{dx} \quad (13)$$

where

- $w_m$  = water flux
- $k_m$  = water permeability coefficient

### Air Movement

Water vapor movement by air can be represented by

$$w = W\rho v \quad (14)$$

where

- $w$  = water vapor flux (flow per unit area)
- $W$  = humidity ratio of source air
- $\rho$  = density of air
- $v$  = airflow velocity

Even small airflows can carry large amounts of water vapor when compared to vapor diffusion. Airflow retarders are designed to inhibit the flow of air and thereby the transport of water vapor into the construction.

### Water Vapor Diffusion

Water vapor also migrates by diffusion through air and building materials. Although moisture diffusion through air is relatively rapid, distribution of vapor in air is dominated by convection. This results in minimal vapor pressure differentials between connected spaces and rapid flow to condensing surfaces, such as cold glass or dehumidifier coils. Although movement by air convection usually dominates, when present, vapor diffusion can be an important mode of transportation in industrial applications such as cold storage facilities or built-in refrigerators. The control of diffusion also becomes more important with increasingly airtight construction.

The equation used to calculate water vapor diffusion flux through materials is based on a form of Fick's law:

$$w = -\mu \frac{dp}{dx} \quad (15)$$

where

$w$  = water vapor flux (flow rate per unit area)  
 $p$  = water vapor pressure  
 $x$  = distance along flow path  
 $\mu$  = water vapor permeability

According to Equation (15), water vapor flow by diffusion is proportional to the water vapor pressure gradient and closely parallels Fourier's equation for heat flow. The actual diffusion of vapor through a material is complex. The apparent water vapor permeability is a function of relative humidity and temperature and may vary spatially due to variations in material properties.

ASTM *Standard E 96* describes test methods for the measurement of water vapor permeability. The rate of moisture transfer through a material is determined gravimetrically while maintaining a steady temperature and vapor pressure differential across the specimen. The standard identifies two tests: a dry cup (0% to 50% rh) and a wet cup (50% to 100% rh). In the wet-cup tests, liquid water movement may occur and the resulting water vapor transport coefficients should be treated with care (Kuenzel 1995).

Permeance is usually expressed in  $\text{ng}/(\text{s} \cdot \text{m}^2 \cdot \text{Pa})$ , and permeability in  $\text{ng}/(\text{s} \cdot \text{m} \cdot \text{Pa})$ . Whereas permeability refers to water vapor flux per unit thickness, the term permeance is used in reference to a material of a specific thickness. For example, a material that is 50 mm thick generally is assumed to have half the permeance of 25 mm thick material, even though permeance of many materials often is not strictly proportional to thickness. In many cases, this assumption ignores the effect of moisture content variations within the material, and the effect of cracks or holes in the surface. It is inappropriate to use the term permeability in reference to inhomogeneous or composite materials, such as plywood or gypsum board with paper facings. Whenever a building product is made of two dissimilar materials, only water vapor permeance is meaningful for characterizing vapor transfer through that product.

Methods have been developed that allow measurement of water vapor transport with temperature gradients across the specimen (Douglas et al. 1992, Krus 1996, Galbraith et al. 1998). These test methods promise more accurate data on isothermal vapor transfer through materials and will eventually allow better distinction between various transport modes.

### Combined Liquid and Vapor Flow

It is nearly impossible to experimentally distinguish between liquid flows and vapor flows in hygroscopic materials. To distinguish the moisture flow in each phase, nonisothermal tests may be performed. In most practical applications in moisture analysis both vapor and liquid flow may be treated as parallel processes. Therefore, moisture flow is often expressed as the sum of two transport equations—one using vapor pressure as a driving potential for vapor flow and the other using either capillary suction or relative humidity as driving potentials for liquid moisture flow. These conservation equations may be written as follows:

$$\frac{\partial m}{\partial t} = -\nabla \cdot (w_v + w_w) + S_w \quad (16)$$

where

$m$  = moisture content of the building material  
 $w_v$  = vapor diffusion flux  
 $w_w$  = liquid transport flux  
 $S_w$  = moisture source or sink

The symbol  $\nabla$  represents the nabla operator, which denotes divergence, or the gradients along the three spatial coordinates. The vapor and liquid transport flux densities may be given by

$$w_v = -\mu \nabla p \quad \text{or} \quad w_v = -\mu \nabla (\phi p_{sat}) \quad (17)$$

$$w_w = -D_p \nabla s \quad \text{or} \quad w_w = -D_\phi \nabla \phi \quad (18)$$

where

$\mu$  = water vapor permeability of building materials  
 $s$  = capillary suction pressure  
 $p_{sat}$  = water vapor saturation pressure  
 $D_p$  = liquid transport coefficient related to capillary suction  
 $D_\phi$  = liquid transport coefficient related to relative humidity  
 $\phi$  = relative humidity

Previous methods of calculation used moisture content and temperature as driving potentials for combined vapor and liquid movement. This approach has the disadvantage that moisture content is discontinuous at interfaces between different materials and, therefore, cannot be used as a moisture flow potential at those interfaces. Equation (17) and Equation (18) provide the advantage of continuity at material interfaces and maintain physically meaningful material parameters.

## WATER VAPOR RETARDERS AND AIRFLOW RETARDERS

Water vapor retarders and airflow retarders combine to control the movement of moisture and air. Although their functions are different, a single component may serve both functions. The designer assesses the needs for moisture and air movement control in the building envelope and provides a system that combines the required vapor retarder and airflow retarder properties.

### Airflow Retarder Functions and Properties

In addition to a vapor retarder, control of moisture requires an effective airflow retarder (also referred to as an air barrier or air infiltration barrier). Without effective control of airflow, vapor retarders are completely ineffective. However, airflow may accelerate the drying of a wet building component, as described by Karagiozis and Salonvaara (1999a,b).

A vapor retarder may also be an airflow retarder, that is, an air/vapor retarder. In the past, many designs were based on this, and measures were taken to ensure that the vapor retarder was continuous in order to control airflow through it. This remains a valid approach. Some recent designs treat airflow retarders and vapor retarders as separate entities, but an airflow retarder should not be placed in a location where it can cause moisture to condense if it also has vapor retarder properties. For example, an airflow retarder placed on the cold side of a building envelope may cause condensation, particularly if the vapor retarder is ineffective and the airflow retarder is impermeable to moisture.

However, a cold-side air/vapor retarder that also has sufficient insulation may result in a lower potential for condensation by raising the temperature of the surface of the air/vapor retarder, but this requires careful installation and sealing of joints.

Air leakage characteristics of airflow retarders can be determined with ASTM *Standard E 283* or ASTM *Standard E 1424*. Di Lenardo et al. (1995) discuss specific air leakage criteria for airflow retarders in cold climates. These specifications call for maximum permissible air leakage rates between 0.05 and 0.2 L/s per square metre (as measured with an air pressure difference of 75 Pa), depending on the water vapor permeance of the outermost layer of the building envelope. The highest permissible air leakage rate of the airflow retarder applies if the permeance of the outermost layer is greater than 570  $\text{ng}/(\text{s} \cdot \text{m}^2 \cdot \text{Pa})$ , and the lowest rate applies if the permeance is less than 60  $\text{ng}/(\text{s} \cdot \text{m}^2 \cdot \text{Pa})$ . Intermediate values are provided as well. The recommendations apply only to heating climates.

The effectiveness of an airflow retarder can be greatly reduced if openings, even small ones, exist in it. Such openings can be

caused by poor design, poor workmanship during application, poorly sealed joints and edges, insufficient coating thickness, improper caulking and flashing, uncompensated thermal expansion, mechanical forces, aging, and other forms of degradation. Common faults or leaks occur at electrical boxes, plumbing penetrations, telephone and television wiring, and other unsealed openings in the structure.

A ceiling airflow retarder needs to be continuous at chases for plumbing, ducts, flues, and electrical wiring. In flat roofing, mechanical fasteners are sometimes used to adhere the system to the deck. These often penetrate the airflow retarder, and the resulting hole may allow air and accompanying moisture leakage into the roof.

Because it resists airflow, an airflow retarder must withstand pressures exerted by chimney (stack) effects, wind effects, or both, during construction and over the life of the building. The magnitude of the pressure varies, depending on the type of building and the sequence of construction. At one extreme, single-family dwellings may be built with the exterior cladding partly or entirely installed and insulation in place before the airflow retarder is added. Chimney effects in such buildings are small even in cold weather, so stresses on the airflow retarder during construction are small.

At the other extreme, in tall buildings, wind and chimney-effect forces are much greater than they are in single-family or other low-rise buildings. A fragile, unprotected sheet material should not be used as an airflow retarder (or vapor retarder) in a tall building because it will probably be torn by the wind before construction is completed.

In summary, an airflow retarder must

- Meet air permeability requirements
- Be continuous, i.e.,
  - Tight joints in the airflow retarder must be constructible
  - Effective bonds in the airflow retarder must be made at intersections (e.g., wall/roof)
  - Dimensional changes due to temperature changes or shrinkage must be accommodated without damage to joints or the retarder material
- Be strong enough to support the stresses applied to it, i.e.,
  - It must not be ruptured or excessively deformed by air pressures due to wind and stack effects
  - Where an adhesive is used to complete a joint, it must be designed to withstand forces that might gradually peel it away

A small penetration across an airflow retarder may seriously affect its performance. A penetration concentrates the air/vapor flow in such a way that large local deposits of water and ice are possible. In this situation calculations of moisture flow and accumulation using permeance values are useless when airflow is involved.

In addition, the following properties of an airflow retarder may be important, depending on the application:

- Elasticity
- Thermal stability
- Fire and flammability resistance
- Inertness to deteriorating elements
- Ease of installation

More information on air leakage in buildings may be found in Chapter 26.

### Vapor Retarder Functions and Properties

A vapor retarder retards water vapor diffusion but does not totally prevent its transmission. The requirements for buildings are entirely different than those for pipes and equipment. Conditions on the inside and outside of buildings vary continually, and air movement and ventilation can provide wetting as well as drying at various times. Moisture entering one side of a wall cavity can be stored

and released at a later time, or transmitted immediately out of the cavity through the other side. Requirements for vapor retarders in building components are therefore not extremely stringent.

In contrast, moisture that enters the insulation of cold storage facilities, cold pipes, or equipment is unlikely to escape, except during periods when the facilities, pipes, or equipment are not in use and are allowed to warm up. Vapor retarders for cold pipe or equipment applications must therefore have an extremely low permeance [e.g., less than  $3 \text{ ng}/(\text{s}\cdot\text{m}^2\cdot\text{Pa})$ , or lower for severe conditions]. However, Korsgaard (1993) demonstrated that water condensing on an insulated cold pipe can be removed continuously by wicking action with a specially designed and installed wick system, as long as pipe temperatures are above freezing.

In HVAC applications, vapor retarders are applied to thermal insulation on tanks, cold pipes, ducts, refrigerated enclosures, and buildings. If conditions are conducive to condensation, water vapor retarders help (1) keep the insulation dry, thereby reducing the cooling load; (2) prevent structural damage by rot, corrosion, or the expansion of freezing water; and (3) reduce paint problems on exterior wall construction (ASTM *Standard C 755*).

In addition to vapor permeance, the following properties of vapor retarders are important, depending on the application:

- Mechanical strength in tension, shear, impact, and flexure
- Adhesion
- Elasticity
- Thermal stability
- Fire and flammability resistance
- Inertness to other deteriorating elements
- Ease of fabrication, application, and joint sealing

Any vapor retarder's effectiveness depends on its vapor permeance, installation, and location within the insulated section. The vapor retarder is usually located at or near the surface exposed to the higher water vapor pressure. For residences in heating climates, this is usually the winter-warm side of the insulation.

Under conditions of reversible water vapor flow that can occur during temperature cycling of industrial insulations or of special-purpose buildings, the selection and location of water vapor retarders require special study and treatment (Stachelek 1955).

Vapor retarder material is usually a thin sheet or coating. However, a construction of several materials, some perhaps of substantial thickness, could also constitute a vapor retarder system.

Water vapor permeances and permeabilities of some vapor retarders and other building materials are given in Table 9 in Chapter 25.

Vapor retarders that allow substantial summer drying while functioning as effective vapor retarders during the heating season are sometimes called "smart" vapor retarders. One type of smart vapor retarder has a low permeance to vapor but is permeable to liquid water, allowing the drying of condensed moisture. Korsgaard and Pedersen (1989, 1992) describe such a vapor retarder composed of a synthetic fabric sandwiched between staggered strips of plastic film. The fabric wicks free water from the building envelope, while the plastic film retards vapor flow into it.

Another smart vapor retarder provides low vapor permeance at low relative humidities but much higher permeance at high relative humidity. During the heating season, indoor humidity usually is below 50%, and the permeance of the smart vapor retarder is low. In the summer and even during winter days with high solar heat gains, when the temperature gradient is reversed, moisture moving from the exterior of the wall or roof raises the relative humidity at the vapor retarder. This leads to a higher vapor permeance of the vapor retarder and the potential for the wall or roof to dry out. One such vapor retarder, a nylon film, is described by Kuenzel (1998). Below 50% rh, the permeance of the film is less than  $60 \text{ ng}/(\text{s}\cdot\text{m}^2\cdot\text{Pa})$ , but it becomes more permeable at above 60% rh, reaching  $2070 \text{ ng}/(\text{s}\cdot\text{m}^2\cdot\text{Pa})$  at 90% rh.

Vapor retarder material for pipes is usually sheet metal with soldered seams; heavy foil with wide, sealed overlaps; plastic pipe; or other very low permeance systems.

**Classification of Vapor Retarders**

Historically, a material or system with a permeance of 60 ng/(s·m<sup>2</sup>·Pa) or less qualifies as a vapor retarder. More recently, further classification of vapor retarders has been proposed. For example, the Canadian General Standards Board (CGSB) has specified Type I vapor retarders as retarders with a permeance of 15 ng/(s·m<sup>2</sup>·Pa) or less, and Type II as retarders with a permeance of 45 ng/(s·m<sup>2</sup>·Pa) or less before aging and 60 ng/(s·m<sup>2</sup>·Pa) or less after aging.

Water vapor retarders are classified as rigid, flexible, or coating materials. Rigid retarders include reinforced plastics, aluminum, and stainless steel. These retarders usually are mechanically fastened in place and are vapor-sealed at the joints.

Flexible retarders include metal foils, laminated foil and treated papers, coated felts and papers, and plastic films or sheets. Such retarders are supplied in roll form or as an integral part of a building material (e.g., insulation). Accessory materials are required for sealing joints.

Coating retarders may be semifluid or mastic; paint (arbitrarily called surface coatings); or hot melt, including thermofusible sheet materials. Their basic composition may be asphaltic, resinous, or polymeric, with or without pigments and solvents, as required to meet design conditions. They can be applied by spray, brush, trowel, roller, dip or mop, or in sheet form, depending on the type of coating and surface to which it is applied. Potentially, each of these materials is an airflow retarder; however, to meet airflow retarder specifications, it must satisfy the requirements for strength, continuity, and air permeance.

Designers have many options. For example, the conditions for control of airflow and moisture movement might be achieved using an interior finish, such as drywall, to provide strength and stiffness, along with a low-permeability coating, such as a vapor retarder paint, to provide the required low level of permeance. In this case, edge sealing is needed to establish continuity with adjacent airflow retarder/vapor retarder components.

Other designs may use more than one component. However, (1) any component that qualifies as a vapor retarder usually also impedes airflow, and is thus subject to pressure differences that it must resist, and (2) any component that impedes airflow often also retards vapor movement and may promote condensation or frost formation.

Additional information regarding the control of moisture and airflow through the use of vapor retarders and airflow retarders may be found in Chapters 24 and 26 and in Construction Specifications Canada (1990).

Several studies found a significant increase in the apparent permeance of vapor retarders as a result of small holes in the vapor retarder. For example, Seiffert (1970) reports a 100-fold increase in the permeance of aluminum foil when it is 0.014% perforated, and a 4000-fold increase when 0.22% of the surface is perforated. In general, penetrations particularly degrade a vapor retarder's effectiveness if the vapor retarder has a very low permeance (e.g., polyethylene or aluminum foil). In addition, perforations may lead to additional air leakage, which further erodes the effectiveness of the vapor retarder.

**STEADY-STATE DESIGN TOOLS**

Traditional methods for moisture design of the exterior building envelope all have severe limitations, and the results are sometimes difficult to interpret. However, these methods are used by design professionals and form the basis for current codes dealing with moisture control and vapor retarders.

The three best-known manual steady-state design tools for evaluating the probability of condensation within exterior envelopes (exterior walls, roofs, or ceilings) are (1) the dew-point method, (2) the Glaser diagram, and (3) the Kieper diagram. All three methods compare the vapor pressures within the envelope, as calculated by simple vapor diffusion equations, with the saturation pressures, which are based on the calculated temperatures within the envelope. If the calculated vapor pressure is above the saturation pressure at any point within the envelope, condensation is indicated.

The **dew-point method**, used in North America, and the **Glaser diagram**, commonly used in Europe and elsewhere, are almost identical. They differ slightly in the formulation of the vapor diffusion equation for flow through a building material and in definition of terms; the main difference lies in the graphical procedures. These methods are often misused, especially when condensation is present.

The **Kieper diagram**, a variant of the previous two methods, was introduced by Kieper et al. (1976) and described in greater detail by Trethewen (1979) and TenWolde (1983, 1994). As with the dew-point method and the Glaser diagram, the Kieper diagram is based entirely on vapor diffusion theory. The advantages of this method are that (1) the same diagram can be used for different wall configurations, as long as indoor and outdoor conditions are not changed; and (2) the calculation does not need to be repeated if condensation is indicated.

Both the dew-point method and the Kieper diagram allow simple estimation of the effect of wall or roof cavity ventilation by representing the effect of ventilation on thermal and vapor transport through the addition of parallel thermal and vapor diffusion resistances (Trethewen 1979, TenWolde and Carl 1992). The parallel resistances account for the heat and vapor bypassing the exterior material layers with outside ventilation air. The magnitude of the parallel resistances may be determined from the following equations:

$$R_{t, par} = \frac{S}{Q\rho c_p} \tag{19}$$

$$R_{v, par} = \frac{S}{Q\rho c} \tag{20}$$

where

- $R_{t,par}$  = parallel thermal resistance, m<sup>2</sup>·K/W
- $R_{v,par}$  = parallel vapor flow resistance, Pa·m<sup>2</sup>·s/ng
- $S$  = surface area of the wall or ceiling, m<sup>2</sup>
- $Q$  = cavity ventilation airflow rate, m<sup>3</sup>/s
- $\rho$  = density of air, kg/m<sup>3</sup>
- $c$  = ratio of humidity ratio and vapor pressure, approximately 6.13 g/(kg·kPa)
- $c_p$  = specific heat, J/(kg·K)

Although this method of including ventilation only approximates the actual effects of ventilation, it can be a useful tool.

Many people advocate abandoning steady-state design tools because of their severe limitations. Perhaps the greatest limitation is that their focus is restricted to prevention of sustained interstitial condensation. Many building failures (such as mold and mildew, buckling of siding, and paint failure) are not necessarily related to surface condensation.

Conversely, limited condensation can often be tolerated, depending on the materials involved, the temperature conditions, and the speed at which the material dries out. Wetting and drying cycles cannot be accurately analyzed with steady-state tools because these tools neglect moisture storage in the building materials. Another weakness is that these methods exclude all moisture transfer mechanisms other than vapor diffusion. Results obtained with any of these methods should therefore be considered as approximations and be used with extreme care.

The validity and usefulness of any of these methods depend on the judicious selection of boundary conditions and material properties. Specifically, they should only be used to estimate seasonal mean conditions, rather than daily or even weekly mean conditions. Furthermore, permeances may vary with moisture content and the effect of rain splash, flashing imperfections, leaky or poorly formed joints, weather exposure, and sunshine can have overriding effects.

For those who want to use these simple tools, despite their shortcomings, a short description of the dew-point method is presented, with an example of its use. The Glaser diagram closely parallels the dew-point method. A comprehensive description of these methods can be found in TenWolde (1994).

**Dew-Point Method**

The dew-point method is based on a slight modification of diffusion Equation (15):

$$w = -\mu \frac{\Delta p}{d} \tag{21}$$

where

- $w$  = water vapor flux through a layer of material,  $\text{ng/s}\cdot\text{m}^2$
- $\mu$  = water vapor permeability of material,  $\text{ng}/(\text{s}\cdot\text{m}\cdot\text{Pa})$
- $\Delta p$  = vapor pressure difference across the layer, Pa
- $d$  = thickness of the layer, m

The term  $\mu/d$  represents the permeance of the material. Water vapor resistance  $Z$  is defined as the inverse of the permeance. Then Equation (21) can be written as

$$w = -\frac{\Delta p}{Z} \tag{22}$$

**Example 1.** The dew-point method is explained and demonstrated for the frame wall construction and materials described in Table 3. Assume 21°C, 40% rh indoors, and -6.7°C, 50% rh outdoors.

**Solution:**

**Step 1.** Calculate the temperature drop across each material. The temperature drop is proportional to the R-value as follows:

$$\frac{\Delta T_{\text{material}}}{\Delta T_{\text{wall}}} = \frac{R_{\text{material}}}{R_{\text{wall}}}$$

Table 4 lists the resulting temperature drops and resulting temperatures at each surface.

**Step 2.** Find the saturation vapor pressures corresponding to the surface temperatures (Table 4). These values can be found in Table 2 in Chapter 6, or in other psychrometric tables or charts.

**Step 3.** Calculate the vapor pressure drops across each material. These are calculated in much the same way as the temperature drops in step 1.

$$\frac{\Delta p_{\text{material}}}{\Delta p_{\text{wall}}} = \frac{Z_{\text{material}}}{Z_{\text{wall}}}$$

where

- $p$  = vapor pressure, Pa
- $Z$  = vapor diffusion resistance,  $\text{Pa}\cdot\text{m}^2\cdot\text{s}/\text{ng}$

From Table 3, the total resistance of the wall with the vapor retarder is

$$\begin{aligned} Z_{\text{wall}} &= 1/9200 + 1/290 + 1/1724 + 1/29 + 1/2010 + 1/57\,000 \\ &= 0.0391 \text{ Pa}\cdot\text{m}^2\cdot\text{s}/\text{ng} \end{aligned}$$

The vapor pressure drop across the wall is calculated from indoor and outdoor relative humidities and the indoor and outdoor saturation vapor pressures (see Table 4).

$$\begin{aligned} \Delta p_{\text{wall}} &= p_{\text{indoor}} - p_{\text{outdoor}} \\ &= (40/100) 2.496 - (50/100) 0.3701 = 0.8134 \text{ kPa} \end{aligned}$$

**Table 3 Approximate Thermal and Vapor Diffusion Properties of Wall in Example 1**

Air Film or Material	Thermal Resistance $R$ , $\text{m}^2\cdot\text{K}/\text{W}$	Permeance $M$ , $\text{ng}/(\text{s}\cdot\text{m}^2\cdot\text{Pa})$	Diffusion Resistance $Z$ , $\text{Pa}\cdot\text{m}^2\cdot\text{s}/\text{ng}$
Air film (still)	0.12	9200 <sup>a</sup>	0.00011 <sup>a</sup>
Gypsum board, painted	0.079	290	0.0035
Insulation	1.9	1700	0.00058
Plywood sheathing	0.11	29	0.0345
Wood siding	0.18 <sup>b</sup>	2010 <sup>b</sup>	0.0005 <sup>b</sup>
Air film (wind)	0.03	57000 <sup>a</sup>	0.000017 <sup>a</sup>
Total	2.42	Not applicable	0.0392

<sup>a</sup>Approximate values; permeances of surface air films are very large compared to those of other materials and do not affect results of calculations.

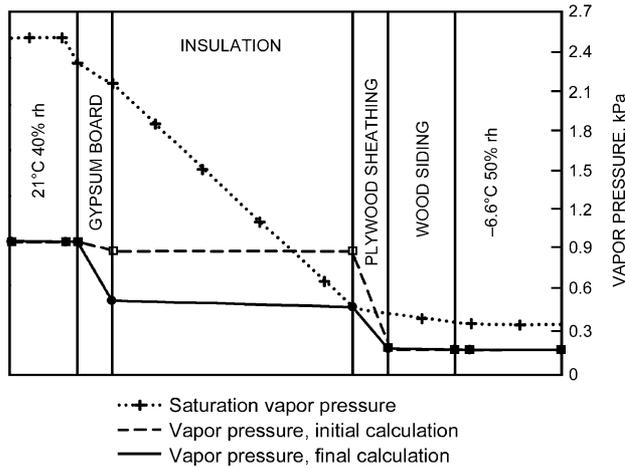

<sup>b</sup>Approximate values; permeance reflects limited ventilation of back of siding.

**Table 4 Calculated Temperature Drops, Surface Temperatures, and Saturation Vapor Pressures in Example 1**

Air Film or Material or Surface	Temperature Drop, °C	Surface Temperature, °C	Saturation Vapor Pressure at Surface, kPa
Indoor air	—	21	2.496
Surface air film	1.3	—	—
Interior wall surface	—	19.7	2.299

**Fig. 10 Dew-Point Calculation in Example 1**

As with temperatures, the vapor pressures at the surfaces of each material can easily be determined from the vapor pressure drops. Table 5 lists the results for the example wall in the initial calculation column.

**Step 4.** Figure 10 shows the saturation and calculated vapor pressures. Comparison with saturation pressures reveals that the calculated vapor pressure on the interior surface of the sheathing (0.9125 kPa) is well above the saturation pressure at that location (0.4843 kPa). This indicates condensation, probably on the surface of the sheathing. *It does not indicate condensation within the insulation.*

If the location of the condensation or the condensation rate is of interest, additional calculations (steps 5 and 6) are necessary.

**Step 5.** Figure 10 shows that the calculated vapor pressure exceeds the saturation vapor pressure by the greatest amount at the interior surface of the plywood sheathing. Therefore, this is the most likely location for condensation to occur. With condensation at that surface, the vapor pressure should equal the saturation vapor pressure at that location (see the final calculation column in Table 5).

**Step 6.** The change of vapor pressure on the plywood sheathing alters all other vapor pressures as well as the vapor flow through the wall. The calculation of vapor pressures is similar to the calculation in step 3, but the wall is now divided into two parts: one part on the interior of the condensation plane (i.e., gypsum board and insulation) and the other part on the exterior (plywood sheathing and wood siding). The vapor pressure drop over the first part of the wall is

$$\Delta p_1 = 0.9986 - 0.4843 = 0.5143 \text{ kPa}$$

and that over the second part is

$$\Delta p_2 = 0.4843 - 0.1851 = 0.2992 \text{ kPa}$$

The vapor diffusion resistances of both parts of the wall are

$$Z_1 = 1/9200 + 1/290 + 1/1724 = 0.0041 \text{ Pa} \cdot \text{m}^2 \cdot \text{s}/\text{ng}$$

$$Z_2 = 1/29 + 1/2010 + 1/5700 = 0.035 \text{ Pa} \cdot \text{m}^2 \cdot \text{s}/\text{ng}$$

The vapor pressure drops across each material can now be calculated from

$$\frac{\Delta p_{\text{material}}}{\Delta p_i} = \frac{Z_{\text{material}}}{Z_i} \quad \text{for } i = 1, 2$$

Final calculations of vapor pressure are shown in Table 5. The vapor pressure no longer exceeds the saturation vapor pressure, which means that the condensation plane was chosen correctly. Figure 10 shows the vapor pressure profile (labeled as Vapor pressure, final calculation).

Vapor flow is no longer the same throughout the wall—vapor flow into the wall from the indoor air increases as a result of the lower vapor pressure at the plywood surface, while flow from the wall to the outside decreases. The difference between the two flows is the rate of moisture accumulation:

$$w_c = \Delta p_1/Z_1 - \Delta p_2/Z_2 = 0.5143/0.0041 - 0.2992/0.035 = 117 \mu\text{g}/(\text{s} \cdot \text{m}^2)$$

This amounts to about 10 g/day·m<sup>2</sup>. In our example, the plywood surface is below freezing, and this moisture would probably accumulate as frost. The moisture content of the plywood would be increased by 1% after about a week of condensation at this rate.

The dew-point method can be summarized as follows:

1. Calculate temperature drops and surface temperatures.
2. Find corresponding saturation vapor pressures.
3. Calculate vapor pressure drops and vapor pressures.
4. Check whether the saturation pressure is above the vapor pressure at all surfaces; if so, no condensation is indicated. Vapor flow through the wall may be determined if desired.

If condensation is indicated, the following steps may be followed:

1. Select the condensation surface. In most cases it is the surface where the difference between the calculated vapor pressure and the saturation vapor pressure is the highest. Vapor pressure at this surface should be set equal to the saturation vapor pressure.
2. Recalculate the vapor pressures; if any vapor pressures are above saturation, steps 5 and 6 should be repeated with a different choice for the condensation surface.
3. If needed, calculate the rate of condensation.

### MATHEMATICAL MODELS

The rapid advance in computer technology has made it possible to develop computer models capable of analyzing and predicting the thermal and moisture behavior of building components. A small number are extensions of the steady-state analysis methods described before, but with the **transient models** it is possible to predict hourly drying and wetting of building components in a variety of conditions, climates, and design configurations. The information in this section is largely based on a review of the state of the art of heat and moisture transport modeling for buildings, which identified 37 different models of various complexity (Hens 1996). Some of those models do not include moisture transport and are therefore not included here. Most of the models are research tools that are not readily available, but some are available either commercially, free of charge, or through a consultant. Karagiozis (2001) describes the more sophisticated design tools, indicating both the capabilities and the limitations. ASTM *Manual 40* covers available design tools and approaches to investigate the performance of building envelope systems in terms of heat and moisture transport.

For many applications, the actual behavior of an assembly under transient climatic conditions must be simulated in order to account for short-term processes like driving rain absorption, summer condensations, and phase changes. Understanding the application limits of each model is an important part of applying mathematical models to develop design guidelines.

The features of a complete moisture analysis model include:

1. Transient heat, air, and moisture transport formulation, incorporating physics of
  - Vapor transport
  - Liquid transport
  - Airflow
  - Heat and moisture storage/capacity
  - Condensation and evaporation
  - Freezing and thawing
2. One- or two-dimensional spatial formulation
3. Material properties as functions of moisture content, relative humidity, or temperature
  - Thermal properties (density, heat capacity, thermal conductivity)
  - Moisture properties (porosity, sorption, water retention, vapor permeability, liquid diffusivity)
  - Airflow properties (air permeability)

4. Boundary conditions (generally on an hourly basis)
  - Incident solar radiation and sky radiation (depending on inclination and orientation)
  - Wind-driven rain at exterior surfaces (depending on location, and aerodynamics)
  - Wind speed, orientation, and pressure
  - Interior and exterior temperature and relative humidity
  - Interior moisture sources and stratification
5. Surface conditions
  - Convective heat transfer coefficients
  - Mass transfer coefficients
  - Short wave absorptivity
  - Long wave emissivity
  - Precipitation absorptivity
6. Building systems and subsystem effects
  - Water penetration rates through subsystems (joints, cracks, etc)
  - Air leakage (cracks, joints, e.g., around a window)
  - Additional sources of moisture

While not all these features are required for every analysis, additional features may be required in some applications, such as moisture flow through unintentional cracks and intentional openings. To accurately model these cracks and openings, supplementary experiments may be used to define their performance under various loads. In Feature 6, additional laboratory-controlled tests provide performance data specific to each subsystem (e.g., water entry through a crack) (Straube and Burnett 1997). In most cases, field measurement of system and subsystem effects is preferred.

The validation, verification, and benchmarking of hygrothermal models is a formidable task. Little internationally accepted experimental data exist to benchmark hygrothermal models. The main difficulty lies in the fact that it is difficult to measure moisture flows and moisture transport potentials even in laboratory-controlled conditions. Even a validated model should be verified for each new application. Two-dimensional and three-dimensional hygrothermal models are extremely complex and mostly require the direct expertise of the authors.

In most hygrothermal models, moisture content, temperature, relative humidity, and related fluxes are common outputs of simulations. Results have to be checked for consistency, accuracy, grid independency, and sensitivity to parameter changes. The results may be used to determine the moisture tolerance of an envelope subjected to various interior and exterior loads. The heat fluxes may be used to determine the thermal performance under the influence of moisture and airflow. Furthermore, the transient output data may be used to assess durability and indoor air quality. Post-processing tools concerning durability (e.g., corrosion, mold growth, freezing and thawing, hygrothermal dilation, and indoor air humidity) are currently being developed. For instance, Karagiozis and Kuenzel (1999) developed a model to estimate the rate of mold growth and corrosion. It is expected that hygrothermal models will be incorporated in whole-building simulation tools (Karagiozis and Salonvaara 1999b).

Transient models enable an hour-by-hour analysis of moisture conditions in building components and a much more realistic calculation than steady-state diffusion models. However, many are not easy to use and require judgment and expertise on the part of the user. Existing moisture transport models are one- or two-dimensional, which requires the user to devise a realistic representation of a three-dimensional building component. Users need to be aware of which transport phenomena and types of boundary conditions are included and which are not. For instance, some models are not able to handle rain wetting of the exterior.

Results from an analysis tend to be very sensitive to the choice of indoor and outdoor conditions, but exact conditions are seldom known. Indoor and outdoor conditions to be used for the purpose of

building design have not yet been established, although standards are being developed. Accurate data for all the materials in a component is difficult to find. Finally, interpretation of the results is not easy; accurate data on what moisture and temperature conditions materials can tolerate are not often available.

### PREVENTING SURFACE CONDENSATION

Surface condensation occurs when water vapor comes in contact with a surface that has a temperature lower than the dew point of that vapor. The insulation should be sufficiently thick to ensure that the insulation surface temperature always exceeds the dew-point temperature to prevent surface condensation from occurring on the warm side of insulated rooms, pipes, ducts, and equipment.

The concept of a **temperature index coefficient**  $\tau$ , also called the condensation resistance factor, is useful for calculating the surface temperature:

$$\tau = \frac{t_s - t_c}{t_a - t_c} \quad (23)$$

where

$t_s$  = surface temperature on warm side of insulation

$t_c$  = temperature on cold side of insulation

$t_a$  = ambient temperature on warm side of insulation

The minimum temperature index coefficient to avoid surface condensation is

$$\tau_{min} = \frac{t_d - t_c}{t_a - t_c} \quad (24)$$

where  $t_d$  is the dew point of ambient air.

For flat surfaces and insulation, the temperature index coefficient can be stated as

$$= \frac{L/k}{L/k + 1/h} \quad (25)$$

where

$L$  = thickness of the insulation

$k$  = thermal conductivity of the insulation

$h_i$  = surface heat transfer coefficient

The minimum insulation thickness to avoid surface condensation on a flat surface can be calculated from

$$L_{min} = \frac{\tau_{min} k}{1 - \tau_{min} h_i} \quad (26)$$

The minimum insulation thickness for pipe insulation is given by

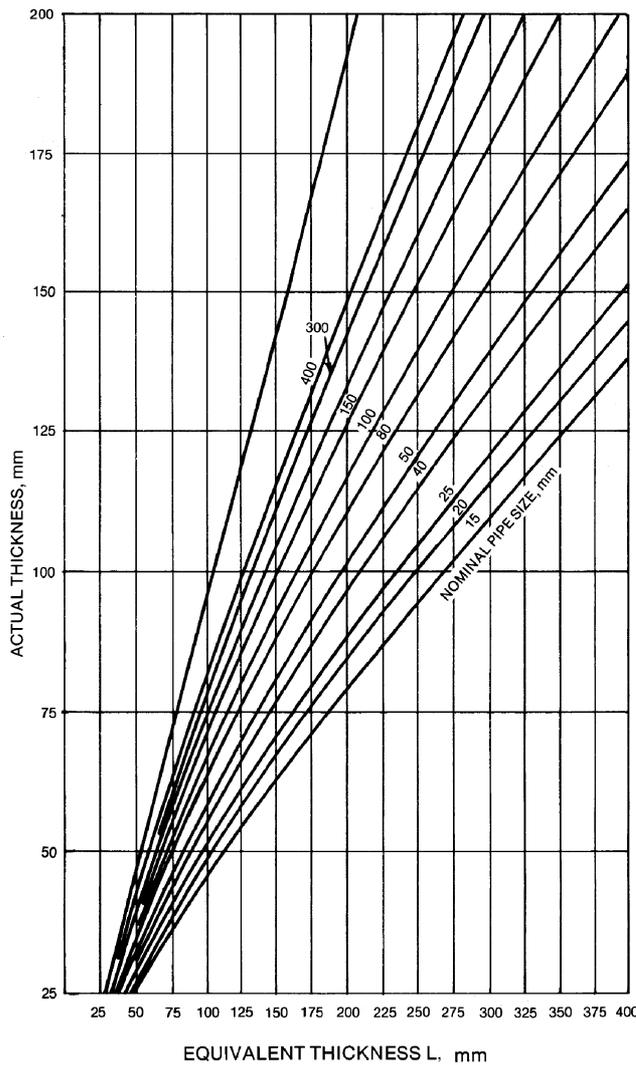

$$r_{s,min} \ln\left(\frac{r_{s,min}}{r_i}\right) = \frac{\tau_{min} k}{1 - \tau_{min} h_i} \quad (27)$$

where

$r_{s,min}$  = minimum outer radius of the insulation

$r_i$  = inner radius of the insulation

The term to the left of the equal sign in Equation (27) is called equivalent thickness. **Equivalent thickness** is the thickness of insulation on a flat surface required to give the same rate of heat transmission per unit area of outer surface of insulation as on a cylinder or pipe. Figure 11 provides a convenient way to convert equivalent thickness to actual thickness.

**Fig. 11 Conversion of Equivalent Thickness to Actual Thickness for Pipe Insulation**

**I**N THE ORIGINAL planning phase of buildings, the thermal and moisture design and long-term performance must be considered. Installation of adequate insulation and moisture control assemblies during construction can be much more economical than installation later. Proper selection of thermal insulation and moisture control assemblies must be based on

- Thermal and moisture properties of the materials
- Other properties required by the location of the materials
- Space availability
- Compatibility of the materials with adjacent materials
- Interior and exterior climate
- Performance expectations

Types of thermal insulation, their properties, economic thickness, and principles of moisture control and moisture transport are discussed in Chapters 23 and 25. Insulation in various assemblies that can be used interchangeably for a given construction, as well as specific moisture control options for various climatic regions, are discussed in this chapter. For specific industrial applications of insulated assemblies see the appropriate chapter in other ASHRAE Handbooks. In the 1998 *ASHRAE Handbook—Refrigeration*, for refrigerators and freezers, see Chapters 47, 48, and 49; for insulation systems for refrigerant piping, see Chapter 32 and this chapter; for refrigerated facility design, see Chapters 13 and 39; for trucks, trailers, and containers, see Chapter 29; for marine refrigeration, see Chapter 30; and for environmental test facilities, see Chapter 37.

## GENERAL BUILDING INSULATION PRACTICE

### WOOD FRAME CONSTRUCTION

Wood framing members and structural panels such as plywood, particleboard, and fiberboard only provide limited resistance to heat flow; therefore, wood frame construction is well suited to application of both cavity insulation and surface-applied insulation. The most common materials for cavity insulation are glass fiber, mineral fiber, cellulose, and spray-applied foams. For surface applications, a wide variety of sheathing insulations exists.

The preparation of this chapter is assigned to TC 4.4, Building Materials and Building Envelope Performance.

**Roof decks** of wood, metal, or preformed units may be insulated on top of or below the deck.

**Attic construction** with conventional rafters and ceiling joists or roof trusses can be insulated between framing members with batt, blanket, or loose-fill insulation. In warm climates, radiant barriers, low emissivity surfaces, and reflective insulations further reduce cooling loads. The Radiant Barrier Attic Fact Sheet (DOE 1991) provides information on climatic areas best suited for radiant barrier applications. This document also provides comparative information on the relative performance of these products versus conventional fibrous insulations.

The cavities of **cathedral ceiling construction** (in which the ceiling insulation and interior finish are parallel to the roof plane) can be insulated using glass fiber, cellulose, rigid foam, or spray-applied insulation. The surface above cathedral ceiling framing may be insulated with insulating panels or structural insulated panels (SIPs). The placement of insulation directly beneath a sloped roof deck in standard flat-ceiling construction, with or without ventilation, has been called “cathedralized” construction.

The **wall cavities** of wood frame construction can be insulated with batt, blanket, and loose-fill or spray-applied insulation. When using insulation materials in wall applications, extra care must be taken during the installation to eliminate voids within the wall cavity. When installing loose-fill insulation during retrofit of existing construction, all cavities should be checked prior to installation for obstructions such as fire stop headers and wiring that could prevent complete filling of the cavity. In addition, the material must be installed at the manufacturer’s recommended density to ensure the desired thermal performance.

In addition to being properly insulated, the **exterior envelope** of a building should be constructed to minimize airflow into or through the building envelope. Airflow may degrade the thermal performance of insulation and cause excessive moisture accumulation in the building envelope. The use and function of airflow retarders are discussed in both in Chapter 23 and in this chapter.

### COLD-FORMED STEEL FRAME CONSTRUCTION

Conventional light frame construction with cold-formed steel framing has many characteristics in common with light frame wood construction. The greatest differences are the increased thermal conductivity and the dimension and shape characteristics of steel framing members. Barbour et al. (1994) and Tuluca and Gorthala (1999) found that the conductivity and framing member spacing

have the most significant roles in determining overall R-value (U-factor). They determined that the thickness of cold-formed steel does not play a significant role in the R-value (U-factor). The parallel path method overestimates the R-values for building assemblies containing cold-formed steel framing, and the isothermal planes calculation methods underestimates the R-value. For methods to calculate heat flow in framing assemblies using cold-formed steel, see Chapter 25.

The most common cavity insulation materials are glass fiber, mineral fiber, cellulose, and spray-applied foams. Cavity insulation should be full width to cover between the steel framing members; it should not be a nominal width such as used for wood stud construction. Surface applications of continuous insulation sheathing, such as rigid foam board (i.e., extruded or expanded polyisocyanurate or polystyrene), may be applied to the exterior or interior of the assembly framing to provide a thermal break. Rigid board insulation applied as a sheathing does not provide structural lateral bracing.

**Thermal bridging** may be more severe with cold-formed steel-framed trusses than with conventional joist and rafter framing. Roof trusses have chords and web members that extend through the insulation into an unconditioned attic space and act as a thermal bridge to the bottom chord. A continuous insulating sheathing on the exterior or interior of the roof framing provides a thermal break.

### HEAVY STEEL FRAME CONSTRUCTION

Buildings and structures with heavy, steel framing supports and exterior metal cladding are usually insulated between the frame and cladding with faced blanket or spray insulation. In heating climates, the facing may serve as a combination vapor retarder and interior finish, which must be protected against physical damage. Other types of insulation can be used by adding framing or furring to the inside of frame or exterior siding. Insulation securements that compress batt and blanket insulations reduce thermal resistance. This reduction, plus the thermal bridging caused by the screw or bolt penetrating the insulation, may cause condensation during cold weather.

The exterior cladding of structural steel-framed buildings may be (1) custom walls for specific projects, where most construction components are developed on a one-time basis; (2) commercial walls, where standard components are adapted to a particular building design; and (3) industrial-type walls, where standard metal sheets are fluted or ribbed to form field-assembled sandwiches to meet job conditions.

The cladding may consist of prefabricated panels or sections that may be classified as one of the following general types:

1. To withstand the elements, **single-thickness facings** are usually inserted in subframing with the windows to form a veneer over separate backup walls. Thermal insulation is integral with, or added to, the exterior of the backup wall and covers the edge of the floor slab or spandrel beam. In heating climates, this method reduces heat loss and keeps floors warm at their exterior edge. Insulating the exterior of the framing reduces thermal movement of the building structure.
2. **Sandwich construction** or adhesive-bonded panels are generally three-ply: exterior skin, core materials, and interior skin. This type of panel, when manufactured with concrete faces and an insulation core, comes in large sizes and can be attached directly to the exterior of the building frame. When using metal facings, the width of the panels is usually restricted to match that of the standard formed sheet. These panels are installed on the exterior of the building framing. The thermal performance required for a particular installation (including the interfaces between walls, floors, ceiling, doors, and windows) should be checked carefully because adding insulation later is difficult.
3. **Mechanically fastened panels** generally have a hollow box shape, with the exterior facing nesting over the interior facing.

The cavity can be filled with flexible or semirigid insulation. The edges should vent to the exterior of the building to allow the panel to serve as a rain screen. The panels are normally installed in a subframing system.

4. **Industrial metal panels** have an exterior facing of standard ribbed, corrugated V-beam materials and an interior facing of proprietary metal pans or standard corrugated or ribbed sheeting. Insulation varies from semirigid to rigid, depending on the design of the inner surfacing materials. It provides good thermal and moisture control when installed with tight inner surface construction.

All curtain wall panels with insulation in the cavity, or as a core, should be sufficiently tight at their edges to prevent the entrance of free water or moisture. However, because some moisture may enter the wall from the inside or outside, the wall should be capable of drying out. Panel edges should not be hermetically sealed. For cold climates, the subframing members or wall mullions should be of noncontinuous construction. The exterior to interior path should have a thermal break or insulated mullion cover on the interior or exterior to reduce the hazard of condensation.

### MASONRY AND CONCRETE CONSTRUCTION

Because concrete masonry unit walls and masonry cavity walls have hollow vertical cavities, insulating materials can be placed within the wall itself. Loose-fill insulation, such as water-repellent perlite and vermiculite, as well as foam inserts and foamed-in-place insulations, are used. This insulation method is more effective with low-density masonry units. Rigid insulation can be placed between the wythes in a cavity wall or veneered construction, and furring on the inside of the wall is still used in many areas.

The thickness and density of concrete masonry wall construction coupled with its interior air cavities moderate the heat transmission. The thermal mass or inertia of such heavy construction causes a time lag in heat migration, which may lower the peak gains or losses. Insulation placed on the outside of a concrete masonry wall enhances this time lag effect and helps protect the structure from expansion and contraction caused by temperature extremes.

Precast or poured-in-place solid concrete walls are insulated similarly to solid masonry construction. The design and method of fabricating the panels dictates the type of insulation selected.

Insulating concrete forms are manufactured from foam plastic. Generally they are made in units that resemble concrete masonry units, although they are typically somewhat larger. The individual units, which have interlocking edges, are stacked to the desired height to create a form for the concrete for a wall. Where openings for doors and windows are desired, units are omitted. The top, bottom, and sides of the opening are formed and braced with framing lumber to retain the concrete in the same way that an opening would be formed in a conventionally formed concrete wall.

Steel reinforcing and anchor bolts, if required, are placed, the forms are plumbed and braced, and concrete is placed in the form. To this point, construction of the concrete wall proceeds in much the same way as it would for a conventionally formed concrete wall. However, the foam plastic forming material is left in place to serve as building insulation and to reduce sound transmission through the wall after the concrete has hardened.

Although the concrete contributes to the R-value of the wall, the primary insulation value is obtained from the foam plastic forms. The R-value for the walls depends on the thickness and type of foam plastic, but the typical R-value for an approximately 200 mm thick wall ranges from 3.5 to 5.3 m<sup>2</sup>·K/W. The method used to tie the foam plastic panels together to create the form also affects the R-value. Ties to connect the outside panels are usually made of plastic or metal, but some manufactured forms use continuous foam plastic across the width of the wall.

## FOUNDATION AND FLOOR SYSTEMS

**Perimeter foundation** insulation may be applied on the outside or inside of foundation walls. Rigid mineral fiber or cellular plastic insulation is commonly used as perimeter exterior insulation. Exterior insulation may be applied below grade vertically or may extend as skirting down and outward from the building. These two profiles have comparable heat loss. Insulation applied on the exterior, especially skirting, should resist compressive forces from the soil and from the backfilling process. The thermal performance of vertically applied insulation may be degraded if it remains wet, so drainage at the base of the foundation may be required by manufacturers of some perimeter insulations. Some insulation products are designed to facilitate vertical drainage.

Perimeter insulation usually needs protection from physical damage and ultraviolet radiation if it extends above grade level. The exposed section of a foundation that extends from grade up to the top of the foundation can be a source of considerable heat loss. However, in buildings subject to termite infestation, the exposed foundation at grade should remain uncovered to facilitate inspection.

Exterior insulation that extends as skirting from a **shallow foundation** can prevent frost heave of the slab without a perimeter footing down to frost depth. The insulation thickness is selected so that even during the coldest weather, the soil beneath the insulation remains above freezing.

A **slab foundation** may be insulated by vertical and horizontal insulation, usually of rigid foam. Insulation at the perimeter of the building provides more resistance to heat loss than beneath the slab inside the building. Perimeter insulation usually includes vertical (installed either inside or outside the stem wall) and horizontal panels. The horizontal panels may extend from the foundation wall inward for a distance of 600 mm or more, or outward as skirting.

In **crawl space construction**, insulation may be applied either to the perimeter walls or to the floor framing. Rigid foam panels are often installed at the inside of the crawl space walls. The cavities at the band joist may be insulated with batts or custom fitted panels of rigid insulation. In vented crawl space construction, the floor framing may be insulated—commonly with batt or blanket insulation. The facing is stapled to the underside of the floor framing and the exposed batt faces down. Unless additional measures are taken to keep the insulation in place, such as wire strapping, rigid insulation panels, or a reinforced plastic membrane (like the “belly paper” used in manufactured housing), it may fall down.

Another floor insulation method uses double-sided, perforated aluminum foil draped and stapled over floor joists (BRANZ 1983). For a sag depth of about 100 mm, laboratory R-values had a mean of  $1.2 \text{ m}^2 \cdot \text{K}/\text{W}$  and ranged from  $1.0$  to  $2.5 \text{ m}^2 \cdot \text{K}/\text{W}$ , depending on the humidity above the floor space. Field measurements have shown R-values up to  $2.5 \text{ m}^2 \cdot \text{K}/\text{W}$  for carpeted floors over good installations with a sag of 100 mm.

**Basement** insulation may be applied at the interior as well as the exterior. Insulation should not be placed on the interior of a basement unless extra measures have been taken to ensure proper drainage. Insulating concrete forms (see above) are often used for basement wall construction. Control of pests around below-grade insulation, especially termites and insects, is a continuing concern.

Details on foundation insulation may be found in the *Building Foundation Design Handbook* (Labs et al. 1988).

## LOW-SLOPE ROOF DECK CONSTRUCTION

Almost all low-slope structural roof deck construction requires thermal insulation to economically maintain the design indoor environment. For low-slope roofs, insulation should be placed on top of the deck, on the outside of the structure. This location moderates the deck temperature, which reduces thermal movement of the deck and the potential for underdeck condensation. Traditionally, the insulation is placed under the roof membrane so that it functions as a base

for the built-up roof (BUR) or single-ply membrane. For a stable base, a good bond must be established between the insulation and the roof deck, and between the insulation and the BUR. Ineffective bonds that allow the BUR to move in reaction to stresses from temperature changes often cause the roof to fail. Single-ply membrane roofs are frequently installed with ballasted, mechanically fastened or fully adhered systems.

Insulation can also be placed above the membrane in a protected or inverted roof system. With this approach, the roof membrane is installed on the deck, where it functions as a waterproofing membrane and vapor retarder. Insulation can be placed above and below membranes to function both as the base and protector for the membrane. Some insulation can be wetted and then successfully dried; however, while wet, it has a greatly reduced insulation value.

## INSULATION FIELD PERFORMANCE CHARACTERISTICS

Convection and air infiltration in some insulation systems may increase the heat transfer across them. Low-density loose-fill, large open-cell, and fibrous insulations, and poorly designed or installed reflective systems are most susceptible to increased heat transfer caused by natural and forced convection (air infiltration). A temperature differential across the insulation, as well as the height, thickness, or width of the insulated space, influences the amount of convection. When a membrane with low air permeance is applied to one surface or when the cavity is filled with insulation, natural convection is reduced significantly and apparent thermal conductivities measured by standard test methods apply. The heat loss due to air convection may not be significant for many types of insulation products, such as batts and higher density loose-fill insulations. Convective heat loss potentials should be obtained from insulation manufacturers.

The effectiveness of thermal insulation is seriously impaired when it is installed incorrectly. For example, a 4% void area in wall insulation with an R-value of  $1.9 \text{ m}^2 \cdot \text{K}/\text{W}$  increases heat loss by 15%. A 4% void area in ceiling insulation with an R-value of  $3.3 \text{ m}^2 \cdot \text{K}/\text{W}$  causes a 50% increase in heat loss. Verschoor (1977) found that air interchange around thin wall insulation installed vertically with air spaces on both sides increases heat loss by 60%. Lecompte (1990) found significant losses (up to 300%) as a function of the size and distribution of openings around insulation materials. Other factors, including vibration, temperature cycling, and other mechanical forces, can affect thermal performance by causing settling or other dimensional changes. Chapter 23 gives more information on the effect of moisture on thermal properties of building structures.

## MOISTURE CONTROL IN BUILDINGS

Not all moisture problems can be avoided at all times. Proper design can help reduce the risk and make a building more tolerant to moisture. The recommendations in this chapter are intended to provide guidance.

Strategies to control moisture accumulation fall into two general categories: (1) minimizing moisture entry into the building envelope and (2) removing moisture from the building envelope. Once basic moisture transport mechanisms and specific moisture control practices are understood, roof, wall, and foundation constructions for various climates can be reviewed to determine whether each significant moisture transport mechanism is controlled. Because it is not possible to prevent moisture migration completely, construction should include drainage, ventilation, removal by capillary suction, or other provisions to carry away unwanted water.

## CONTROL OF LIQUID WATER ENTRY

Moisture problems in buildings are frequently caused by liquid water entering through leaking roofs or the foundation, or through

the walls due to wind-driven rain or rain splashing. Poor flashing details are often a major cause of water entry into walls and roofs. Rainwater should be carried away from the foundation through gutters, downspouts, and positive grading. A rain screen can minimize penetration of walls due to raindrop momentum, capillarity, gravity, and air pressure difference. The rain screen wall is designed so that the air pressure difference across the exterior rain screen is nearly zero at all times. A rain screen wall contains three components: an airflow retarder system, a pressure-equalization chamber, and a rain screen. The airflow retarder must be able to resist pressures from wind, the stack effect, and mechanical ventilation. The pressure-equalization chamber separates the rain screen and the air flow retarder system. It may be an air cavity or may be filled with a self-draining material to prevent water that penetrates the rain screen from reaching the airflow retarder system. The chamber should consist of separate compartments to avoid lateral airflow, especially around corners of the building. Each chamber compartment is vented to the outside through the rain screen to provide pressure equalization and must be flashed to the outside to drain water that has penetrated the rain screen. The rain screen must contain sufficient vents to provide pressure equalization; that is, the airflow resistance of the rain screen must be much lower than that of the airflow retarder.

### CONTROL OF WATER VAPOR MIGRATION

Water vapor entry into the building envelope can be limited by airflow retarders and water vapor retarders. As described in Chapter 23, airflow retarders are intended to restrict airflow, and thereby water vapor flow, whereas water vapor retarders are designed to restrict vapor flow by diffusion.

#### Air Leakage Control

Past research demonstrated that air movement is more effective than water vapor diffusion for transporting water vapor within the building envelope. In order to minimize moisture penetration by air leakage, the building envelope should be as airtight as possible. The airflow retarder must also be sufficiently strong and well supported to resist wind loads.

In the past, air leakage in residential buildings provided sufficient ventilation, and the air leakage paths rarely led to interstitial condensation. However, in airtight buildings mechanical ventilation must be provided to ensure acceptable air quality and prevent moisture and health problems caused by excessive indoor humidity. Ventilation or drainage must go to the outside of the airtight layer of construction or it will increase air leakage of the building. To avoid condensation on the airtight layer, either the temperature of the layer must be kept above the dew point by locating it on the warm side of the insulation, or the permeance of the layer must be adequate to permit vapor transmission.

As described in the section on Leakage Distribution in Residential Buildings in Chapter 26, air leakage through the building envelope is not confined to doors and windows. Although 6 to 22% of the air leakage occurs at windows and doors, 18 to 50% typically takes place through walls, and 3 to 30% through the ceiling. Leakage often occurs between the sill plate and the foundation, through interior walls, electrical outlets, plumbing penetrations, and cracks at the top and bottom of the exterior walls. More detailed information can be found in Chapter 26.

Not all cracks and openings can be sealed in existing buildings, nor can absolutely tight construction be achieved in new buildings. However, an effort should be made to provide as tight an enclosure as possible to reduce leakage and minimize potential condensation within the envelope. Such measures also reduce energy loss.

Moisture accumulation in the building envelope can also be minimized by controlling the dominant direction of airflow. This can be accomplished by operating the building at a small negative or

positive air pressure, depending on climate. In cooling climates, the pressure should be positive to prevent the entry of humid outside air into the envelope. In heating climates, the building pressure should be neither strongly negative, which could risk drawing soil gas or combustion products to the indoors, nor strongly positive, which could risk driving moisture into building envelope cavities.

### MOISTURE CONTROL OPTIONS

Options for moisture control under heating conditions often differ from those under cooling conditions, even though the physical principles of moisture movement are the same. Therefore, the selection of moisture control options depends on whether the local climate is predominantly a heating or cooling climate. The *Moisture Control Handbook* (Lstiburek and Carmody 1991) recommends a three-step procedure for designing energy-efficient roofs, walls, and foundations with inherent moisture control capabilities:

1. Identify the climate: heating, cooling, or mixed
2. Determine the potential moisture transport mechanisms in each part of the exterior envelope: liquid flow, capillary suction, air movement, and vapor diffusion
3. Select the moisture control strategies: control moisture entry, control liquid moisture accumulation (condensation), or remove moisture by draining, venting, or diffusion

The definitions of climate zones are somewhat arbitrary. Lstiburek and Carmody (1991) recommend that heating climates be defined as climates with 2200 heating kelvin-days (base 18.3°C) or more. Cooling climates are defined as warm, humid climates where one or both of the following conditions occur: (1) a 19.5°C or higher wet-bulb temperature for 3000 or more hours during the warmest six consecutive months of the year; (2) a 23°C or higher wet-bulb temperature for 1750 or more hours during the warmest six consecutive months of the year.

Mixed climates are all climates that do not fall under the definitions of heating or cooling. Regions with heating climates in North America generally include the northern half of the United States, Alaska, and all of Canada. The climate in southeastern coastal regions of the United States generally can be characterized as cooling. However, the local climate should be evaluated to determine whether to design for heating, cooling, or mixed-climate conditions.

### MOISTURE CONTROL OPTIONS FOR HEATING CLIMATES

#### Surface Condensation

Heating climates are defined as climates with 2200 heating kelvin-days (base 18.3°C) or more. In such climates, occasional window condensation is common in buildings during winter and fall.

Lowering indoor humidity to minimize surface condensation on windows is one approach, but increasing the interior surface temperature of the window using multiple glazing, low-emittance glazing, low-conductivity spacers, appropriate selection of window frame, or gas-filled glazing may be more effective. Higher thermal resistance in windows has the added advantages of saving energy, improving occupant comfort, and reducing the possibility of condensate damage to the interior adjacent to the window (e.g., staining of the wall, rotting of the window sill, and mold growth).

Windows should remain clear most of the time. Some condensation may appear around the window perimeter, but should disappear with a warming trend. This criterion should be used to decide which glazing should be installed to maintain the desired humidity, or whether to reduce the humidity to avoid condensation during the coldest periods.

Local condensation and mildew growth on walls and ceilings is often the result of low inside surface temperatures due to insufficient or faulty insulation. Increasing the thermal insulation or eliminating

the voids in the insulation is the obvious remedy. If the problem is due to infiltration of cold air, an attempt should be made to eliminate the air leakage. However, in existing buildings these measures are often difficult or too expensive. In these cases, the only alternatives are lowering the indoor humidity, raising the indoor temperature, or increasing the air circulation near the surface.

### Indoor Humidity Control

A common cause of moisture problems during the heating season is excessive indoor humidity. This is caused by an improper balance between moisture generation and moisture removal. This balance can be changed by reducing the sources of moisture or by increasing the removal rate, usually by ventilation or dehumidification. However, it is important to avoid lowering the relative humidity too far below the lower comfort limit, which is generally about 25 to 30% rh.

Because water vapor is introduced into the building from various sources, the moisture content of the air in an occupied building without dehumidification is always higher than that of the outdoor air. Christian (1994) provides a detailed discussion of various individual moisture sources, primarily in residences. The section on Internal Moisture Gains in Chapter 20 of the 2000 *ASHRAE Handbook—Systems and Equipment* states that a family of four produces an average of 320 g/h of moisture. TenWolde (1988, 1994) reports production rates between 135 and 330 g/h for one to two adults, with an average of 230 g/h. European sources report rates between 270 and 540 g/h for families without children, and rates between 210 and 950 g/h for families with one to three children (Christian 1994). These numbers demonstrate that moisture production rates in residences can vary widely. Moisture production rates for various kinds of livestock and plants can be found in Chapter 10.

A residential crawl space or basement can contribute significant amounts of additional water vapor. Trethowen (1994) reported an average moisture release of 0.40 kg/m<sup>2</sup>-day from moist or wet crawl spaces. Moisture released from building materials that are drying (construction moisture) in a new building can add large amounts of water vapor. Exposed soil surfaces in crawl spaces or cellars should be covered with vapor retarder membranes (see the section on Crawl Spaces).

If indoor humidity is excessive, and source reduction is impossible, increasing the ventilation rate should be considered. Ventilation may be natural or mechanical, and mechanical ventilation may be exhaust, inlet, or balanced. An air-to-air heat recovery device can be included to reduce the heating energy penalty from an exhaust fan. Other approaches include the use of mechanical dehumidifiers and insulated vent stacks that extend from the living space through the roof.

Short-term ventilation procedures such as occasionally opening a window or door may lower humidity momentarily, but it will rise to its original level soon after the window or door has been closed. This is due to the evaporation of stored moisture into the indoor air. When water vapor is released from showers or cooking, much of it is adsorbed by hygroscopic materials (paper, wood, fabrics, etc.) in the building. Some temporary storage in the form of surface condensation may also occur. This moisture is released more slowly at a later time. Moisture storage effectively dampens the effect of short-term (hourly or daily) changes in moisture release or weather conditions on indoor humidity. Stored moisture also slows the effect of ventilation and dehumidification because this moisture needs to be released and removed before the indoor humidity can be lowered permanently. The evaporation of moisture stored during the summer's periods of high relative humidities is the cause of high relative humidity and window condensation in early fall.

In cold or cool winter climates, house ventilation can be an effective method for moisture removal. In these climates, a ventilation level of 0.35 air changes per hour (ACH) (as recommended in *ASHRAE Standard 62*) is generally sufficient to prevent excessive

indoor humidity and most window condensation (TenWolde 1994). Ventilation is primarily required to ensure acceptable indoor air quality. If the recommended minimum ventilation levels are achieved, additional ventilation is probably unnecessary and ineffective for humidity control. In mild, humid climates, ventilation rates greater than 0.35 ACH may be needed for humidity control, but in such climates other means of moisture removal, such as dehumidifiers, should be considered.

Some suggest that high indoor humidity is caused by vapor retarders that lock in moisture. However, only a small fraction of the total moisture generated can be removed by vapor diffusion through the building envelope. Most high indoor humidity is due to inadequate ventilation, inadequate dehumidification and air conditioning, or an unusually large moisture source in the building.

### Vapor Retarders and Airflow Retarders

Vapor retarders are recommended and often mandated in heating climates, and should be placed on the interior (warm) side of the insulation. Airflow retarders are also necessary, but their placement in the wall or ceiling assembly is probably less critical and still subject to debate. Vapor retarder and airflow retarder functions may be combined in one material. Airflow retarder placement on the exterior prevents cold air from penetrating the insulation (wind washing) and therefore improves thermal performance of the building envelope. However, in heating climates, airflow retarders on the exterior should have a high water vapor permeance. Special airflow retarder materials for exterior use with sufficiently high water vapor permeance are commonly available. Exterior airflow retarders do not prevent penetration and circulation of warm indoor air inside the wall or ceiling/roof cavity. Conversely, interior airflow retarders do not prevent wind washing. Interior airflow retarders do not need to have a high water vapor permeance. For additional general guidance on the placement and properties of airflow retarders, see Chapter 23.

The use of vapor retarders in compact low-slope roofing systems has been a long-standing issue for the roofing industry. Unlike other portions of the building envelope, water intrusion into a low-slope roof due to membrane failure is inevitable. Wet insulation performs below thermal performance levels specified during design. A survey by Kyle and Desjarlais (1994) has indicated that the average energy efficiency of the entire roofing inventory in the United States is reduced by approximately 40% due to moisture contamination.

Powell and Robinson (1971) studied these problems and stated that the "most practical and economical solution to the problem of moisture in insulated flat-roof constructions (is) to provide a design that would have in-service self-drying characteristics." A self-drying roof uses the local meteorological conditions to create a vapor drive into the building interior. Desjarlais (1995) demonstrated that climates with up to 5000 heating kelvin-days create annually averaged downward vapor drives. In a self-drying roof, any leakage into the roofing system is passively driven into the building interior; if the leak is repaired, the roof system will dry.

A vapor retarder prevents including the self-drying characteristics in the roofing design by placing an impermeable layer between the roof insulation and the building interior. A vapor retarder should only be placed in a roofing system when the amount of wintertime water uptake that the roofing system experiences exceeds the moisture limit of the insulation material in the roof. Desjarlais (1995) offers guidelines on how to determine these limits.

Penetrations through the airflow retarder (such as electrical outlets, light fixtures, or plumbing stacks) should be minimized. Any penetration should be sealed carefully. Special airtight electrical boxes are available. Limited or minor penetrations of the vapor retarder are not of great concern, if an effective airflow retarder is placed elsewhere in the wall or ceiling.

## Attics and Cathedral Ceilings

Attics and cathedral ceilings are protected from interior moisture in heating climates first by limiting the entry of moisture into roof cavities, and second by ventilating the cavities to minimize accumulation of moisture. Entry of interior moisture is limited by designing and constructing effective airflow and vapor retarders between the interior space and roof cavities.

**Attics.** Ventilation is required in all United States and Canadian Model Building Codes. Studies on roof cavity and attic ventilation aimed at reducing paint peeling were conducted by Rowley et al. (1939), Britton (1948), and Jordan et al. (1948). These studies concluded with recommendations for venting of attics. Britton found that air movement from a wet foundation through chases and wall space could reach the attic and cause moisture damage to roof sheathing. Jordan et al. and later reports demonstrated the use of air barriers as the primary requirement for keeping moisture out of attics. Colder attics were found to require more ventilation to prevent frost. A review of the studies (Rose 1992) concluded that support for attic ventilation was at times contradictory and the specific requirement for 1 m<sup>2</sup> of vent area for 300 m<sup>2</sup> of floor space not resolved by the findings.

The four commonly cited reasons for attic ventilation are (1) preventing moisture damage, (2) enhancing the service life of temperature-sensitive roofing materials, (3) preventing ice dams, and (4) reducing the cooling load (TenWolde and Rose 1999). In some cases, venting may be inconsistent with the moisture control design approach. If the attic is vented, care should be taken to prevent entry of snow and to prevent airflow that might degrade the thermal performance of insulating materials (Hens and Janssens 1999).

**Moisture.** Vents have been shown to provide effective lowering of moisture levels in roof sheathing for attics constructed with a single unconditioned space, sloped roof, and a tight ceiling plane (Jordan 1948). It is relatively easy and inexpensive to install vents in such an attic without compromising the effectiveness of the ceiling insulation. In heating climates, attic ventilation usually provides a measure of protection from excessive moisture accumulation in the roof sheathing. If indoor humidity is high and humid indoor air leaks into the attic, attic vents by themselves may not prevent moisture accumulation.

Moisture control in attics in heating climates depends primarily on (1) maintaining lower indoor humidity levels during cold weather, (2) assuring maintainable airtightness and vapor resistance in the ceiling, and (3) attic ventilation (NRC 1963).

**Temperature.** A ventilated attic is cooler in the summer than an unventilated attic, and ventilation can reduce the temperature of shingles during daylight hours. Asphalt shingle manufacturers encourage ventilation as a prescriptive practice (ARMA 1997). In one study, the temperature difference due to power or turbine ventilation over soffit ventilation led to significant differences in maximum attic air temperatures, but was not shown to be an effective energy conservation method in moderately or heavily insulated ceilings (Burch and Treado 1978). It is not clear that attic air temperature reduction is a significant factor in extending the service life of shingles (TenWolde and Rose 1999), since the long term studies on the temperature effects on shingle service life are incomplete.

**Ice Dams.** Ventilation of roofs, coupled with additional insulation and reductions in air exfiltration, reduces ice dam damage during winter in cold regions (Buska et al 1998). Where heat sources are located in the unconditioned attic space, large amounts of ventilation may be needed to prevent ice dams, necessitating mechanical attic ventilation (Tobiasson et al. 1994). Such heat sources may include furnaces, air handlers, or ductwork with conductive or convective heat losses.

Reducing heat loss into the attic by effective insulation, air leakage control, and avoidance of heat sources such as uninsulated or leaky heating ducts in the attic, possibly coupled with ventilation, is

a positive way of reducing ice dams and moisture damage (Fugler 1999). Damage due to ice damming in roof valleys and eaves can also be prevented by installing a waterproof underlayment of sufficient width beneath the shingles.

**Other Considerations.** Roofs with absorbent claddings, such as wood shingles or cement or clay tiles are subject to solar-driven moisture penetration (Cunningham et al. 1990). Moisture is driven into the roof when it is wetted by rain or dew and subsequently exposed to sunshine. When the moisture source is from the exterior, an impermeable membrane under the shingles or tiles can greatly reduce moisture transfer into the roof; but measures should be taken to prevent water accumulation on the underside of this membrane.

Leaks cause another moisture load on roofs. Roof leaks are properly addressed by repair rather than by ventilation.

**Cathedral Ceilings.** Cathedral ceiling construction is inherently prone to a wider range of conditions than attic construction because this type of construction has isolated air cavities in each rafter bay. Vented attics perform better than vented cathedral ceilings for the same framing type (Goldberg 1999). Although providing effective ventilation to attics with simple geometries is relatively easy and inexpensive, providing soffit and ridge ventilation to each individual cavity in a cathedral ceiling may be difficult or impractical. Improperly installed insulation can obstruct the area designed or intended to provide ventilation. (Tobiasson 1994). An airtight ceiling plane, a vapor retarder, and foam air chutes between the sheathing and the top of the insulation effectively control moisture in cathedral ceilings with fiberglass insulation (Rose 1995). Hens and Janssens (1999) pointed out that moisture control is assured only if airtightness is effective and can be maintained. They showed that the consequences of air entry and wind washing in insulated cathedral ceilings are detrimental, leading to degraded thermal performance, moisture response and overall durability. TenWolde and Carll (1992) showed that ventilation of roof cavities may cause increased air leakage, and that the net moisture effect depends on whether the principal source of makeup air is from indoors or outdoors.

Goldberg et al. (1999) noted that unvented attics and cathedral ceilings show a better retention of thermal resistance of the fibrous insulation than similar vented assemblies, though this benefit is smaller for attics than for cathedral ceilings. With careful attention to design for air- and vapor-tightness, unvented cathedral ceilings can be expected to perform satisfactorily in cold heating climates.

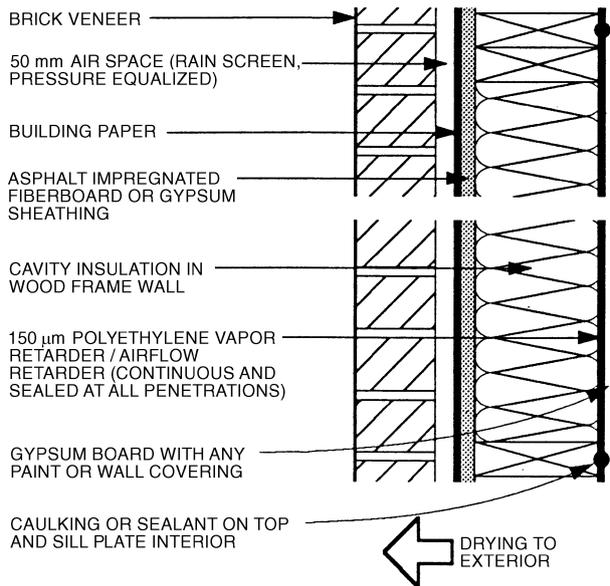

## Operating Practices

Details of indoor humidity control are discussed in the section on Indoor Humidity Control. Buildings in heating climates should not be operated at substantial positive indoor air pressures, which drive moist air into the building envelope and increase the potential for moisture accumulation. Large negative pressures should also be avoided if any unsealed combustion equipment is operated in the building. Negative pressure in the basement or in slab-on-grade buildings should also be avoided when there is potential radon leakage from the soil into the building, unless a subslab depressurization system has been installed.

## Other Considerations

In heating climates, it is important to design for excessive indoor humidity. If the anticipated indoor humidity will be high, then extra care must be taken in design and construction by using air barriers in conjunction with building pressure regulation.

In general, mechanical equipment should be kept within the conditioned space of the building. This approach reduces the number of openings through the building envelope and reduces the energy losses associated with exterior equipment and ductwork. Several design options permit installation of insulation below the roof plane, as in cathedralized construction (Rose 1995).

### Example of Residential Wall Construction for Heating Climates

Figure 1 shows the cross section of a residential wall for heating climates. Moisture control is handled in the following ways:

- **Rain.** The brick veneer, an air space, and the building paper form an effective rain screen. The air space behind the brick veneer provides a capillary break for any rainwater absorbed by the brick and mortar. Mortar should not breach the air space and touch the building paper, as this would allow rainwater to bypass the capillary break. The building paper protects the fiberboard or gypsum from any water penetrating the rain screen.
- **Air movement.** The sheathing and building paper serve as an airflow retarder. Sufficient airtightness can be obtained by airtight installation of the sheathing (i.e., installed vertically with joints over the studs, with sealant or caulk used at the joints).
- **Vapor diffusion.** Vapor diffusion from the inside is inhibited by the polyethylene vapor retarder.

### MOISTURE CONTROL OPTIONS FOR MIXED CLIMATES

Mixed or temperate climates fall neither under the definition of a heating climate, nor under the definition of a hot, humid climate. Mixed climates may be heating- or cooling-dominated. This zone includes areas with hot and dry climates (e.g., Arizona). Buildings in mixed climates may encounter high interior levels of humidity during winter and high exterior levels of humidity during summer.

Summer cooling or winter heating for comfort in mixed climates does not usually create serious vapor problems in exterior walls and ceilings. The summer outdoor dew point, especially during peak values, may exceed the design dew-point temperature in common use, but it seldom exceeds 24°C for a prolonged period. Condensation within exterior walls exposed to an indoor temperature of 24°C is seldom as serious as winter condensation.

In a study of a wood-sided house in Athens, Georgia, Duff (1956) showed that under summer cooling conditions, temperatures were lower outside than inside long enough to prevent moisture buildup from damaging the structure. This was true regardless of whether or

not a low-permeance material was placed near the inner surface. However, masonry or brick-veneered structures with a low-permeance vapor retarder (e.g., vinyl wallpaper or polyethylene) near inner surfaces do have a moisture buildup under summer cooling conditions.

### Vapor Retarders and Airflow Retarders

Airtight construction is recommended in all climates. Airflow retarders provide protection from excessive moisture accumulation in the building envelope during cooling and heating, and may reduce energy consumption. In mixed climates, the need for low-permeance vapor retarders in most types of buildings is less pronounced than in heating climates or in warm, humid climates.

However, if a vapor retarder is deemed necessary in a mixed climate zone, its placement presents somewhat of a dilemma. Under cooling conditions, a vapor retarder would normally be located on the outside of the insulation. But under winter conditions, it would be located on the inner side. Use of vapor retarders at both locations is undesirable because it restricts moisture movement into the insulation as well as the escape of any moisture. In dwelling construction, the vapor retarder should be placed to protect against the more serious condensation (winter or summer). However, if indoor humidity is kept below 35% (at 21°C) during winter, a vapor retarder on the inside of the insulation is probably not necessary in mixed climates.

The choice and placement of a vapor retarder, airflow retarder, and other materials minimize the potential for condensation while allowing for some drying. For example, if a vapor retarder is installed on the interior, an exterior airflow retarder and/or sheathing should have sufficient permeance to allow drying. The corresponding situation in cold storage buildings, in which a more serious reversal of vapor flow conditions from winter to summer may occur, requires individual analysis.

### Attics and Cathedral Ceilings

Venting of attics and cathedral ceilings during winter in a mixed climate has similar benefits and drawbacks as in a heating climate. Venting may provide benefits for moisture control in attics where effective vents can be installed relatively easily and cheaply, and where the ceiling is tightened against air leakage. Unvented cathedral ceilings can provide satisfactory moisture performance in mixed climates when the system (1) is designed to control moisture migration, and (2) contains an airflow retarder that is maintained. More detailed discussion of ventilation of attics and cathedral ceilings can be found in the sections on Attics and Cathedral Ceilings under Moisture Control Options for Heating Climates.

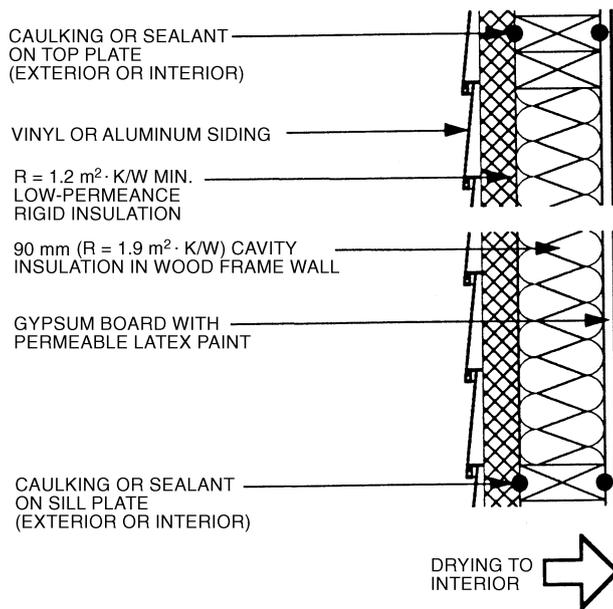

Both vented and unvented construction should be designed and constructed to exclude interior moisture from cathedral ceiling cavities. As in heating climates, vents in cathedral ceilings may be less effective and beneficial than vents in attics; therefore, vents should be considered a design option.

Ductwork should be kept in the conditioned space of the building in order to improve energy efficiency. In hot, dry climates, energy losses through ductwork located in unconditioned attics is greater than energy losses in attics using cathedral construction, in which the insulated envelope is located at the roof (Rudd 1998).

### Example of Residential Wall Construction for Mixed Climates

Figure 2 shows an example of a residential wall detail for mixed climates, with rigid insulating sheathing serving as a vapor retarder and air retarder. Moisture control is handled in the following ways:

- **Rain.** The combination of siding and airtight foam sheathing serves as a screen system and controls rain penetration. The air cavities behind the siding should be sufficient to act as a capillary break. If the air space is insufficient, the siding may be installed

**Fig. 2 Example of Residential Wall Construction for Mixed Climates**

Source: Lstiburek and Carmody (1991). Reprinted with permission.

on furring strips to provide the air space. With vinyl or aluminum siding, liquid absorption and capillary moisture transfer are not a concern.

- **Air movement.** The rigid insulating sheathing can be caulked at the top and bottom plates and at the joints to provide an exterior air flow retarder. Alternatively, caulking of the gypsum board can provide an interior airflow retarder.
- **Vapor diffusion.** The impermeable rigid insulation acts as a vapor retarder. During cooling periods, vapor diffusion from the outside is impeded at the exterior sheathing surface. During heating periods, vapor diffusion from the inside is inhibited at the interior surface of the foam sheathing. To keep moisture condensation to a minimum, this first condensing surface temperature should be elevated through the use of foam sheathing with a high R-value. For mixed climates, the thermal resistance of the insulating sheathing in this example should be  $1.2 \text{ m}^2 \cdot \text{K/W}$  or greater, with  $R = 2 \text{ m}^2 \cdot \text{K/W}$  in the cavity.

### MOISTURE CONTROL OPTIONS FOR WARM, HUMID CLIMATES

Warm, humid cooling climates are defined as climates where one or both of the following conditions occur: (1) a  $19.5^\circ\text{C}$  or higher wet-bulb temperature for 3000 or more hours during the warmest six consecutive months of the year; (2) a  $23^\circ\text{C}$  or higher wet-bulb temperature for 1500 or more hours during the warmest six consecutive months of the year. Depending on local experience with moisture problems, humid climate design criteria may also be desirable in locations that do not quite meet the foregoing conditions.

In warm, humid climates dehumidification by air conditioning or other means is the most practical approach to moisture removal from the conditioned space. The overall latent-cooling load is composed of diffusion, ventilation, infiltration, and internally generated latent cooling loads. Because the latent-cooling load on an air conditioner in high-humidity climates frequently exceeds the sensible load, a system should be capable of handling the latent load without overcooling. In residential buildings, oversized air conditioners may not alleviate the problem of high humidity due to short cycling.

Approaches to solving this problem include proper sizing of the system, the use of reheat, or design for variable flow rates.

### Airflow Retarders and Water Vapor Retarders

Construction should be airtight, as in all other climates. Many moisture and condensation problems in cooling climates have been found to be caused by excessive leakage of outside air into the building envelope. Airflow retarders in cooling climates are best placed on the exterior. Negative pressures of the indoor space should be avoided. Under high-humidity conditions, ambient water vapor diffuses through building materials from the outside into air-conditioned spaces. Exterior surfaces should have lower permeance than interior surfaces in high-humidity climates. Paints and finishes can provide the necessary permeance, with lower permeance at the outside surface and higher permeance toward the inside.

Low-permeance paints, vinyl wall paper, or any other similar low-permeance material should not be used on the inside of walls and ceilings in warm, humid cooling climates.

Vapor retarders, if used, should be on the outside of the insulation. Then, any water vapor that enters the construction can flow to the inside of the building, where it can be removed by the air conditioner instead of accumulating in the wall or roof. Note that this recommendation is the reverse of the recommended practice for cold climates.

### Attics and Cathedral Ceilings

The commonly stated rules for attic and cathedral ceiling construction—ventilation and vapor retarder toward the inside—pertain to cold climates and not to warm, humid climates with indoor air conditioning. Common sense suggests that venting with relatively humid outdoor air means higher levels of moisture in the attic or cathedral ceiling. Higher moisture levels in vented attics in hot, humid climates do not lead to moisture damage in sheathing or framing. However, higher moisture levels in attic cavities may affect chilled surfaces of the ceiling and cold surfaces of mechanical equipment. When cooling ducts are located in the attic space, attic ventilation with humid outdoor air may increase the chance of condensation on the ducts.

As in all climates, airtight construction is desirable. In warm, humid climates, airtight construction usually reduces the latent load. Insulation and interior finishes should be selected and installed with an understanding that vapor diffusion is primarily inward.

As with other climates, a ventilated attic in a warm, humid climate is noticeably cooler in the summer than an unventilated attic. Beal and Chandra (1995) found that venting can greatly affect the temperature difference across the ceiling.

### Other Considerations

To encourage drying, shaded exterior surfaces that do not benefit from the evaporative effects of sun and wind (such as inside corners) should be avoided or minimized. Building components that are prone to thermal bridging (such as exterior cantilevers, columns, foundations, or window and door frames) are of special concern. Although these solutions may not totally eliminate mold and mildew growth, they substantially reduce the potential.

Serious wetting within walls can occur in summer under certain conditions. The National Research Council of Canada tested the walls of huts of brick masonry finished inside with furring, insulation, a vapor retarder, and plasterboard. The walls were opened during a sunny period following rain. Extensive wetting was observed in the insulation, particularly on the back of the vapor retarder. The absorptive brick wall had accumulated substantial quantities of water during the rainfall. Subsequent heating by the sun had driven the moisture as vapor into the wall, where it condensed and caused

serious wetting. The construction had no protection in the form of parging or paper on the inside of the brick.

The study showed that walls with exterior coverings capable of absorbing and storing considerable quantities of water during a rain, and providing little resistance to vapor flow into the insulation from outdoors, may experience serious interior wetting by condensation. No wetting occurred in a similar construction when a saturated sheathing paper was placed between the insulation and the brick. Thus, a moderate vapor flow resistance, such as that provided by parging or a good sheathing paper on the outside of the insulation, can effectively stop vapor flow in such cases.

**Operation and Maintenance**

Because the potential for damage to a building and its contents is substantial in an air-conditioned building in humid climates, it is more important to properly operate and maintain the building and its air conditioning system in humid climates than it is in others. The chilled water supply temperature and flow should be reliable, and multiple chillers and pumps should be considered to ensure continuous uninterrupted dehumidification.

Raising the chilled water supply temperature to conserve energy should not be attempted under these conditions, as this would impair the dehumidification capacity of the air-conditioning system.

Lowering the cooling thermostat setting generally increases the chance for mold and condensation in exterior walls, especially in locations where the cooled air is blown directly towards the wall.

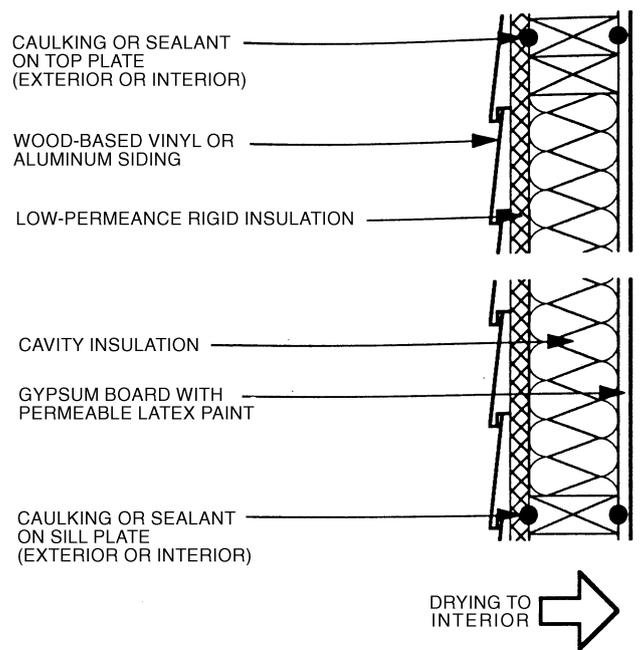

**Example of Residential Wall Construction for Warm, Humid Climates**

Figure 3 shows an example of a residential wall detail for warm, humid climates, with rigid insulation serving as a vapor retarder and airflow retarder. Moisture control is handled in the following ways:

- **Rain.** The combination of airtight foam sheathing and siding serves as a rain screen system and controls rain penetration. The air cavities behind the siding should be sufficient to act as a capillary break. If the air space is insufficient, the siding may be installed on furring strips to provide the air space. With vinyl or aluminum siding, liquid absorption and capillary moisture transfer are not a concern. Wood siding may be backprimed to prevent moisture absorption through the back, and installation of wedges and clips on wood lapped siding should be considered to minimize capillary transport between the boards.
- **Air movement.** The exterior sheathing is the best location for an air seal, using either an adhesive or caulk to fasten the sheathing to the framing members.
- **Vapor diffusion.** In warm, humid climates, the dominant source of moisture is the outside air, and moisture is typically driven toward the interior. This means that the best location for the vapor retarder is at or near the exterior wall surface. Vapor-permeable paint should be used on the interior gypsum wallboard.

**MEMBRANE ROOF SYSTEMS**

Because most membrane roof systems in commercial and institutional construction are highly resistant to vapor leakage, condensation must be prevented when insulation is placed between the heated interior and the roof membrane. Wet insulation in low-slope roof construction is difficult to dry. Drainage is likely to be so slow as to be ineffective. Ventilation to the outside is not effective for drying roof insulation, because forces acting to remove the moisture are small. The vents themselves may present a hazard to the insulation by admitting moisture and drifting snow. Also, water leaks can occur where the vents penetrate the roof unless they are properly installed. Finally, vents may allow chimney action to carry air upward through openings in the deck and ceiling. Then as air flows

**Fig. 3 Example of Residential Wall Construction for Warm, Humid Climates**

Source: Lstiburek and Carmody (1991). Reprinted with permission.

to the outside, further moisture is drawn into the roof with the replacement air and may condense.

A vapor retarder in a conventional flat roof can trap moisture in the roof cavity. The decision whether to use a vapor retarder depends on interior humidity and climate. The absence of a vapor retarder allows vapor to enter a roof during the heating season, but it also facilitates the removal of moisture in warm weather. This may not be acceptable in buildings with high indoor humidity or in extremely cold climates, when a large accumulation of frost or liquid condensation results in dripping. Where humidities are lower, or the climate less severe, the roof system may successfully store moisture through the heating season without problems (Baker 1980). The success of this strategy, however, also depends on the airtightness of the roof assembly. More information on this can be found in the section on Self-Drying, Low-Slope Roof Systems.

Regular inspection of the membrane and flashings helps prevent water leakage into the roof. Infrared scanners or capacitance meters can help detect wet insulation, which can be removed or possibly dried out.

**Inverted Roof Systems**

The top layers in protected membrane or inverted roof systems are not waterproof; therefore, insulation is exposed to rainwater. To remain effective, it must be able to resist moisture penetration. Extruded polystyrene board has been used extensively. Insulation moisture content commonly ranges up to 4 or 5% by volume.

Some insulations are damaged by freezing and thawing, which fracture cell walls and allow water into an otherwise low-permeance material. When free moisture is available, the rate of entry increases rapidly as the temperature gradient increases (Hedlin 1977). Even when insulation is immersed in ponded water, moisture absorption through the edges is less than through the upper and lower surfaces, because the temperature gradient is normal to the roof surface.

Protective measures can reduce moisture gains. Roof slope performs much the same function for protected membrane roofs as it does for conventional ones. Covering the bottom surface of the insulation with a low-permeance layer inhibits moisture entry

there. The upper surface should be open to the atmosphere so that water can evaporate freely. If it is trapped against the upper surface (e.g., by paving stones), solar heating may drive the water into the insulation.

Where a high thermal resistance is required, roofs may combine conventional and protected membrane systems when they are applied in two separate lifts. The protected membrane system may be applied to existing conventional roofs to increase the thermal resistance, if the roof structure can support the added weight. This addition keeps the roof membrane warmer, so that the chance of moisture condensation on the underside of the roof membrane is significantly reduced.

### Self-Drying, Low-Slope Roof Systems

A major cause of roof replacement is excessive accumulation of water in the roofing system. Historically, this accumulation has been minimized by delaying its ingress into the roofing system through the use of improved roofing membranes and periodic planned maintenance. Of course, most roofing systems eventually leak. Without periodic inspection, small leaks in a roofing system containing a vapor retarder or some other low-permeance layer (such as an asphalt mopping) can go undetected for long periods and lead to a major roof system failure. The self-drying roof facilitates the controlled out flow of water vapor into the building interior, preventing any long-term accumulation of water in the roof. Although they have not been optimized, the roofing industry has constructed self-drying roofs for many years. A roof installed without a vapor retarder or a low-permeance layer is effectively a self-drying roof.

A self-drying roof should be considered whenever the average yearly vapor drive is into the building interior. Tobiasson and Harrington (1985) have produced vapor drive maps for the continental United States. Desjarlais (1995) reported that this condition (vapor drive to the interior) is satisfied for climatic regions having less than 5000 heating kelvin-days (18.3°C base).

The self-drying roof system must be carefully designed and include special features. The deck system must be reasonably permeable to water vapor so that downward drying can be maximized. The water vapor permeance of the insulation materials must be selected so that the anticipated wintertime wetting is maintained at a level that the insulation materials can tolerate. Water vapor absorptive layer(s) should be included in the roof system so that a major leak into the roof can be controlled without leakage into the building interior. The self-drying roof must not contain a vapor retarder or any layers that are relatively impermeable. A suggested roof design procedure for self-drying roofs has been proposed by Kyle and Desjarlais (1994). The drying rate at the bottom depends on the airflow and the drying potential beneath the roof.

## MOISTURE CONTROL IN FOUNDATIONS

### Grading

Many of the problems related to moisture in foundations are due to the failure to discharge rainwater away from the building foundation.

Good construction practice generally requires exposed foundation between soil grade and the top of the foundation, as an inspection site for pest control. Traditionally the height of exposed foundation has been 200 mm, although recent codes have reduced this requirement to 150 mm. Because of the likelihood of heat loss through this exposed foundation, covering with an insulating material is desirable wherever pest inspections are not necessary.

The soil should slope away from the building at a 5% grade for the first 3 m around the building perimeter. That is, the fall from grade to a point 3 m away from the building should be a minimum of 150 mm. The soil should be covered with a cap of relatively impermeable soil, in order to maximize surface flow of water away

from the foundation. The soil backfill around the foundation is likely to settle in the first years after construction, requiring correction to achieve the proper grade. If the general slope of the soil on the site is toward the building, then swales or drains should be used to divert surface flow around the building.

Rainwater discharge from the downspouts should be managed to ensure that it does not contribute to saturation of any soil that is in contact with the foundation. The discharge may consist of extenders, splash blocks, or designed drainage systems to carry the roof runoff away from the building. On sloped lots, downspouts should discharge on the downhill side where possible.

Footing drains are traditionally installed to ensure against a rising water table; nevertheless, they may assist in draining water that may accumulate directly from surface rains. The footing drains should discharge water to an appropriate discharge site such as a storm sewer, a sump pump, or, if the site permits, daylight. Any footings for basements or crawl spaces, where the interior grade is below the exterior, should be provided with footing drains.

Gutters, downspouts, and below-grade drainage systems require maintenance. Below-grade drainage systems should be designed with cleanouts.

### Floor Slab

Summer surface condensation may form on concrete floors on grade, especially during the first few years after construction. Carpeting tends to lower the interior slab surface temperature, increasing the condensation potential. Dehumidification and ventilation may be sufficient to avoid odors or floor cover bonding problems caused by moisture, which are generally more objectionable than actual damage to the floor covering.

Entry of ground moisture can be further reduced by isolating the slab with the placement of a low-permeability membrane over the soil beneath the slab and by using coarse gravel to break the capillary moisture rise. Application of a membrane is difficult, however, because it can be easily damaged during construction.

Sealing of floor slabs and basements against the entry of radon should also be considered. Although soil cover sheets are commonly referred to as vapor retarders, they can also act as a waterproofing membrane when exposed to liquid water.

Control of the slab surface temperature is important in order to minimize the need for mechanical dehumidification, particularly with solar-oriented designs that emphasize the effects of thermal mass. In localities with severe summer surface condensation problems, low-density concrete should be considered for floor slabs to increase their insulating value, or insulation should be added under the slab.

### Crawl Spaces

Moisture problems generally occur when improper drainage or grading around the house leads to wet soil or even standing water in the crawl space. Evaporation of moisture then causes high humidity in the crawl space and often in the rest of the building. Sometimes the wet soil leads to high moisture content in wood framing members in the floor and in the band joist (header joist). Any source of subfloor warmth (heating ducts, furnaces) is likely to seriously increase the evaporation from wet subfloor soil (Trethowen and Middlemass 1988, Trethowen 1988). Providing proper drainage of water away from the foundation is critical for moisture control (ASHRAE 1994).

Dewatering techniques, including sump pumps, drain tiles, etc., should be used to keep the soil in the crawl space as dry as possible. Ground covers that restrict evaporation of water from the soil into the crawl space provide an effective way to prevent moisture and humidity problems. It is important to seal any ducts in the crawl space, to avoid venting clothes dryers into the crawl space, and to repair any leaking water pipes. A minimum clearance of 450 mm.

between the crawl space soil and the underside of any wood framing members is recommended and often required. Good access into and around the crawl space is very important.

Whether or not to ventilate a crawl space has been a controversial issue. Most building codes require installation of vents to provide ventilation with outside air, but a symposium on crawl space design concluded that there is no compelling technical basis for crawl space ventilation requirements (ASHRAE 1994). A distinction must be made between conditioned and unconditioned crawl spaces. Conditioned crawl spaces have insulated perimeter walls and may contain plumbing and heating runs. Conditioned crawl spaces should not be ventilated with outdoor air. If air circulation is desired, indoor air should be used. One way to accomplish this is by exhausting indoor air through the insulated crawl space, which may be done in conjunction with an air-to-air heat exchanger for energy efficiency (Samuelson 1994). Unconditioned crawl spaces have an insulated floor above the crawl space. Ventilation with outside air is permitted but not always necessary. Unvented crawl spaces must have a ground cover, which should cover 100% of the crawl space soil. Ground cover treatments for conditioned and unconditioned crawl spaces are similar.

The ground cover material should have a permeance of no more than  $57 \text{ ng}/(\text{s}\cdot\text{m}^2\cdot\text{Pa})$  and must be rugged enough to withstand foot and knee traffic. The most commonly used material is 0.15 mm polyethylene. The membrane ground cover may be covered with a thin slab of concrete to prevent entry of rodents. Before laying the membrane, all debris must be removed and the soil leveled. Edges need only be lapped 100 to 150 mm, and no sealing is required. The membrane need not be carried up the face of the wall.

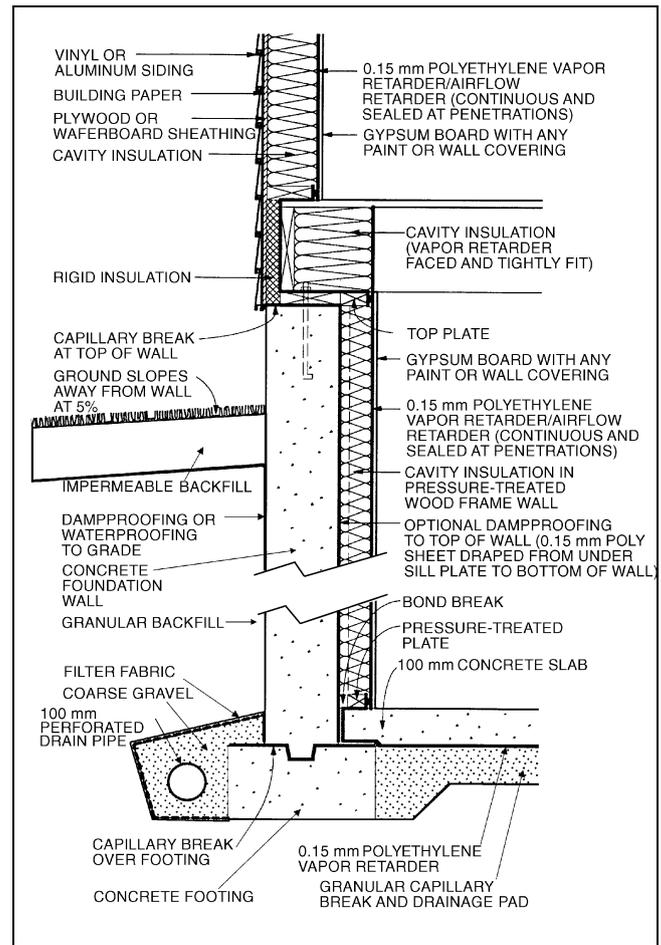

If control of entry of radon or other soil gases is desired, a minimum 0.15 mm polyethylene ground cover is recommended. Some have recommended that the ground cover should be weighted down and sealed at the perimeter and overlapped to retard radon entry, but others argue that weighting and sealing may lead to water ponding on top of the ground cover. If radon control is not of primary importance, the ground cover may be cut in several low spots to provide drainage should ponding occur. The primary function of the ground cover (i.e., moisture control or radon control) should govern the decision.

**Example of Residential Foundation Construction Details**

Figure 4 shows a cross section detail of a typical residential basement for mixed climates. Moisture control has been handled in the following ways:

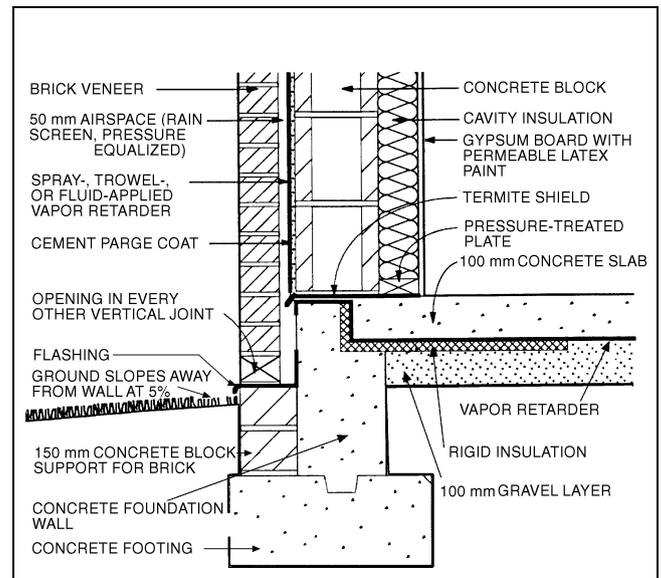

- **Rain and groundwater.** Rain is carried away by gutters, downspouts, grading away from the building, and a cap of low-permeance backfill material. Subgrade drainage prevents water from reaching the foundation wall by use of a drain screen (gravel and footer drain connected to daylight, sump, or storm sewer).
- **Liquid moisture transport.** A dampproof coating is installed on the exterior of the foundation wall and over the top of the footing to control water entry. Capillary moisture movement into the slab is inhibited by a gravel pad 100 mm thick.
- **Air movement.** All air leakage openings (i.e., floor slab/wall intersection, rim joist area) are caulked and sealed.
- **Vapor diffusion.** Dampproofing on the wall and polyethylene under the slab inhibit vapor diffusion into the slab and foundation walls. During heating periods, vapor may diffuse from the interior into the rim joist framing, where it may accumulate. To reduce moisture accumulation, the temperature of the rim joist is raised through the installation of exterior insulation.

Figure 5 shows an example of a moisture-controlling residential slab-on-grade foundation detail for warm, humid climates, with insulation laid horizontally beneath the perimeter of the floor. Rigid insulation is also placed in the vertical joint between the wall and the slab. Because the rigid insulation can act as a conduit for insects

**Fig. 4 Example of Residential Basement Construction for Mixed Climates**

**Fig. 5 Example of Residential Slab-on-Grade Construction in Warm, Humid Climates**

Source: Lstiburek and Carmody (1991). Reprinted with permission.

into the building, additional protection such as metal flashings or other treatments may be necessary.

- **Rain and groundwater.** The bottom of the gravel layer is the grade level adjacent to the perimeter. The ground should be graded to direct water away from the building.
- **Liquid moisture transport.** The granular layer under the slab provides a capillary break between the soil and the slab. This pad can also be integrated into a subslab ventilation system to provide radon mitigation, if needed. Extension of the vapor diffusion

retarder over the top of the foundation wall and appropriate flashing for the brick facing serve as a capillary break protecting the above-grade wall from moisture.

- **Air movement and vapor diffusion.** The vapor retarder placed under the slab restricts both moist soil gas entry and vapor diffusion through the slab. Ductwork located in slabs increases the risk of ground source moisture entering the conditioned space if groundwater and soil gas are permitted to seep into the ducts.

### ENVELOPE COMPONENT INTERSECTIONS

A moisture control strategy must consider not only envelope components, but also how these components come together. Component intersections are especially prone to air leakage and thermal bridging and therefore require special care.

**Exterior Wall Corners.** Mold and mildew often grow in exterior corners during heating periods due to cold surfaces caused by (1) thermal bridges, where structural members penetrate the insulation and provide a low-resistance heat flow path; (2) wind washing; (3) increased heat loss due to the fin effect; and (4) poor circulation of indoor air. Figure 6 shows heat loss effects at building corners. Insulating sheathings and two-stud corners help prevent cold interior surfaces and corner moisture problems.

**Wall/Window Intersections.** Restricting air-transported moisture at all potential openings makes a major contribution to the overall building tightness. The airflow retarder must be continuous. Figure 7 shows several details that help form a continuous airflow retarder at a window jamb.

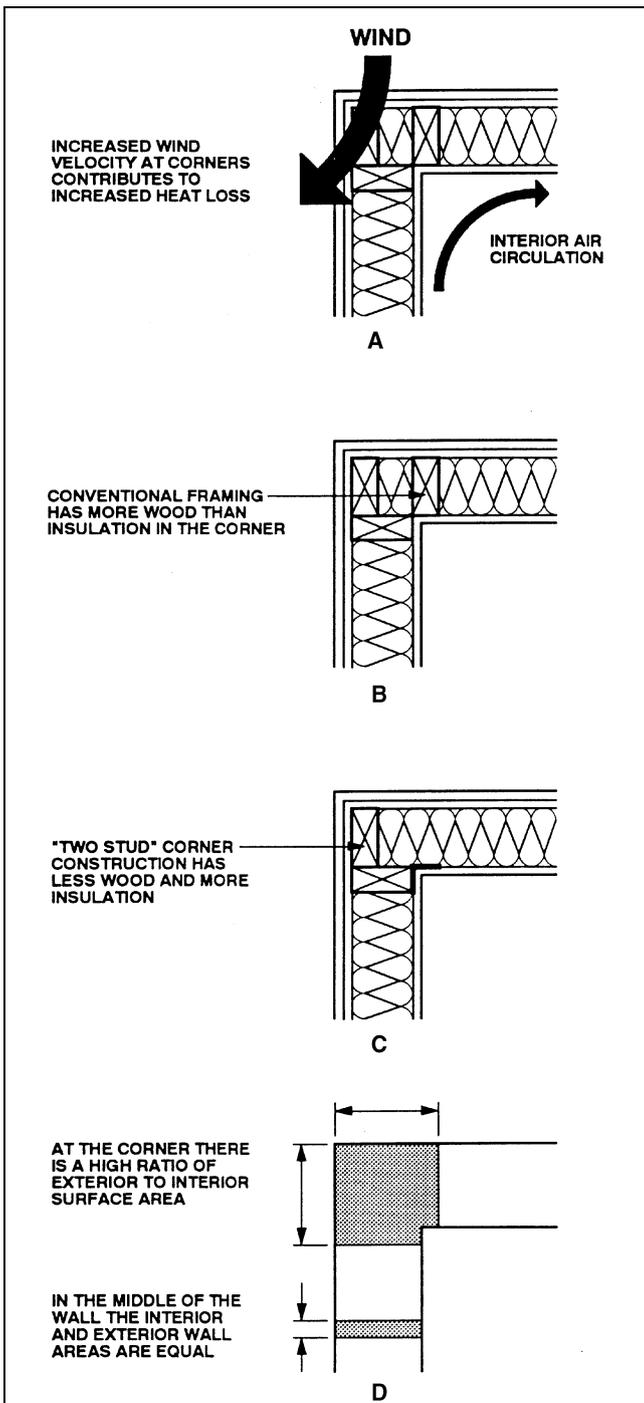

**Wall/Roof Intersections.** Exterior wall/ceiling intersections are other common cool spots during the heating season caused by reduced attic insulation at the eaves and wind washing. High-heel trusses that allow installation of more insulation, wind baffles, and rigid insulation exterior sheathing all help control moisture at these locations. Figure 8 shows the heat loss mechanisms at attic/wall intersections and how to minimize the risk of moisture problems.

**Wall/Floor Intersections.** Air leakage at rim joist assemblies is avoided by making sure the airflow retarder is continuous. Caulking and sealing are necessary at all polyethylene seams, as shown in Figure 4. Floor structural members penetrating the insulation can cause thermal bridging, but the use of insulating sheathing helps minimize this (see Figure 4).

**Wall/Foundation Intersections.** Concrete footings are frequently poured directly in contact with the ground, which occasionally becomes damp or wet. Concrete used for most residential foundations has the right degree of porosity to provide capillary suction, which draws water into the footings and then into the foundation wall. This water usually evaporates into the inside space undetected. However, the moisture occasionally manifests itself as a ring of dampness visible at the bottom interior surface of a basement or crawl space wall. Gravel and capillary breaks installed between the footing and the foundation wall are effective moisture control strategies in these below-grade envelope intersections. Several techniques to control capillary moisture below grade are shown in Figure 4 and Figure 5.

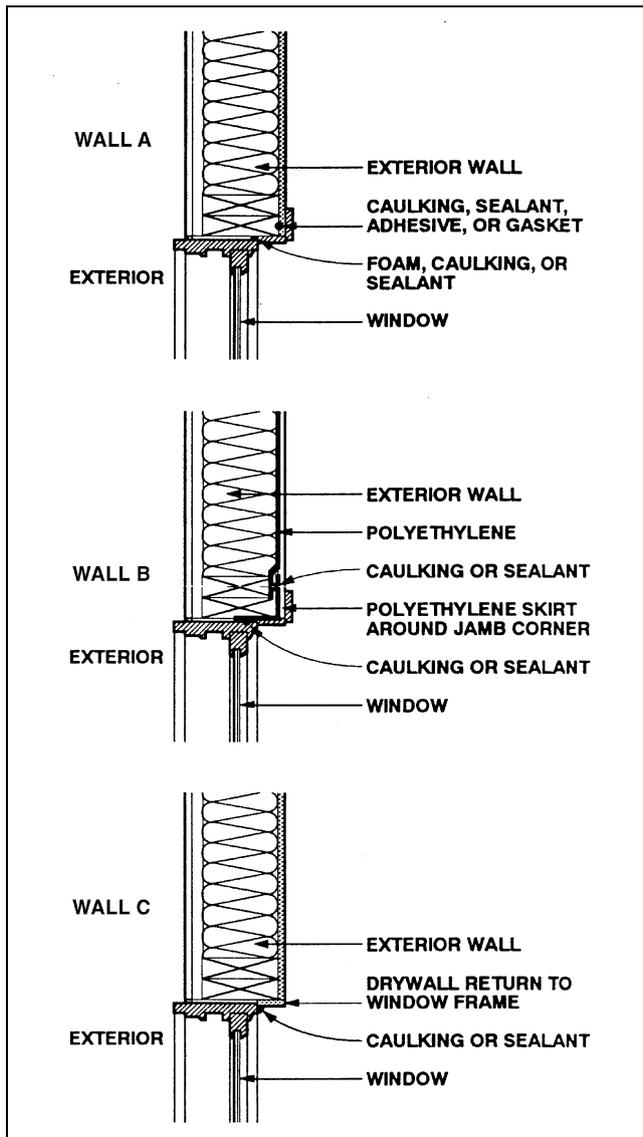

### MOISTURE CONTROL IN COMMERCIAL AND INSTITUTIONAL BUILDINGS

Moisture control in commercial and institutional buildings often requires approaches different from those in residential buildings. Indoor humidity conditions can vary greatly from one building to the next, depending on the use and requirements. The building envelope should be designed to perform well with these indoor conditions. Special thought should be given to the moisture control features of the HVAC equipment and the building envelope for certain buildings with special indoor humidity conditions or requirements, such as swimming pools, hospitals, and museums.

**Fig. 6 Heat Loss at Building Corners**

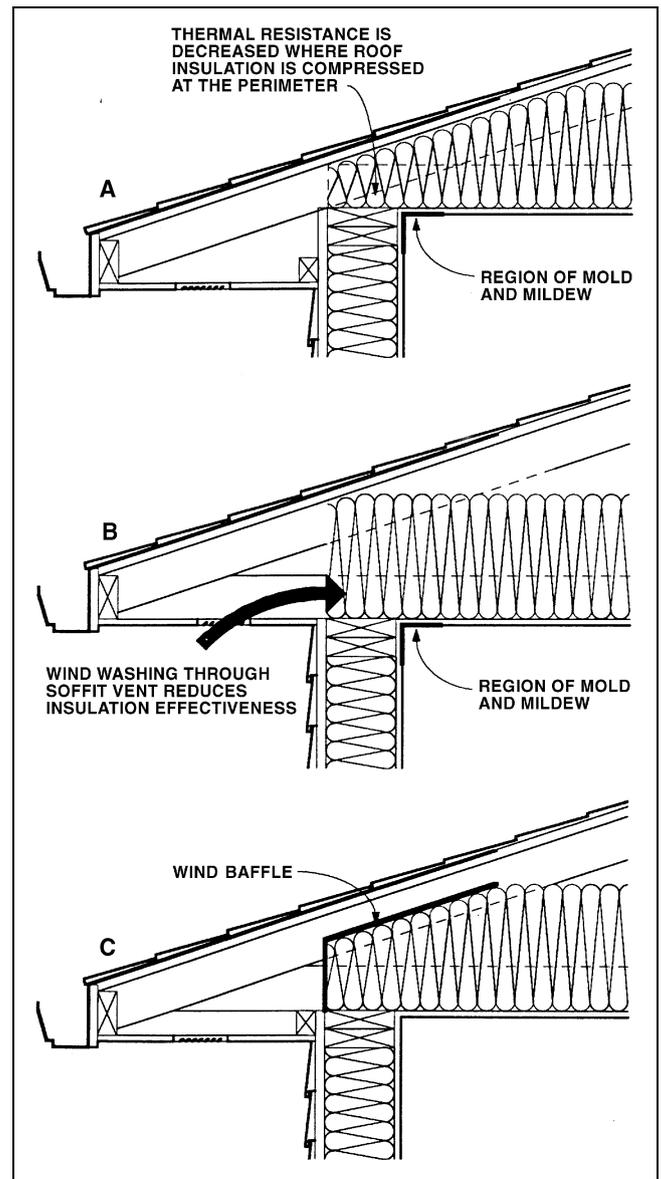

Source: Lstiburek and Carmody (1991). Reprinted with permission.

**Fig. 7 Interior Airflow Retarder Details at Window Jamb**  
 Source: Lstiburek and Carmody (1991). Reprinted with permission.

Materials commonly used in commercial and institutional construction tend to be more moisture-tolerant and decay-resistant than those used in residential construction. Airflow retarder systems are often poorly designed and executed. As a result, air leakage through the building envelope is common. Air leakage through hollow concrete masonry is often greater than in other types of construction. Upward airflow in the cavities is not always adequately blocked, and parallel random leakage paths are found between gypsum wall-board or other finishes and the block face.

Air can leak through exterior walls where the structural system or services penetrate the air barrier or at joints between dissimilar materials or components. For example, masonry cannot form a tight seal with structural steel columns and beams. To reduce this problem, the structural frame should be inside and separate from the exterior wall. The resulting curtain wall can then incorporate a more continuous air barrier and be protected from the fluctuating weather by insulation applied to the outside. Exterior cladding to control rain penetration is best applied following the weather-tightening system. The interior wythe (masonry course) and air barrier should be accessible for maintenance of the air seal and joints.

The deterioration of exterior structural elements of a building and damage to the interior through condensation from air leakage has an important bearing on the operation and maintenance costs of the building. Improving the airtightness of internal floors and partitions, particularly in high-rise buildings, redistributes the pressure differences caused by the stack effect and reduces the pressure difference across the exterior wall on each floor. This approach also improves ventilation and air distribution and reduces the air circulation between occupancies on different floors. It also helps control smoke movement in the case of fire and may enable a more equitable apportioning of energy charges for space heating between individual units in apartment buildings.

Leakage in actual buildings often occurs through holes cut accidentally or deliberately in a reasonably tight membrane or component, such as the penetration of services through specified air or vapor retarders or solid components. Other leakage openings in the exterior envelope result from dimensional changes in improperly placed materials or from inadequate sealants or membranes applied to bridge joints or cracks that will eventually open.

## INDUSTRIAL AND COMMERCIAL INSULATION PRACTICE

For pipe materials, selection, application, and installation, see Chapter 41 of the 2000 *ASHRAE Handbook—Systems and Equipment*. For insulation systems for refrigerant piping, see also Chapter 32 of the 1998 *ASHRAE Handbook—Refrigeration*.

If the equipment is subject to wide changes in temperature, the insulation installation should be designed to accommodate the associated dimensional change. If the equipment is operated at below ambient temperature, the application should be designed to resist the accumulation of moisture in the insulation.

### PIPES

Small pipes are insulated with cylindrical half-sections of insulation, with factory-applied jackets that form a hinge-and-lap, or with flexible, closed-cell material. Large pipes can be insulated with flexible material or with curved, flat segmented, or cylindrical half-, third-, or quarter-sections of rigid insulation, particularly where removal for frequent servicing of the pipe is necessary. Fittings (valves, tees, crosses, and elbows) are insulated with preformed fitting insulation, fabricated fitting insulation, individual pieces cut from sectional straight pipe insulation, or insulating cements. Fitting insulations should always be equal in thermal performance to the pipe insulation.

### Securing Methods

The method of securement varies with the size of pipe, form and weight of the insulation, and the type of jacketing (i.e., separate or factory-applied). Insulation with certain factory-applied jacketing can be secured on small piping by cementing the overlapping jacket. Large piping may require supplemental wiring or banding. Insulation on large piping requiring separate jacketing is wired or banded in place, and the jacket is cemented, wired, or banded, depending on the type. Insulation with factory-applied metal or PVC jacketing is secured by specific design of the jacket and its joint closure. The flexible closed-cell materials require no jacket for most applications and are applied using specially formulated contact adhesives.

### Insulation Finish for Above-Ambient Temperatures

Pipe insulation finishes for indoor use are usually governed by location. The finishes are factory-applied jackets designed to meet fire safety requirements. For maximum fire safety, unusual exposure conditions, or appearance, factory or separately applied metal or PVC jackets may be used. An outdoor finish protects the insulation from the weather. Chemical exposure, mechanical abuse, and appearance are additional considerations.

Pipes that operate at temperatures above 260°C may require two layers of insulation in order to accommodate the large dimension change of pipe and insulation materials.

### Insulation Finish for Below-Ambient Temperatures

Piping at temperatures below ambient is insulated to control heat gain and prevent condensation of moisture from the ambient air. Because piping is an absolute barrier to the passage of water vapor, the outer surface of the insulation must be covered by an impervious membrane or cover, which also helps protect the pipe against corrosion.

Retarder treatment should be recommended by the insulation manufacturer as established by performance testing. The insulation should be as dry as possible, and therefore should be protected from undue weather exposure.

Vapor seals for straight pipe insulation are generally designed to meet operating temperature, fire safety, and appearance requirements. Jacketing commonly consists of various combinations of laminates of paper, aluminum foil, plastic film, and glass fiber

reinforcing. An important feature of such jacketing is very low permeance in a relatively thin layer, which provides flexibility for ease of cementing and sealing laps and end-joint strips. This type of jacketing is commonly used indoors without additional treatment. In some cases of operating temperatures below -20°C, multilayer insulation and jacketing may be used. Flexible closed-cell materials must be carefully cemented to avoid openings in the insulations.

Insulation fittings are usually vapor sealed by applying suitable materials in the field, and may vary with the type of insulation and operating temperature. For temperatures above -12°C, the vapor seal can be a lapped spiral wrap of plastic film adhesive tape or a relatively thin coat of vapor-seal mastic. For temperatures below -12°C, common practice is to apply two coats of vapor-seal mastic reinforced with open weave glass or other fabric. The thickness of the mastic increases with decreasing temperature. With long lines of piping, the insulation should be sealed off every 5 or 6 m to limit water penetration if vapor seal damage occurs.

For dual-temperature service, where piping is alternately cold and hot, the vapor-seal finish, including mastics, must withstand pipe movement and exposure temperatures without deterioration. When flexible closed-cell insulation is used, it should be applied slightly compressed to prevent it from being strained when the piping expands.

Outdoor pipe insulation may be vapor-sealed in the same manner as indoor piping, by applying added weather protection jacketing without damage to the retarder and sealing it to keep out water. In some instances, heavy-duty weather and vapor-seal finish may be used.

Because cold piping frequently operates year-round, a constant vapor drive exists under humid conditions. Even with vapor retarder insulation, jackets, and vapor sealing of joints and fittings, moisture inevitably accumulates in permeable insulations. This moisture not only reduces the thermal resistance of the insulation, it also accelerates condensation on the jacket surface. Since periodic insulation replacement is the only known solution, the piping installation should be accessible for such replacement and should have a means for draining water. As an alternative, very low-permeance insulating materials (e.g., materials not exceeding  $0.6 \text{ ng}/(\text{s} \cdot \text{m}^2 \cdot \text{Pa})$  by the wet cup method) have been used to extend the life of the system and reduce replacement frequency. The lower the permeance of the insulation material, the longer its life, provided good workmanship is practiced during installation.

### Surface Temperature

In elevated-temperature applications, the surface temperature of the insulation system should be below that at which personnel coming into contact with the surface could be harmed. In below-ambient temperature applications, the surface temperature of the system should be above the dew point to prevent condensation.

Compared to a jacket with a nonreflective surface, a jacket with a reflective surface has a higher surface temperature for hot applications and a lower surface temperature for cold-temperature applications, because the lower emissivity reduces the rate of heat exchange. Therefore, adding a reflective jacket could produce a surface temperature capable of burning personnel on hot applications and causing condensation on cold applications. The jacketing material used also contributes to the relative safety at a given surface temperature. For example, at 80°C, a stainless steel jacket blisters skin more severely than a canvas jacket does.

### Insulating Pipes to Prevent Freezing

If the surrounding air temperature remains sufficiently low for an extended period, insulation cannot prevent freezing of still water or of water flowing at a rate insufficient for the available heat content to offset the heat loss. Insulation can only prolong the time required

**Table 1 Estimated Requirements to Prevent Freezing of Water in Pipes**

Steel Pipe Nominal Diameter, mm	Insulation Thickness, mm					
	50	75	100	50	75	100
	Time to Cool Water to Freezing, h			Water Mass Flow Rate per Unit Length of Exposed Pipe to Prevent Freezing, g/(s·m)		
15	0.27	0.32	0.36	0.23	0.19	0.16
25	0.61	0.75	0.85	0.29	0.23	0.20
40	1.16	1.46	1.69	0.37	0.29	0.24
50	1.67	2.13	2.49	0.44	0.33	0.27
80	2.83	3.71	4.42	0.61	0.43	0.35
100	4.07	5.43	6.54	0.77	0.53	0.42
125	5.45	7.36	8.96	0.97	0.64	0.50
150	6.86	9.37	11.5	1.20	0.76	0.58
200	9.59	13.3	16.5	1.79	1.03	0.76
250	12.6	17.6	22.1	2.54	1.32	0.93
300	15.4	21.7	27.4	3.71	1.69	1.14

*Design Conditions:* Surrounding air temperature  $t_a = -28^\circ\text{C}$ , initial water temperature  $t_i = 5.5^\circ\text{C}$ , and insulation thermal conductivity  $k_I = 0.043 \text{ W}/(\text{m}\cdot\text{K})$ . Thermal resistances of pipe and air film at surface of insulation are ignored. Calculations are for 40ST steel pipe. See Table 2 in Chapter 41 of the 2000 ASHRAE Handbook—Systems and Equipment for actual pipe dimensions.

for water to freeze or prevent freezing if water flow is maintained at a sufficient rate. The first section of Table 1 can be used to estimate the thickness of insulation necessary to prevent freezing of still water in pipes. The second section of Table 1 gives the minimum flow of water at an initial temperature of  $5.5^\circ\text{C}$  to prevent the temperature of the pipe from reaching  $0^\circ\text{C}$  at the end of the exposed length.

To calculate time  $\theta$  (in hours) required for water to cool to  $0^\circ\text{C}$ , the following equation can be used:

$$\theta = \frac{\rho c_p \pi \left(\frac{D_i}{2}\right)^2 R_{T(\alpha)} \ln \left[ \frac{t_i - t_a}{t_f - t_a} \right]}{3600} \quad (1)$$

where

- $\theta$  = time for water to cool to freezing, h
- $\rho$  = density of water =  $1000 \text{ kg}/\text{m}^3$
- $c_p$  = specific heat of water =  $4200 \text{ J}/(\text{kg}\cdot\text{K})$
- $D_i$  = inside diameter of pipe, m
- $D_p$  = outer diameter of pipe or inner diameter of insulation, m
- $D_I$  = outer diameter of insulation, m
- $R_T = R_p + R_I + R_a$  = combined thermal resistance of pipe wall, insulation, and exterior air film per metre of pipe,  $\text{m}\cdot\text{K}/\text{W}$
- $R_a = 1/(h_a \pi D_I)$  = resistance between ambient air and outer surface of insulation per metre of pipe,  $\text{m}\cdot\text{K}/\text{W}$
- $h_a$  = air heat transfer coefficient (see Chapter 3 for values)
- $R_I = \ln(D_I/D_p)/(2\pi k_I)$  = resistance of thermal insulation per metre of pipe,  $\text{m}\cdot\text{K}/\text{W}$
- $R_p = \ln(D_p/D_i)/(2\pi k_p)$  = resistance of pipe per metre of pipe,  $\text{m}\cdot\text{K}/\text{W}$  ( $R_p \approx 0$  for metal pipe)
- $k_I$  = thermal conductivity of insulation,  $\text{W}/(\text{m}\cdot\text{K})$
- $k_p$  = thermal conductivity of pipe material,  $\text{W}/(\text{m}\cdot\text{K})$  (see Table 7 in Chapter 41 of the 2000 ASHRAE Handbook—Systems and Equipment for thermal conductivity of various plastic pipes)
- $t_a$  = ambient air temperature,  $^\circ\text{C}$
- $t_i$  = initial water temperature,  $^\circ\text{C}$
- $t_f$  = freezing temperature,  $^\circ\text{C}$

When unusual conditions make it impractical to maintain protection with insulation alone, a hot trace pipe or, preferably, electric resistance heating cable is required along the bottom or top of the water pipe. The heating system then supplies the heat lost through the insulation. The insulation thickness is determined by the cost of the heating system, the insulation, and the heat loss.

Pipe bursting is not an immediate consequence of water pipes reaching freezing temperatures. Clean water and pipes usually supercool several degrees below freezing before any ice is formed. Then, upon nucleation, dendritic ice forms in the water and the temperature rises to freezing. Ice can be formed from water only by the release of the latent heat of fusion ( $334 \text{ kJ}/\text{kg}$ ) through the pipe insulation. With well-insulated pipes, this release of latent heat may be greatly retarded. Pipe bursting in water pipes has been shown (Gordon 1996) to be a consequence not of ice crystal growth in the pipe, but of elevated fluid pressure within a confined pipe section occluded by a growing ice blockage.

### Underground Pipe Insulation

Both heated and cooled underground piping systems are insulated. Protecting underground insulated piping is more difficult than protecting aboveground piping. Groundwater conditions, including chemical or electrolytic contributions by the soil and the existence of water pressure, require a special design to protect insulated pipes from corrosion. Walk-through tunnels, conduits, or integral protective coverings are generally provided to protect the pipe and insulation from water. Examples and general design features of conduits and a description of tunnels can be found in Chapter 11 of the 2000 ASHRAE Handbook—Systems and Equipment.

**Temperatures Above Ambient.** Piping for heated systems in walk-through tunnels is usually covered with sectional insulation and finished with effective mechanical protection such as metal or waterproofing jackets. The use of walk-through tunnels is declining because of cost.

Conduit systems are generally used for underground insulated piping systems. The most successful application is sectional insulation with the conduit sized for drainage and adequate drying of insulation on heated piping in the event of accidental flooding. BRAB (1975) gives detailed design criteria for conduit systems. The criteria require that (1) all systems provide for draining and insulation drying, (2) the insulation withstand boiling and drying without physical damage and loss of insulating value, and (3) the conduit casing is watertight in the field. The insulation should be a nonconductor of electricity, verminproof, and chemically and dimensionally stable at the operating temperature of the pipe.

BRAB (1964) describes evaluative tests and field investigations, which have shown that calcium silicate is resistant to severe boiling action. Fibrous glass (density of  $64$  to  $110 \text{ kg}/\text{m}^3$ ) will not withstand boiling when a conduit becomes flooded, and wet poured-in-place insulations are likely to remain partially wet for their installed life.

The thickness of insulation for underground piping is not determined on the same basis as above ground piping. Chapter 11 of the 2000 ASHRAE Handbook—Systems and Equipment provides details for determining thickness.

**Temperatures Below Ambient.** Integrally protected, insulated piping buried directly in the ground is commonly used for chilled water. However, since no heat is available to drive out moisture, an absolute protective covering against water and insulation with low permeance and water absorption is extremely important. Cellular glass with proper protection has been widely used for this type of application. The acceptance of plastic foams is increasing, but their long-term performance has not yet been established.

Conduit for chilled water piping requires a different approach than for hot piping. Insulation must have low conductivity, and conduit design must use this low conductivity and maintain continuing performance. More recent designs use low-conductivity plastic foam insulation with plastic pipe as the internal water-carrying piping and as the external conduit.

Where the temperature difference between the pipe at  $5^\circ\text{C}$  and the soil at  $13$  to  $16^\circ\text{C}$  is small, pipe size, length, and flow rate may economically justify direct burial without insulation. However, good piping protection may be required.

## DUCTS

The need for duct insulation is influenced by (1) duct location, whether indoors or outdoors; (2) the effect of heat loss or gain on equipment size and operating cost; (3) the need to prevent condensation on low-temperature ducts; (4) the need to control temperature change in long duct lengths; and (5) the need to control noise with interior duct lining.

All ducts exposed to outdoor conditions, as well as those passing through unconditioned spaces, should be insulated. While analyses of temperature change, heat loss or gain, and other factors affecting the economics of thermal insulation are seldom made for residential installations, they are essential for large commercial and industrial projects.

The U-factor for uninsulated sheet metal ducts is affected by air velocity, the emittance of the metal, and the shape of the duct. An approximate value of  $5.7 \text{ W}/(\text{m}^2 \cdot \text{K})$  may be used. For insulated ducts, U-factors of 1.4 and  $0.74 \text{ W}/(\text{m}^2 \cdot \text{K})$  represent 25 and 50 mm thick rigid insulation with a thermal conductivity of  $0.039 \text{ W}/(\text{m} \cdot \text{K})$  at  $24^\circ\text{C}$  mean temperature. A method for determining heat loss or gain for ducts is given in Chapter 34.

### Materials for Ducts, Insulations, and Liners

Ducts within buildings can be of insulated sheet metal, fibrous glass, or insulated flexible ducts, all of which provide combined air barrier, thermal insulation, and sound absorption. Ducts embedded in or below floor slabs may be of compressed fiber, ceramic tile, or other rigid materials.

Duct insulations include semirigid boards and flexible blanket types, composed of organic and inorganic materials in fibrous, cellular, or bonded particle forms. Insulations for exterior surfaces may have attached vapor barriers or facings, or vapor barriers may be applied separately. When applied to the duct interior as a liner, insulation both insulates thermally and absorbs sound. Duct liner insulations have sound-permeable coatings or other treatment on the side facing the airstream to withstand air velocities or duct cleaning without deterioration.

Per UL *Standard* 181, fibrous glass air ducts are tested to 63.5 m/s and are rated at 25 m/s and at a pressure of at least 500 Pa. Primary use is for low-pressure systems tested at 1.5 times the recommended static pressure. Maximum recommended air temperature is  $120^\circ\text{C}$ . A complete system provides greater decibel attenuation than is usually provided by standard duct liners, with greater reduction in airborne equipment noise and crosstalk. Higher design velocities are also possible.

To satisfy most building codes, duct insulation and fibrous glass duct materials must meet the fire hazard requirements of (1) NFPA *Standard* 90A, to restrict spread of smoke, heat, and fire through duct systems, and to minimize ignition sources; and (2) NFPA *Standard* 90B, on supply ducts, controls, clearances, heating panels, return ducts, air filters, and heat pumps. Local code authorities should also be consulted.

Where thermally insulated air-conditioning ducts pass through unconditioned spaces, such as attics, the maximum allowable heat flux should be no greater than that required by NFPA *Standard* 90A.

### Securing Methods

Exterior rigid duct insulation can be attached with adhesive, with supplemental preattached pins and clips, or with wiring or banding. Liners can be attached with adhesive and supplemental pins and clips. Flexible duct wraps do not require attachment except on bottom duct panels greater than 600 mm wide. For larger ducts a pin no more than 600 mm on center is sufficient.

Manufacturers provide information on the construction of fibrous glass duct systems. Preformed round duct for straight runs is combined with fittings fabricated from straight duct. Rectangular ducts and fittings are fabricated by grooving, folding, and taping.

Metal accessories such as turning vanes, splitters, and dampers are incorporated into the system. When rectangular ducts exceed predetermined dimensions for particular static pressures, ductwork must be reinforced. The Sheet Metal and Air Conditioning Contractors National Association's (SMACNA) *Fibrous Glass Duct Construction Standards* (1992) have further information.

### Heating Ducts

The effect of duct insulation on residential heating system equipment size can be marginal. However, insulation can reduce operating costs significantly, depending on unit costs for heating and the extent of duct exposed to outside conditions. In addition, duct insulation maintains the supply air temperature, which may keep the air entering the conditioned space within a more comfortable range.

Vapor retarders are not required on exterior insulation of ducts used only for heating, but they must be provided for ducts used for alternate heating and cooling.

### Cooling Ducts

Insulation can significantly reduce operating costs and cooling equipment size. The advantage of adequate insulation is especially significant in areas with high dry-bulb and dew-point temperatures. Ducts for summer air conditioning are insulated with the same materials as heating ducts. Ducts in any unconditioned space should be insulated and have vapor retarders to prevent condensation. Joints and laps in the vapor retarder must be sealed. Flexible closed-cell insulation does not always need a supplemental vapor retarder, but care must be taken to form vapor-tight seams at joints.

*Calculating Heat Flow for Buried Pipelines* ..... 25.20

**T**HIS CHAPTER presents thermal and water vapor transmission data based on steady-state or equilibrium conditions. Chapter 3 covers heat transfer under transient or changing temperature conditions. Chapter 23 discusses selection of insulation materials and procedures for determining overall thermal resistances by simplified methods.

## BUILDING ENVELOPES

### Thermal Transmission Data for Building Components

The steady-state thermal resistances (R-values) of building components (walls, floors, windows, roof systems, etc.) can be calculated from the thermal properties of the materials in the component; or the heat flow through the assembled component can be measured directly with laboratory equipment such as the guarded hot box (ASTM *Standard C 236*) or the calibrated hot box (ASTM *Standard C 976*).

Tables 1 through 6 list thermal values, which may be used to calculate thermal resistances of building walls, floors, and ceilings. The values shown in these tables were developed under ideal conditions. In practice, overall thermal performance can be reduced significantly by such factors as improper installation and shrinkage, settling, or compression of the insulation (Tye and Desjarlais 1983; Tye 1985, 1986).

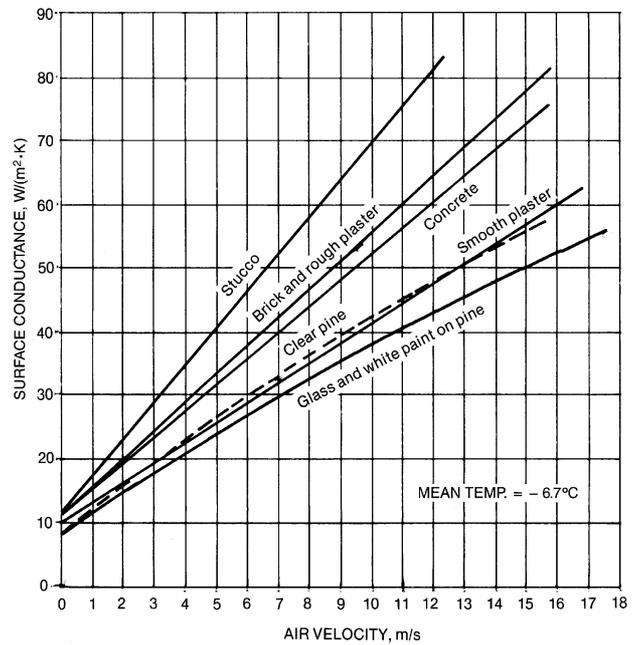

Most values in these tables were obtained by accepted ASTM test methods described in ASTM *Standards C 177* and *C 518* for materials and ASTM *Standards C 236* and *C 976* for building envelope components. Because commercially available materials vary, not all values apply to specific products.

The most accurate method of determining the overall thermal resistance for a combination of building materials assembled as a building envelope component is to test a representative sample by a hot box method. However, all combinations may not be conveniently or economically tested in this manner. For many simple constructions, calculated R-values agree reasonably well with values determined by hot box measurement.

The performance of materials fabricated in the field is especially subject to the quality of workmanship during construction and installation. Good workmanship becomes increasingly important as the insulation requirement becomes greater. Therefore, some engineers include additional insulation or other safety factors based on experience in their design.

Figure 1 shows how convection affects surface conductance of several materials. Other tests on smooth surfaces show that the average value of the convection part of the surface conductance decreases as the length of the surface increases.

Vapor retarders, which are discussed in Chapters 23 and 24, require special attention. Moisture from condensation or other

**Fig. 1** Surface Conductance for Different Surfaces as Affected by Air Movement

sources may reduce the thermal resistance of insulation, but the effect of moisture must be determined for each material. For example, some materials with large air spaces are not affected significantly if the moisture content is less than 10% by mass, while the effect of moisture on other materials is approximately linear.

Ideal conditions of components and installations are assumed in calculating overall R-values (i.e., insulating materials are of uniform nominal thickness and thermal resistance, air spaces are of uniform thickness and surface temperature, moisture effects are not involved, and installation details are in accordance with design). The National Institute of Standards and Technology Building Materials and Structures Report BMS 151 shows that measured values differ from calculated values for certain insulated constructions. For this reason, some engineers decrease the calculated R-values a moderate amount to account for departures of constructions from requirements and practices.

Tables 3 and 2 give values for well-sealed systems constructed with care. Field applications can differ substantially from laboratory test conditions. Air gaps in these insulation systems can seriously degrade thermal performance as a result of air movement due to both natural and forced convection. Sabine et al. (1975) found that the tabular values are not necessarily additive for multiple-layer, low-emittance air spaces, and tests on actual constructions should be conducted to accurately determine thermal resistance values.

The preparation of this chapter is assigned to TC 4.4, Thermal Insulation and Moisture Retarders.

**Table 1 Surface Conductances and Resistances for Air**

Position of Surface	Direction of Heat Flow	Surface Emittance, $\epsilon$					
		Non-reflective $\epsilon = 0.90$		Reflective $\epsilon = 0.05$			
		$h_i$	$R$	$h_i$	$R$	$h_i$	$R$
<b>STILL AIR</b>							
Horizontal	Upward	9.26	0.11	5.17	0.19	4.32	0.23
Sloping—45°	Upward	9.09	0.11	5.00	0.20	4.15	0.24
Vertical	Horizontal	8.29	0.12	4.20	0.24	3.35	0.30
Sloping—45°	Downward	7.50	0.13	3.41	0.29	2.56	0.39
Horizontal	Downward	6.13	0.16	2.10	0.48	1.25	0.80
<b>MOVING AIR (Any position)</b>		$h_o$	$R$				
Wind (for winter)	Any	34.0	0.030	—	—	—	—
6.7 m/s (24 km/h)							
Wind (for summer)	Any	22.7	0.044	—	—	—	—
3.4 m/s (12 km/h)							

- Notes:*
1. Surface conductance  $h_i$  and  $h_o$  measured in  $W/(m^2 \cdot K)$ ; resistance  $R$  in  $m^2 \cdot K/W$ .
  2. No surface has both an air space resistance value and a surface resistance value.
  3. For ventilated attics or spaces above ceilings under summer conditions (heat flow down), see Table 5.
  4. Conductances are for surfaces of the stated emittance facing virtual blackbody surroundings at the same temperature as the ambient air. Values are based on a surface-air temperature difference of 5.5 K and for surface temperatures of 21°C.
  5. See Chapter 3 for more detailed information, especially Tables 5 and 6, and see Figure 1 for additional data.
  6. Condensate can have a significant impact on surface emittance (see Table 2).

Values for foil insulation products supplied by manufacturers must also be used with caution because they apply only to systems that are identical to the configuration in which the product was tested. In addition, surface oxidation, dust accumulation, condensation, and other factors that change the condition of the low-emittance surface can reduce the thermal effectiveness of these insulation systems (Hooper and Moroz 1952). Deterioration results from contact with several types of solutions, either acidic or basic (e.g., wet cement mortar or the preservatives found in decay-resistant lumber). Polluted environments may cause rapid and severe material degradation. However, site inspections show a predominance of well-preserved installations and only a small number of cases in which rapid and severe deterioration has occurred. An extensive review of the reflective building insulation system performance literature is provided by Goss and Miller (1989).

**CALCULATING OVERALL THERMAL RESISTANCES**

Relatively small, highly conductive elements in an insulating layer called thermal bridges can substantially reduce the average thermal resistance of a component. Examples include wood and metal studs in frame walls, concrete webs in concrete masonry walls, and metal ties or other elements in insulated wall panels. The following examples illustrate the calculation of R-values and U-factors for components containing thermal bridges.

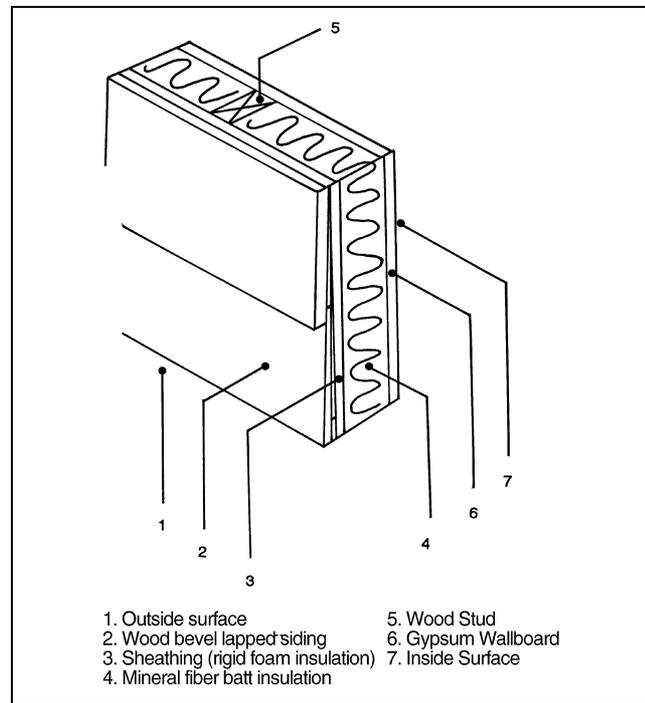

The following conditions are assumed in calculating the design R-values:

- Equilibrium or steady-state heat transfer, disregarding effects of thermal storage
- Surrounding surfaces at ambient air temperature
- Exterior wind velocity of 6.7 m/s (24 km/h) for winter (surface with  $R = 0.03 m^2 \cdot K/W$ ) and 3.4 m/s (12 km/h) for summer (surface with  $R = 0.044 m^2 \cdot K/W$ )
- Surface emittance of ordinary building materials is 0.90

**Table 2 Emittance Values of Various Surfaces and Effective Emittances of Air Spaces<sup>a</sup>**

Surface	Average Emittance $\epsilon$	Effective Emittance $\epsilon_{eff}$ of Air Space	
		One Surface Emittance $\epsilon$ ; Other, 0.9	Both Surfaces Emittance $\epsilon$
Aluminum foil, bright	0.05	0.05	0.03
Aluminum foil, with condensate just visible ( $> 0.5 g/m^2$ )	0.30 <sup>b</sup>	0.29	—
Aluminum foil, with condensate clearly visible ( $> 2.0 g/m^2$ )	0.70 <sup>b</sup>	0.65	—
Aluminum sheet	0.12	0.12	0.06
Aluminum coated paper, polished	0.20	0.20	0.11
Steel, galvanized, bright	0.25	0.24	0.15
Aluminum paint	0.50	0.47	0.35
Building materials: wood, paper, masonry, nonmetallic paints	0.90	0.82	0.82
Regular glass	0.84	0.77	0.72

<sup>a</sup>These values apply in the 4 to 40  $\mu m$  range of the electromagnetic spectrum.  
<sup>b</sup>Values are based on data presented by Bassett and Trethowen (1984).

**Fig. 2 Insulated Wood Frame Wall (Example 1)**

**Wood Frame Walls**

The average overall R-values and U-factors of wood frame walls can be calculated by assuming either parallel heat flow paths through areas with different thermal resistances or by assuming isothermal planes. Equations (1) through (5) from Chapter 23 are used.

The framing factor or fraction of the building component that is framing depends on the specific type of construction, and it may vary based on local construction practices—even for the same type of construction. For stud walls 400 mm on center (OC), the fraction of insulated cavity may be as low as 0.75, where the fraction of studs, plates, and sills is 0.21 and the fraction of headers is 0.04. For studs 600 mm OC, the respective values are 0.78, 0.18, and 0.04.

These fractions contain an allowance for multiple studs, plates, sills, extra framing around windows, headers, and band joists. These assumed framing fractions are used in the following example, to illustrate the importance of including the effect of framing in determining the overall thermal conductance of a building. The actual framing fraction should be calculated for each specific construction.

**Example 1.** Calculate the U-factor of the 38 mm by 90 mm stud wall shown in Figure 2. The studs are at 400 mm OC. There is 90 mm mineral fiber batt insulation ( $R = 2.3 \text{ m}^2 \cdot \text{K}/\text{W}$ ) in the stud space. The inside finish is 13 mm gypsum wallboard; the outside is finished with rigid foam insulating sheathing ( $R = 0.7 \text{ m}^2 \cdot \text{K}/\text{W}$ ) and 13 mm by 200 mm wood bevel lapped siding. The insulated cavity occupies approximately 75% of the transmission area; the studs, plates, and sills occupy 21%; and the headers occupy 4%.

**Solution:** Obtain the R-values of the various building elements from Tables 1 and 4. Assume  $R = 7.0 \text{ m}^2 \cdot \text{K}/\text{W}$  for the wood framing. Also, assume the headers are solid wood, in this case, and group them with the studs, plates, and sills.

Because the U-factor is the reciprocal of R-value,  $U_1 = 0.297 \text{ W}/(\text{m}^2 \cdot \text{K})$  and  $U_2 = 0.588 \text{ W}/(\text{m}^2 \cdot \text{K})$ .

If the wood framing (thermal bridging) is not included, Equation (3) from Chapter 23 may be used to calculate the U-factor of the wall as follows:

$$U_{av} = U_1 = \frac{1}{R_1} = 0.30 \text{ W}/(\text{m}^2 \cdot \text{K})$$

Element	R (Insulated Cavity)	R (Studs, Plates, and Headers)
1. Outside surface, 24 km/h wind	0.03	0.03
2. Wood bevel lapped siding	0.14	0.14
3. Rigid foam insulating sheathing	0.70	0.70
4. Mineral fiber batt insulation	2.30	—
5. Wood stud	—	0.63
6. Gypsum wallboard	0.08	0.08
7. Inside surface, still air	<u>0.12</u>	<u>0.12</u>
	3.37	1.70

If the wood framing is accounted for using the parallel-path flow method, the U-factor of the wall is determined using Equation (5) from Chapter 23 as follows:

$$U_{av} = (0.75 \times 0.297) + (0.25 \times 0.588) = 0.37 \text{ W}/(\text{m}^2 \cdot \text{K})$$

If the wood framing is included using the isothermal planes method, the U-factor of the wall is determined using Equations (2) and (3) from Chapter 23 as follows:

$$T_{(av)} = 4.98 + 1/ [(0.75/ 2.30) + (0.25/ 0.63)] + 0.2$$

$$= 2.47 \text{ K} \cdot \text{m}^2/\text{W}$$

$$U_{av} = 0.40 \text{ W}/(\text{m}^2 \cdot \text{K})$$

For a frame wall with a 600 mm OC stud space, the average overall R-value is  $0.25 \text{ m}^2 \cdot \text{K}/\text{W}$ . Similar calculation procedures may be used to evaluate other wall designs, except those with thermal bridges.

**Masonry Walls**

The average overall R-values of masonry walls can be estimated by assuming a combination of layers in series, one or more of which provides parallel paths. This method is used because heat flows laterally through block face shells so that transverse isothermal planes result. Average total resistance  $R_{T(av)}$  is the sum of the resistances of the layers between such planes, each layer calculated as shown in Example 2.

**Example 2.** Calculate the overall thermal resistance and average U-factor of the 194 mm thick insulated concrete block wall shown in Figure 3. The two-core block has an average web thickness of 25 mm and a face

shell thickness of 30 mm. Overall block dimensions are 194 mm by 194 mm by 395 mm. Measured thermal resistances of  $1700 \text{ kg}/\text{m}^3$  concrete and  $110 \text{ kg}/\text{m}^3$  expanded perlite insulation are  $0.70$  and  $20 \text{ K} \cdot \text{m}^2/2$ , respectively.

**Solution:** The equation used to determine the overall thermal resistance of the insulated concrete block wall is derived from Equations (2) and (5) from Chapter 23 and is given below:

$$R_{T(av)} = R_i + R_f + \left( \frac{a_w}{R_w} + \frac{a_c}{R_c} \right)^{-1} + R_o$$

where

$R_{T(av)}$  = overall thermal resistance based on assumption of isothermal planes

$R_i$  = thermal resistance of inside air surface film (still air)

$R_o$  = thermal resistance of outside air surface film (24 km/h wind)

$R_f$  = total thermal resistance of face shells

$R_c$  = thermal resistance of cores between face shells

$R_w$  = thermal resistance of webs between face shells

$a_w$  = fraction of total area transverse to heat flow represented by webs of blocks

$a_c$  = fraction of total area transverse to heat flow represented by cores of blocks

From the information given and the data in Table 1, determine the values needed to compute the overall thermal resistance.

$$R_i = 0.12$$

$$R_o = 0.03$$

$$R_f = 2 \times 0.032 \times 0.70 = 0.045$$

$$R_c = (0.194 - 2 \times 0.032)(20) = 2.60$$

$$R_w = (0.194 - 2 \times 0.032)(0.70) = 0.091$$

$$a_w = 3 \times 25/395 = 0.190$$

$$a_c = 1 - 0.190 = 0.810$$

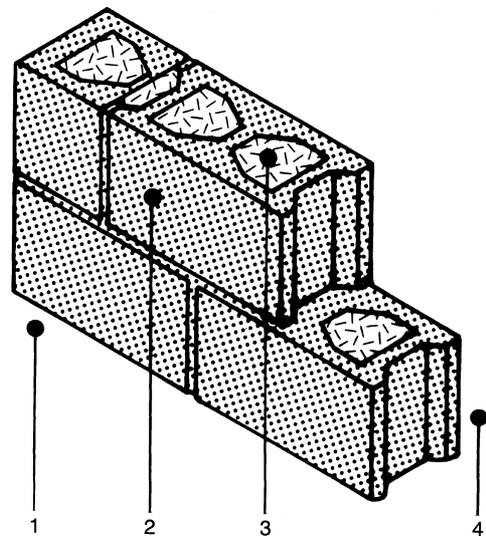

Using the equation given, the overall thermal resistance and average U-factor are calculated as follows:

$$R_{T(av)} = 0.12 + 0.045 + \frac{(0.091 \times 2.60)}{(0.810 \times 0.91) + (0.190 \times 2.60)} + 0.03$$

$$= 0.612 \text{ K} \cdot \text{m}^2/\text{W}$$

$$U_{av} = 1/ 0.612 = 1.63 \text{ W}/(\text{m}^2 \cdot \text{K})$$

Based on guarded hot box tests of this wall without mortar joints, Tye and Spinney (1980) measured the average R-value for this insulated concrete block wall as  $0.551 \text{ m}^2 \cdot \text{K}/\text{W}$ .

<sup>a</sup>See Chapter 23, section Factors Affecting Heat Transfer Across Air Spaces. Thermal resistance values were determined from the relation,  $R = 1/C$ , where  $C = h_c + \epsilon_{eff} h_r$ ,  $h_c$  is the conduction-convection coefficient,  $\epsilon_{eff} h_r$  is the radiation coefficient  $\approx 0.227\epsilon_{eff}[(t_m + 273)/100]^3$ , and  $t_m$  is the mean temperature of the air space. Values for  $h_c$  were determined from data developed by Robinson et al. (1954). Equations (5) through (7) in Yarbrough (1983) show the data in this table in analytic form. For extrapolation from this table to air spaces less than 12.5 mm (as in insulating window glass), assume  $h_c = 21.8(1 + 0.00274 t_m)/l$  where  $l$  is the air space thickness in mm, and  $h_c$  is heat transfer in  $W/(m^2 \cdot K)$  through the air space only.

<sup>b</sup>Values are based on data presented by Robinson et al. (1954). (Also see Chapter 3, Tables 3 and 4, and Chapter 38). Values apply for ideal conditions (i.e., air spaces of uniform thickness bounded by plane, smooth, parallel surfaces with no air leakage to or from the space). When accurate values are required, use overall U-factors deter-

mined through calibrated hot box (ASTM C 976) or guarded hot box (ASTM C 236) testing. Thermal resistance values for multiple air spaces must be based on careful estimates of mean temperature differences for each air space.

<sup>c</sup>A single resistance value cannot account for multiple air spaces; each air space requires a separate resistance calculation that applies only for the established boundary conditions. Resistances of horizontal spaces with heat flow downward are substantially independent of temperature difference.

<sup>d</sup>Interpolation is permissible for other values of mean temperature, temperature difference, and effective emittance  $\epsilon_{eff}$ . Interpolation and moderate extrapolation for air spaces greater than 90 mm are also permissible.

<sup>e</sup>Effective emittance  $\epsilon_{eff}$  of the air space is given by  $1/\epsilon_{eff} = 1/\epsilon_1 + 1/\epsilon_2 - 1$ , where  $\epsilon_1$  and  $\epsilon_2$  are the emittances of the surfaces of the air space (see Table 2).

Notes for Table 4

- <sup>a</sup> Values are for a mean temperature of 24°C. Representative values for dry materials are intended as design (not specification) values for materials in normal use. Thermal values of insulating materials may differ from design values depending on their in-situ properties (e.g., density and moisture content, orientation, etc.) and variability experienced during manufacture. For properties of a particular product, use the value supplied by the manufacturer or by unbiased tests.
- <sup>b</sup> The symbol  $\lambda$  is also used to represent thermal conductivity.
- <sup>c</sup> Resistance values are the reciprocals of  $C$  before rounding off  $C$  to two decimal places.
- <sup>d</sup> Lewis (1967).
- <sup>e</sup> U.S. Department of Agriculture (1974).
- <sup>f</sup> Does not include paper backing and facing, if any. Where insulation forms a boundary (reflective or otherwise) of an airspace, see Tables 2 and 3 for the insulating value of an airspace with the appropriate effective emittance and temperature conditions of the space.
- <sup>g</sup> Conductivity varies with fiber diameter. (See Chapter 23, Factors Affecting Thermal Performance.) Batt, blanket, and loose-fill mineral fiber insulations are manufactured to achieve specified R-values, the most common of which are listed in the table. Due to differences in manufacturing processes and materials, the product thicknesses, densities, and thermal conductivities vary over considerable ranges for a specified R-value.
- <sup>h</sup> This material is relatively new and data are based on limited testing.
- <sup>i</sup> For additional information, see Society of Plastics Engineers (SPI) *Bulletin* U108. Values are for aged, unfaced board stock. For change in conductivity with age of expanded polyurethane/polyisocyanurate, see Chapter 23, Factors Affecting Thermal Performance.
- <sup>j</sup> Values are for aged products with gas-impermeable facers on the two major surfaces. An aluminum foil facer of 25  $\mu\text{m}$  thickness or greater is generally considered impermeable to gases. For change in conductivity with age of expanded polyisocyanurate, see Chapter 23, Factors Affecting Thermal Performance, and SPI *Bulletin* U108.
- <sup>k</sup> Cellular phenolic insulation may no longer be manufactured. The thermal conductivity and resistance values do not represent aged insulation, which may have a higher thermal conductivity and lower thermal resistance.
- <sup>l</sup> Insulating values of acoustical tile vary, depending on density of the board and on type, size, and depth of perforations.

- <sup>m</sup> Cavity is framed with 20 mm wood furring strips. Caution should be used in applying this value for other framing materials. The reported value was derived from tests and applies to the reflective path only. The effect of studs or furring strips must be included in determining the overall performance of the wall.
- <sup>n</sup> Values for fully grouted block may be approximated using values for concrete with a similar unit density.
- <sup>o</sup> Values for concrete block and concrete are at moisture contents representative of normal use.
- <sup>p</sup> Values for metal or vinyl siding applied over flat surfaces vary widely, depending on amount of ventilation of airspace beneath the siding; whether airspace is reflective or nonreflective; and on thickness, type, and application of insulating backing-board used. Values are averages for use as design guides, and were obtained from several guarded hot box tests (ASTM C 236) or calibrated hot box (ASTM C 976) on hollow-backed types and types made using backing of wood fiber, foamed plastic, and glass fiber. Departures of  $\pm 50\%$  or more from these values may occur.
- <sup>q</sup> Vinyl specific heat = 1.0 kJ/(kg·K)
- <sup>r</sup> See Adams (1971), MacLean (1941), and Wilkes (1979). The conductivity values listed are for heat transfer across the grain. The thermal conductivity of wood varies linearly with the density, and the density ranges listed are those normally found for the wood species given. If the density of the wood species is not known, use the mean conductivity value. For extrapolation to other moisture contents, the following empirical equation developed by Wilkes (1979) may be used:

$$k = 0.7494 + \frac{(4.895 \times 10^{-3} + 1.503 \times 10^{-4} M)\rho}{1 + 0.01M}$$

where  $\rho$  is density of the moist wood in  $\text{kg/m}^3$ , and  $M$  is the moisture content in percent.

- <sup>s</sup> From Wilkes (1979), an empirical equation for the specific heat of moist wood at 24°C is as follows:

$$c_p = 0.1442 \left[ \frac{(0.299 + 0.01M)}{(1 + 0.01M)} \right] + \Delta c_p$$

where  $\Delta c_p$  accounts for the heat of sorption and is denoted by

$$\Delta c_p = M(0.008037 - 1.325 \times 10^{-4} M)$$

where  $M$  is the moisture content in percent by mass.

Assuming parallel heat flow only, the calculated resistance is higher than that calculated on the assumption of isothermal planes. The actual resistance generally is some value between the two calculated values. In the absence of test values, examination of the construction usually reveals whether a value closer to the higher or lower calculated R-value should be used. Generally, if the construction contains a layer in which lateral conduction is high compared with transmittance through the construction, the calculation with isothermal planes should be used. If the construction has no layer of high lateral conductance, the parallel heat flow calculation should be used.

Hot box tests of insulated and uninsulated masonry walls constructed with block of conventional configuration show that thermal resistances calculated using the isothermal planes heat flow method agree well with measured values (Van Geem 1985, Valore 1980, Shu et al. 1979). Neglecting horizontal mortar joints in conventional block can result in thermal transmittance values up to 16% lower than actual, depending on the density and thermal properties of the masonry, and 1 to 6% lower, depending on the core insulation material (Van Geem 1985, McIntyre 1984). For aerated concrete block walls, other solid masonry, and multicore block walls with full mortar joints, neglecting mortar joints can cause errors in R-values up to 40% (Valore 1988). Horizontal mortar joints usually found in concrete block wall construction are neglected in Example 2.

**Constructions Containing Metal**

Curtain and metal stud-wall constructions often include metallic and other thermal bridges, which can significantly reduce the ther-

mal resistance. However, the capacity of the adjacent facing materials to transmit heat transversely to the metal is limited, and some contact resistance between all materials in contact limits the reduction. Contact resistances in building structures are only 0.01 to 0.1  $\text{K}\cdot\text{m}^2/\text{W}$ —too small to be of concern in many cases. However, the contact resistances of steel framing members may be important. Also, in many cases (as illustrated in Example 3), the area of metal in contact with the facing greatly exceeds the thickness of the metal, which mitigates the contact resistance effects.

Thermal characteristics for panels of sandwich construction can be computed by combining the thermal resistances of the various layers. R-values for the assembled sections should be determined on a representative sample by using a hot box method. If the sample is a wall section with air cavities on both sides of fibrous insulation, the sample must be of representative height since convective airflow can contribute significantly to heat flow through the test section. Computer modeling can also be useful, but all heat transfer mechanisms must be considered.

In Example 3, the metal member is only 0.5 mm thick, but it is in contact with adjacent facings over a 32 mm-wide area. The steel member is 90 mm deep, has a thermal resistance of approximately 0.0019  $\text{K}\cdot\text{m}^2/\text{W}$ , and is virtually isothermal. The calculation involves careful selection of the appropriate thickness for the steel member. If the member is assumed to be 0.5 mm thick, the fact that the flange transmits heat to the adjacent facing is ignored, and the heat flow through the steel is underestimated. If the member is assumed to be 32 mm thick, the heat flow through the steel is overestimated. In Example 3, the steel member behaves in much the same way as a rectangular member 32 mm thick and 90 mm deep

with a thermal resistance of  $0.0019 (32/0.5) = 0.12 \text{ K}\cdot\text{m}^2/\text{W}$  does. The Building Research Association of New Zealand (BRANZ) commonly uses this approximation.

**Example 3.** Calculate the C-factor of the insulated steel frame wall shown in Figure 4. Assume that the steel member has an R-value of  $0.12 \text{ K}\cdot\text{m}^2/\text{W}$  and that the framing behaves as though it occupies approximately 8% of the transmission area.

**Solution.** Obtain the R-values of the various building elements from Table 4.

Element	R (Insul.)	R (Framing)
1. 13 mm gypsum wallboard	0.08	0.08
2. 90 mm mineral fiber batt insulation	1.94	—
3. Steel framing member	—	0.12
4. 13 mm gypsum wallboard	0.08	0.08
	$R_1 = 2.10$	$R_2 = 0.28$

Therefore,  $C_1 = 0.476$ ;  $C_2 = 3.57 \text{ W}/(\text{m}^2\cdot\text{K})$ .

If the steel framing (thermal bridging) is not considered, the C-factor of the wall is calculated using Equation (3) from Chapter 23 as follows:

$$C_{av} = C_1 = 1 / R_1 = 0.476 \text{ W}/(\text{m}^2 \cdot \text{K})$$

If the steel framing is accounted for using the parallel flow method, the C-factor of the wall is determined using Equation (5) from Chapter 23 as follows:

$$C_{av} = (0.92 \times 0.476) + (0.08 \times 3.57) = 0.724 \text{ W}/(\text{m}^2 \cdot \text{K})$$

$$R_{T(av)} = 1.38 \text{ m}^2 \cdot \text{K} / \text{W}$$

If the steel framing is included using the isothermal planes method, the C-factor of the wall is determined using Equations (2) and (3) from Chapter 23 as follows:

$$R_{T(av)} = 0.08 + \frac{1}{(0.92)(1.94) + (0.08 / 0.12)} + 0.08$$

$$= 1.037 \text{ m}^2 \cdot \text{K} / \text{W}$$

$$C_{av} = 0.96 \text{ W}/(\text{m}^2 \cdot \text{K})$$

For this insulated steel frame wall, Farouk and Larson (1983) measured an average R-value of  $1.16 \text{ m}^2\cdot\text{K}/\text{W}$ .

In ASHRAE/IESNA Standard 90.1-1989, one method given for determining the thermal resistance of wall assemblies containing metal framing involves using a parallel path correction factor  $F_c$ , which is listed in Table 8C-2 of the standard. For 38 mm by 90 mm

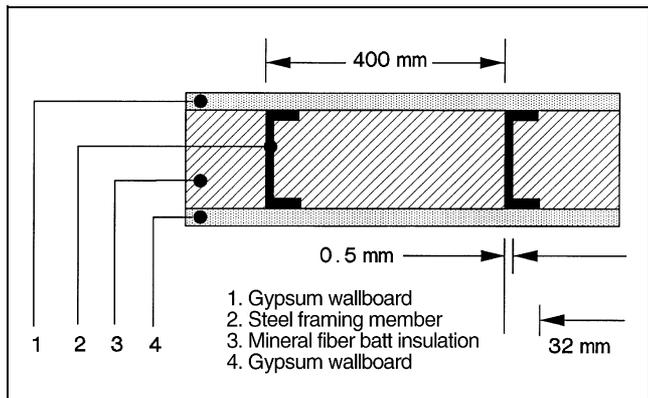

Fig. 4 Insulated Steel Frame Wall (Example 3)

steel framing, 400 mm OC,  $F_c = 0.50$ . Using the correction factor method, an R-value of  $1.13 \text{ m}^2\cdot\text{K}/\text{W}$  ( $0.08 + 1.94 \times 0.50 + 0.08$ ) is obtained for the wall described in Example 3.

**Zone Method of Calculation**

For structures with widely spaced metal members of substantial cross-sectional area, calculation by the isothermal planes method can result in thermal resistance values that are too low. For these constructions, the **zone method** can be used. This method involves two separate computations—one for a chosen limited portion, Zone A, containing the highly conductive element; the other for the remaining portion of simpler construction, Zone B. The two computations are then combined using the parallel flow method, and the average transmittance per unit overall area is calculated. The basic laws of heat transfer are applied by adding the area conductances CA of elements in parallel, and adding area resistances R/A of elements in series.

The surface shape of Zone A is determined by the metal element. For a metal beam (see Figure 5), the Zone A surface is a strip of width W that is centered on the beam. For a rod perpendicular to panel surfaces, it is a circle of diameter W. The value of W is calculated from Equation (1), which is empirical. The value of d should not be less than 13 mm for still air.

$$W = m + 2d \tag{1}$$

where

- m = width or diameter of metal heat path terminal, mm
- d = distance from panel surface to metal, mm

Generally, the value of W should be calculated using Equation (1) for each end of the metal heat path; the larger value, within the limits of the basic area, should be used as illustrated in Example 4.

**Example 4.** Calculate transmittance of the roof deck shown in Figure 5. Tee-bars at 600 mm OC support glass fiber form boards, gypsum concrete, and built-up roofing. Conductivities of components are: steel,  $45 \text{ W}/(\text{m}\cdot\text{K})$ ; gypsum concrete,  $0.24 \text{ W}/(\text{m}\cdot\text{K})$ ; and glass fiber form board,  $0.036 \text{ W}/(\text{m}\cdot\text{K})$ . Conductance of built-up roofing is  $17 \text{ W}/(\text{m}\cdot\text{K})$ .

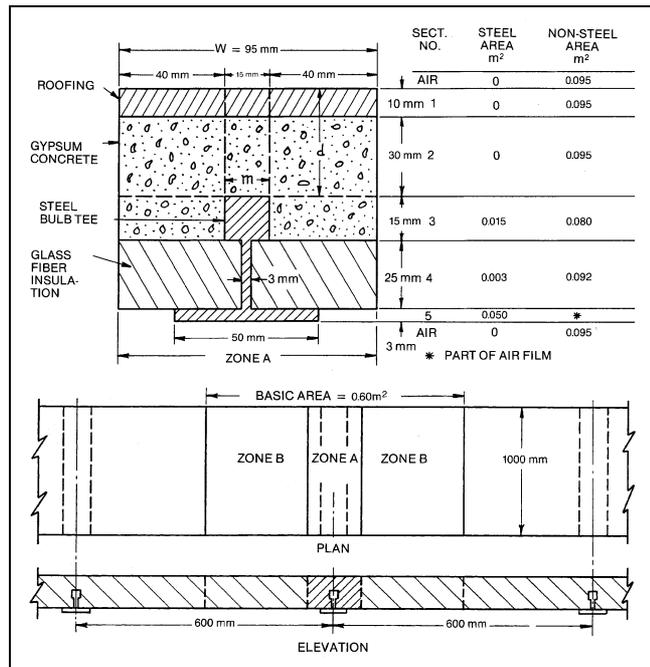

Fig. 5 Gypsum Roof Deck on Bulb Tees (Example 4)

shown in Figure 6, is divided into two zones: the zone of thermal anomalies around metal stud  $w$  and the cavity zone  $cav$ . Wall material layers are grouped into an exterior and interior surface sections—A (sheathing, siding) and B (wallboard)—and interstitial sections I and II (cavity insulation, metal stud flange).

Assuming that the layers or layer of wall materials in wall section A are thicker than those in wall section B, as show by the cross section in Figure 6, they can be described as follows:

$$\sum_{i=1}^n d_i \geq \sum_{j=1}^m d_j \quad (2)$$

where

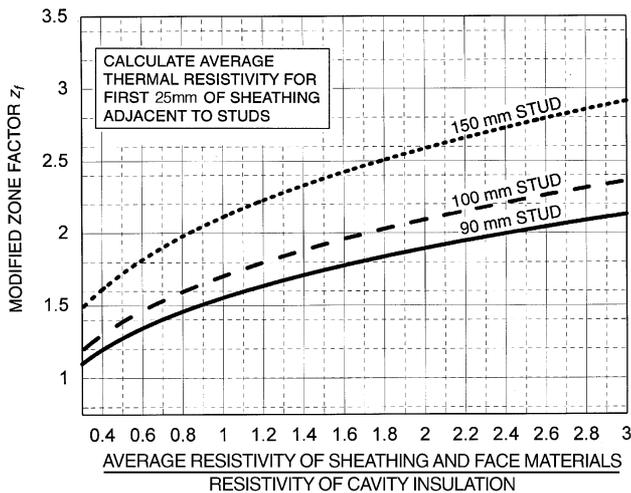

- $n$  = number of material layer (of thickness  $d_i$ ) between metal stud flange and wall surface for section A
- $m$  = number of material layer (of thickness  $d_j$ ) for section B

Then, the width of the zone of thermal anomalies around the metal stud  $w$  can be estimated by

$$w = L + z_f \sum_{i=1}^n d_i \quad (3)$$

where

- $L$  = stud flange size
- $d_i$  = thickness of material layer in section A
- $z_f$  = zone factor, which is shown in Figure 7 ( $z_f = 2$  for zone method)

Use  $z_f = -0.5$  for walls when total thickness of layer of materials attached to one side of metal frame  $\leq 16$  mm and thermal resistivity of sheathing  $\leq 10.4$  m $\cdot$ K/W.

Use  $z_f = -0.5$  for walls when total thickness of layer of materials attached to one side of metal frame  $\leq 16$  mm and thermal resistivity of sheathing  $> 10.4$  m $\cdot$ K/W.

Find  $z_f$  in chart above for walls when total thickness of layer of materials attached to one side of metal frame  $> 16$  mm.

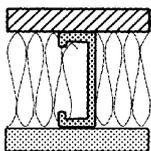

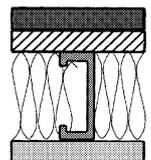

Fig. 7 Modified Zone Factor for Calculating R-Value of Metal Stud Walls with Cavity Insulation

Kosny and Christian (1995) verified the accuracy of the modified zone method for over 200 simulated cases of metal frame walls with insulated cavities. For all configurations considered the discrepancy between results were within  $\pm 2\%$ . Hot box measured R-values for 15 metal stud walls tested by Barbour et al. (1994) were compared with results obtained by Kosny and Christian (1995) and McGowan and Desjarlais (1997). The modified zone method was found to be the most accurate simple method for estimating the clear wall R-value of light-gage steel stud walls with insulated cavities. However, this analysis does not apply to construction with metal sheathing. Also, ASHRAE Standard 90.1 may require a different method of analysis.

### Ceilings and Roofs

The overall R-value for ceilings of wood frame flat roofs can be calculated using Equations (1) through (5) from Chapter 23. Properties of the materials are found in Tables 1, 3, 2, and 4. The fraction of framing is assumed to be 0.10 for joists at 400 mm OC and 0.07 for joists at 600 mm OC. The calculation procedure is similar to that shown in Example 1. Note that if the ceiling contains plane air spaces (see Table 3), the resistance depends on the direction of heat flow, i.e., whether the calculation is for a winter (heat flow up) or summer (heat flow down) condition.

For ceilings of pitched roofs under winter conditions, calculate the R-value of the ceiling using the procedure for flat roofs. Table 5 can be used to determine the effective resistance of the attic space under summer conditions for varying conditions of ventilation air temperature, airflow direction and rates, ceiling resistance, roof or sol-air temperatures, and surface emittances (Joy 1958).

The R-value is the total resistance obtained by adding the ceiling and effective attic resistances. The applicable temperature difference is that difference between room air and sol-air temperatures or between room air and roof temperatures (see Table 5, footnote f). Table 5 can be used for pitched and flat residential roofs over attic spaces. When an attic has a floor, the ceiling resistance should account for the complete ceiling-floor construction.

### Windows and Doors

Table 4 of Chapter 30 lists U-factors for various fenestration products. Table 6 lists U-factors for exterior wood and steel doors. All U-factors are approximate, because a significant portion of the resistance of a window or door is contained in the air film resistances, and some parameters that may have important effects are not considered. For example, the listed U-factors assume the surface temperatures of surrounding bodies are equal to the ambient air temperature. However, the indoor surface of a window or door in an actual installation may be exposed to nearby radiating surfaces, such as radiant heating panels, or opposite walls with much higher or lower temperatures than the indoor air. Air movement across the indoor surface of a window or door, such as that caused by nearby heating and cooling outlet grilles, increases the U-factor; and air movement (wind) across the outdoor surface of a window or door also increases the U-factor.

#### $U_o$ Concept

$U_o$  is the combined thermal transmittance of the respective areas of gross exterior wall, roof or ceiling or both, and floor assemblies. The  $U_o$  equation for a wall is as follows:

$$U_o = (U_{wall}A_{wall} + U_{window}A_{window} + U_{door}A_{door}) / A_o \quad (4)$$

where

- $U_o$  = average thermal transmittance of gross wall area
- $A_o$  = gross area of exterior walls

Table 5 Effective Thermal Resistance of Ventilated Attics<sup>a</sup> (Summer Condition)

<sup>a</sup>Although the term effective resistance is commonly used when there is attic ventilation, this table includes values for situations with no ventilation. The effective resistance of the attic added to the resistance ( $1/U$ ) of the ceiling yields the effective resistance of this combination based on sol-air (see Chapter 29) and room temperatures. These values apply to wood frame construction with a roof deck and roofing that has a conductance of 5.7 W/(m<sup>2</sup>·K).  
<sup>b</sup>This condition cannot be achieved in the field unless extreme measures are taken to tightly seal the attic.

<sup>c</sup>Based on air discharging outward from attic.  
<sup>d</sup>When attic ventilation meets the requirements stated in Chapter 26, 0.5 L/s per square metre is assumed as the natural summer ventilation rate.  
<sup>e</sup>When determining ceiling resistance, do not add the effect of a reflective surface facing the attic, as it is accounted for in the Reflective Surface part of this table.  
<sup>f</sup>Roof surface temperature rather than sol-air temperature (see Chapter 29) can be used if 0.04 is subtracted from the attic resistance shown.  
<sup>g</sup>Surfaces with effective emittance  $\epsilon_{eff} = 0.05$  between ceiling joists facing attic space.

Table 6 Transmission Coefficients  $U$  for Wood and Steel Doors, W/(m<sup>2</sup>·K)

Nominal Door Thickness, mm	Description	No Storm Door	Wood Storm Door <sup>c</sup>	Metal Storm Door <sup>d</sup>
<b>Wood Doors<sup>a,b</sup></b>				
35	Panel door with 11 mm panels <sup>e</sup>	3.24	1.87	2.10
35	Hollow core flush door	2.67	1.70	1.82
35	Solid core flush door	2.21	1.48	1.59
45	Panel door with 11 mm panels <sup>e</sup>	3.07	1.82	2.04
45	Hollow core flush door	2.61	1.65	1.82
45	Panel door with 29 mm panels <sup>e</sup>	2.21	1.48	1.59
45	Solid core flush door	2.27	—	1.48
57	Solid core flush door	1.53	1.14	1.19
<b>Steel Doors<sup>b</sup></b>				
45	Fiberglass or mineral wool core with steel stiffeners, no thermal break <sup>f</sup>	3.41	—	—

45	Polystyrene core without thermal break [18 gage (1.31 mm) commercial steel] <sup>f</sup>	1.99	—	—
45	Polyurethane core without thermal break (18 gage commercial steel) <sup>f</sup>	1.65	—	—
45	Polyurethane core without thermal break [24 gage (0.70 mm) residential steel] <sup>f</sup>	1.65	—	—
45	Polyurethane core with thermal break and wood perimeter (24 gage residential steel) <sup>f</sup>	1.14	—	—
45	Solid urethane foam core with thermal break <sup>a</sup>	1.14	—	0.91

Note: All U-factors for exterior doors in this table are for doors with no glazing, except for the storm doors which are in addition to the main exterior door. Any glazing area in exterior doors should be included with the appropriate glass type and analyzed as a window (see Chapter 30). Interpolation and moderate extrapolation are permitted for door thicknesses other than those specified.  
<sup>a</sup>Values are based on a nominal 810 mm by 2030 mm door size with no glazing.

<sup>b</sup>Outside air conditions: 24 km/h wind speed, -18°C air temperature; inside air conditions: natural convection, 21°C air temperature.  
<sup>c</sup>Values for wood storm door are for approximately 50% glass area.  
<sup>d</sup>Values for metal storm door are for any percent glass area.  
<sup>e</sup>55% panel area.  
<sup>f</sup>ASTM C 236 hot box data on a nominal 910 mm by 2130 mm door size with no glazing.

$U_{wall}$  = thermal transmittance of all elements of opaque wall area  
 $A_{wall}$  = opaque wall area  
 $U_{window}$  = thermal transmittance of window area (including frame)  
 $A_{window}$  = window area (including frame)  
 $U_{door}$  = thermal transmittance of door area  
 $A_{door}$  = door area (including frame)

Where more than one type of wall, window, or door is used, the  $UA$  term for that exposure should be expanded into its subelements, as shown in Equation (3).

$$\begin{aligned}
 U_o A_o &= U_{wall 1} A_{wall 1} + U_{wall 2} A_{wall 2} + \dots + U_{wall m} A_{wall m} \\
 &+ U_{window 1} A_{window 1} + U_{window 2} A_{window 2} + \dots \\
 &+ U_{window n} A_{window n} + U_{door 1} A_{door 1} \\
 &+ U_{door 2} A_{door 2} + \dots + U_{door o} A_{door o}
 \end{aligned} \quad (5)$$

**Example 5.** Calculate  $U_o$  for a wall 10 m by 2.4 m, constructed as in Example 1. The wall contains two double-glazed (12.7 mm airspace) fixed windows with wood/vinyl frames. (From Table 4 in Chapter 30,  $U = 2.98 \text{ W}/(\text{m}^2 \cdot \text{K})$ .) One window is 1500 mm by 860 mm and the second 900 mm by 760 mm. The wall also contains a 45 mm solid core flush door with a metal storm door 860 mm by 2000 mm ( $U = 1.42 \text{ W}/(\text{m}^2 \cdot \text{K})$  from Table 6).

**Solution:** The U-factor for the wall was obtained in Example 1. The areas of the different components are

$$A_{window} = (1.500 \times 0.860) + (0.900 \times 0.760) = 1.97 \text{ m}^2$$

$$A_{door} = (0.860 \times 2.000) = 1.72 \text{ m}^2$$

$$A_{wall} = (10 \times 2.4) - (1.97 + 1.72) = 20.31 \text{ m}^2$$

Therefore, the combined thermal transmittance for the wall is

$$\begin{aligned}
 U_o &= \frac{(0.404 \times 20.31) + (2.90 \times 1.97) + (1.42 \times 1.72)}{10 \times 2.4} \\
 &= 0.68 \text{ W}/(\text{m}^2 \cdot \text{K})
 \end{aligned}$$

### Slab-on-Grade and Below-Grade Construction

Heat transfer through basement walls and floors to the ground depends on the following factors: (1) the difference between the air temperature within the room and that of the ground and outside air, (2) the material of the walls or floor, and (3) the thermal conductivity of the surrounding earth. The latter varies with local conditions and is usually unknown. Because of the great thermal inertia of the surrounding soil, ground temperature varies with depth, and there is a substantial time lag between changes in outdoor air temperatures and corresponding changes in ground temperatures. As a result, ground-coupled heat transfer is less amenable to steady-state representation than above-grade building elements. However, several simplified procedures for estimating ground-coupled heat transfer have been developed. These fall into two principal categories: (1) those that reduce the ground heat transfer problem to a closed form solution, and (2) those that use simple regression equations developed from statistically reduced multidimensional transient analyses.

Closed form solutions, including the ASHRAE arc-length procedure discussed in Chapter 28 by Latta and Boileau (1969), generally reduce the problem to one-dimensional, steady-state heat transfer. These procedures use simple, "effective" U-factors or ground temperatures or both. Methods differ in the various parameters averaged or manipulated to obtain these effective values. Closed form solutions provide acceptable results in climates that have a single dominant season, because the dominant season persists long enough to permit a reasonable approximation of steady-state conditions at shallow depths. The large errors (percentage) that are likely during transition seasons should not seriously affect

building design decisions, since these heat flows are relatively insignificant when compared with those of the principal season.

The ASHRAE arc-length procedure is a reliable method for wall heat losses in cold winter climates. Chapter 28 discusses a slab-on-grade floor model developed by one study. Although both procedures give results comparable to transient computer solutions for cold climates, their results for warmer U.S. climates differ substantially.

Research conducted by Hougten et al. (1942) and Dill et al. (1945) indicates a heat flow of approximately  $6.3 \text{ W}/\text{m}^2$  through an uninsulated concrete basement floor with a temperature difference of 11 K between the basement floor and the air 150 mm above it. A U-factor of  $5.7 \text{ W}/(\text{m}^2 \cdot \text{K})$  is sometimes used for concrete basement floors on the ground. For basement walls below grade, the temperature difference for winter design conditions is greater than for the floor. Test results indicate that at the midheight of the below-grade portion of the basement wall, the unit area heat loss is approximately twice that of the floor.

For concrete slab floors in contact with the ground at grade level, tests indicate that for small floor areas (equal to that of a 7.5 m by 7.5 m house) the heat loss can be calculated as proportional to the length of exposed edge rather than total area. This amounts to 1.40 W per linear metre of exposed edge per degree Celsius difference between the indoor air temperature and the average outdoor air temperature. This value can be reduced appreciably by installing insulation under the ground slab and along the edge between the floor and abutting walls. In most calculations, if the perimeter loss is calculated accurately, no other floor losses need to be considered. Chapter 28 contains data for load calculations and heat loss values for below-grade walls and floors at different depths.

The second category of simplified procedures uses transient two-dimensional computer models to generate the ground heat transfer data that are then reduced to compact form by regression analysis (Mitalas 1982, 1983; Shipp 1983). These are the most accurate procedures available, but the database is very expensive to generate. In addition, these methods are limited to the range of climates and constructions specifically examined. Extrapolating beyond the outer bounds of the regression surfaces can produce significant errors.

### Apparent Thermal Conductivity of Soil

Effective or apparent soil thermal conductivity is difficult to estimate precisely and may change substantially in the same soil at different times due to changed moisture conditions and the presence of freezing temperatures in the soil. Figure 8 shows the typical apparent soil thermal conductivity as a function of moisture content for different general types of soil. The figure is based on data presented in Salomone and Marlowe (1989) using envelopes of thermal behavior coupled with field moisture content ranges for different soil types. In Figure 8, the term well-graded applies to granular soils with good representation of all particle sizes from largest to smallest. The term poorly graded refers to granular soils with either a uniform gradation, in which most particles are about the same size, or a skip (or gap) gradation, in which particles of one or more intermediate sizes are not present.

Although thermal conductivity varies greatly over the complete range of possible moisture contents for a soil, this range can be narrowed if it is assumed that the moisture contents of most field soils lie between the "wilting point" of the soil (i.e., the moisture content of a soil below which a plant cannot alleviate its wilting symptoms) and the "field capacity" of the soil (i.e., the moisture content of a soil that has been thoroughly wetted and then drained until the drainage rate has become negligibly small). After a prolonged dry spell, the moisture will be near the wilting point, and after a rainy period, the soil will have a moisture content near its field capacity. The moisture contents at these limits have been studied by many agricultural researchers, and data for different types of soil are given by Salomone and Marlowe (1989) and Kersten (1949). The shaded

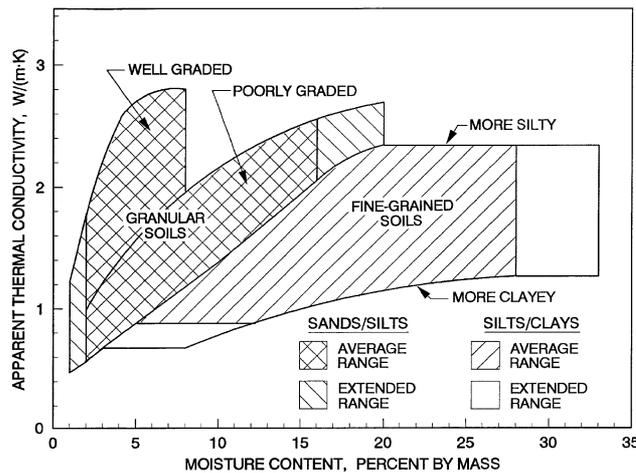

Fig. 8 Trends of Apparent Thermal Conductivity of Moist Soils

Table 7 Typical Apparent Thermal Conductivity Values for Soils, W/(m<sup>2</sup> · K)

	Normal Range	Recommended Values for Design <sup>a</sup>	
		Low <sup>b</sup>	High <sup>c</sup>
Sands	0.6 to 2.5	0.78	2.25
Silts	0.9 to 2.5	1.64	2.25
Clays	0.9 to 1.6	1.12	1.56
Loams	0.9 to 2.5	0.95	2.25

<sup>a</sup>Reasonable values for use when no site- or soil-specific data are available.  
<sup>b</sup>Moderately conservative values for minimum heat loss through soil (e.g., use in soil heat exchanger or earth-contact cooling calculations). Values are from Salomone and Marlowe (1989).  
<sup>c</sup>Moderately conservative values for maximum heat loss through soil (e.g., use in peak winter heat loss calculations). Values are from Salomone and Marlowe (1989).

Table 8 Typical Apparent Thermal Conductivity Values for Rocks, W/(m<sup>2</sup> · K)

	Normal Range
Pumice, tuff, obsidian	0.5 to 2.2
Basalt	0.5 to 2.6
Shale	0.9 to 4.0
Granite	1.7 to 4.3
Limestone, dolomite, marble	1.2 to 4.3
Quartzose sandstone	1.4 to 7.8

areas on Figure 8 approximate (1) the full range of moisture contents for different soil types and (2) a range between average values of each limit.

Table 7 gives a summary of design values for thermal conductivities of the basic soil classes. Table 8 gives ranges of thermal conductivity for some basic classes of rock. The value chosen depends on whether heat transfer is being calculated for minimum heat loss through the soil, as in a ground heat exchange system, or a maximum value, as in peak winter heat loss calculations for a basement. Hence, a high and a low value are given for each soil class.

As heat flows through the soil, the moisture tends to move away from the source of heat. This moisture migration provides initial mass transport of heat, but it also dries the soil adjacent to the heat source, hence lowering the apparent thermal conductivity in that zone of soil.

Trends typical in a soil when other factors are held constant are:

- *k* increases with moisture content
- *k* increases with increasing dry density of a soil
- *k* decreases with increasing organic content of a soil
- *k* tends to decrease for soils with uniform gradations and rounded soil grains (because the grain-to-grain contacts are reduced)
- *k* of a frozen soil may be higher or lower than that of the same unfrozen soil (because the conductivity of ice is higher than that of water but lower than that of the typical soil grains). Differences in *k* below moisture contents of 7 to 8% are quite small. At approximately 15% moisture content, differences in *k*-factors may vary up to 30% from unfrozen values.

When calculating annual energy use, values that represent typical site conditions as they vary during the year should be chosen. In climates where ground freezing is significant, accurate heat transfer simulations should include the effect of the latent heat of fusion of water. The energy released during this phase change significantly retards the progress of the frost front in moist soils.

### Water Vapor Transmission Data for Building Components

Table 9 gives typical water vapor permeance and permeability values for common building materials. These values can be used to calculate water vapor flow through building components and assemblies using equations in Chapter 23.

## MECHANICAL AND INDUSTRIAL SYSTEMS

### Thermal Transmission Data

Table 10 lists the thermal conductivities of various materials used as industrial insulations. These values are functions of the arithmetic mean of the temperatures of the inner and outer surfaces for each insulation.

### Heat Loss from Pipes and Flat Surfaces

Tables 11A, 11B, and 12 give heat losses from bare steel pipes and flat surfaces and bare copper tubes. These tables were calculated using ASTM Standard C 680. User inputs for the programs described in the standard include operating temperature, ambient temperature, pipe size, insulation type, number of insulation layers, and thickness for each layer. A program option allows the user to input a surface coefficient or surface emittance, surface orientation, and wind speed. The computer uses this information to calculate the heat flow and the surface temperature. The programs calculate the surface coefficients if the user has not already supplied them.

The equations used in ASTM C 680 are

$$h_{cv} = C \left( \frac{1}{d} \right)^{0.2} \left( \frac{1}{T_{avg}} \right)^{0.181} (\Delta T^{0.266}) \sqrt{1 + 0.7935(\text{Wind})} \quad (6)$$

where

$h_{cv}$  = convection surface coefficient, W/(m<sup>2</sup> · K)  
 $d$  = diameter for cylinder, mm. For flat surfaces and large cylinders ( $d > 600$  mm), use  $d = 600$  mm.

$T_{avg}$  = average temperature of air film =  $(T_a + T_s)/2$ , K

$T_a$  = temperature of ambient air, K

$T_s$  = temperature of surface, K

$\Delta T$  = surface to air temperature difference, K

Wind = air speed, km/h

$C$  = constant depending on shape and heat flow condition

= 11.58 for horizontal cylinders

= 14.08 for longer vertical cylinders

= 15.89 for vertical plates

= 20.40 for horizontal plates, warmer than air, facing upward

= 10.15 for horizontal plates, warmer than air, facing downward

= 10.15 for horizontal plates, cooler than air, facing upward

= 20.40 for horizontal plates, cooler than air, facing downward

Table 9 Typical Water Vapor Permeance and Permeability Values for Common Building Materials<sup>a</sup>

$$h_{rad} = \frac{\epsilon \sigma (T_a^4 - T_s^4)}{T_a - T_s} \quad (7)$$

where

$h_{rad}$  = radiation surface coefficient, W/(m<sup>2</sup>·K)

$\epsilon$  = surface emittance

$\sigma$  = Stefan-Boltzmann constant =  $5.4 \times 10^{-8}$  W/(m<sup>2</sup>·K<sup>4</sup>)

**Example 6.** Compute the total annual heat loss from 50 m of nominal 50 mm bare steel pipe in service 4000 h per year. The pipe is carrying steam at 70 kPa (gauge) and is exposed to an average air temperature of 27°C.

**Solution:** The pipe temperature is taken as the steam temperature, which is 115.2°C, obtained by interpolation from Steam Tables. By interpolation in Table 11A between 82 and 138°C, heat loss from a nominal 50 mm pipe is 274 W/m. Total annual heat loss from the entire line is  $274 \times 50 \times 4000 \times 3600 = 197$  GJ.

In calculating heat flow, Equations (8) and (9) from Chapter 23 generally are used. For dimensions of standard pipe and fitting sizes, refer to the *Piping Handbook*. For insulation product dimensions, refer to ASTM *Standard C 585*, or to the insulation manufacturers' literature.

<sup>a</sup>This table permits comparisons of materials; but in the selection of vapor retarder materials, exact values for permeance or permeability should be obtained from the manufacturer or from laboratory tests. The values shown indicate variations among mean values for materials that are similar but of different density, orientation, lot, or source. The values should not be used as design or specification data. Values from dry-cup and wet-cup methods were usually obtained from investigations using ASTM E 96 and C 355; values shown under others were obtained by two-temperature, special cell, and air velocity methods.

<sup>b</sup>Depending on construction and direction of vapor flow.

<sup>c</sup>Usually installed as vapor retarders, although sometimes used as an exterior finish and elsewhere near the cold side, where special considerations are then required for warm side barrier effectiveness.

<sup>d</sup>Dry-cup method.

<sup>e</sup>Wet-cup method.

<sup>f</sup>Other than dry- or wet-cup method.

<sup>g</sup>Low permeance sheets used as vapor retarders. High permeance used elsewhere in construction.

<sup>h</sup>Resistance and resistance/mm values have been calculated as the reciprocal of the permeance and permeability values.

<sup>i</sup>Cast at 0.25 mm wet film thickness.

<sup>a</sup>Representative values for dry materials, which are intended as design (not specification) values for materials in normal use. Insulation materials in actual service may have thermal values that vary from design values depending on their in-situ properties (e.g., density and moisture content). For properties of a particular product, use the value supplied by the manufacturer or by unbiased tests.

<sup>b</sup>These temperatures are generally accepted as maximum. When operating temperature approaches these limits, follow the manufacturers' recommendations.

<sup>c</sup>Some polyurethane foams are formed by means that produce a stable product (with respect to *k*), but most are blown with refrigerant and will change with time.

<sup>d</sup>See Table 4, footnote i.

<sup>e</sup>See Table 4, footnote j.

Examples 7 and 8 illustrate how Equations (8) and (9) from Chapter 23 can be used to determine heat loss from both flat and cylindrical surfaces. Figure 9 shows surface resistance as a function of heat transmission for both flat and cylindrical surfaces. The surface emittance is assumed to be 0.85 to 0.90 in still air at 27°C.

**Example 7.** Compute the heat loss from a boiler wall if the interior insulation surface temperature is 600°C and ambient still air temperature is 27°C. The wall is insulated with 115 mm of mineral fiber block and 13 mm of mineral fiber insulating and finishing cement.

**Solution:** Assume that the mean temperature of the mineral fiber block is 370°C, the mean temperature of the insulating cement is 93°C, and the surface resistance  $R_s$  is 0.11 m<sup>2</sup>·K/W.

From Table 10,  $k_1 = 0.089$  and  $k_2 = 0.115$ . Using Equation (8) from Chapter 23,

$$q_s = \frac{600 - 27}{(0.115 / 0.089) + (0.013 / 0.115) + 0.11} = 378 \text{ W/m}^2$$

As a check, from Figure 9, at 378 W/m<sup>2</sup>,  $R_s \cong 0.10$ . The mean temperature of the mineral fiber block is

$$0.115 / 0.089 = 1.292; 1.292 / 2 = 0.646$$

$$600 - \frac{0.646}{1.505}(600 - 27) = 354^\circ\text{C}$$

and the mean temperature of the insulating cement is

$$0.013 / 0.115 = 0.113; 0.113 / 2 = 0.057; 1.292 - 0.057 = 1.345$$

$$600 - \frac{1.349}{1.505}(600 - 27) = 87^\circ\text{C}$$

From Table 10, at 354°C,  $k_1 = 0.087$ ; at 87°C,  $k_2 = 0.114$ .

Using these adjusted values to recalculate  $q_s$ ,

$$q_s = \frac{573}{(0.115 / 0.087) + (0.013 / 0.114) + 0.11} = 372.1 \text{ W/m}^2$$

From Figure 9, at 373 W/m<sup>2</sup>,  $R_s = 0.10$ . The mean temperature of the mineral fiber block is

$$0.115 / 0.087 = 1.322; 1.322 / 2 = 0.661$$

$$600 - \frac{0.661}{1.536}573 = 353^\circ\text{C}$$

and the mean temperature of the insulating cement is

$$0.013 / 0.114 = 0.1140; 0.1140 / 2 = 0.057; 1.322 + 0.057 = 1.379$$

$$600 - \frac{1.379}{1.536}573 = 86^\circ\text{C}$$

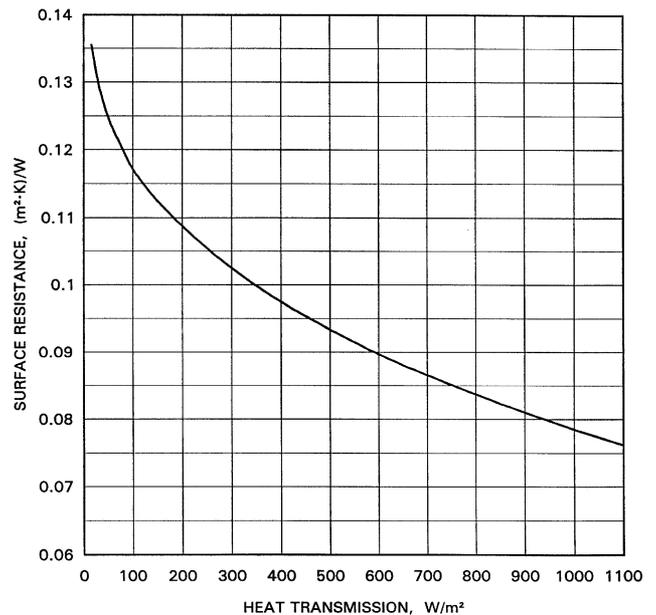

From Table 10, at 353°C,  $k_1 = 0.087$ ; at 86°C,  $k_2 = 0.114$ .

Because  $R_s$ ,  $k_1$ , and  $k_2$  do not change at these values,  $q_s = 373.1$  W/m<sup>2</sup>.

**Example 8.** Compute heat loss per square foot of outer surface of insulation if pipe temperature is 650°C and ambient still air temperature is 27°C. The pipe is nominal 150 mm steel pipe, insulated with a nominal 75 mm thick diatomaceous silica as the inner layer and a nominal 50 mm thick calcium silicate as the outer layer.

**Solution:** From Chapter 41 of the 2000 ASHRAE Handbook—Equipment,  $r_o = 84.1$  mm. A nominal 75 mm thick diatomaceous silica insulation to fit a nominal 150 mm steel pipe is 76.7 mm thick. A nominal 50 mm thick calcium silicate insulation to fit over the 52.8 mm diatomaceous silica is 52.8 mm thick. Therefore,  $r_i = 160.8$  mm and  $r_s = 213.6$  mm.

Assume that the mean temperature of the diatomaceous silica is 315°C, the mean temperature of the calcium silicate is 120°C and the surface resistance  $R_s$  is 0.09. From Table 10,  $k_1 = 0.095$ ;  $k_2 = 0.060$ . By Equation (9) from Chapter 23,

**Fig. 9** Surface Resistance as Function of Heat Transmission for Flat Surfaces and Cylindrical Surfaces Greater than 600 mm in Diameter

$$q_s = \frac{650 - 27}{\frac{0.2136 \ln(160.8 / 84.1)}{0.095} + \frac{0.2136 \ln(213.6 / 160.8)}{0.060} + 0.09} = \frac{623}{(1.457 + 1.011 + 0.09)} = 243 \text{ W/m}^2$$

From Figure 9, at 2.43 W/m<sup>2</sup>,  $R_s = 0.11$ . The mean temperature of the diatomaceous silica is

$$2136 \ln(160.8 / 84.1) / 0.095 = 1.46; 1.46 / 2 = 0.7$$

$$650 - \frac{(650 - 27)0.73}{1.457 + 1.011 + 0.11} = 474^\circ\text{C}$$

and the mean temperature of the calcium silicate is

$$\frac{0.2136 \ln(213.6 / 160.8)}{0.060} = 1.01; \frac{1.01}{2} = 0.51; 1.46 + 0.51 = 1.97$$

$$650 - \frac{(650 - 27)1.97}{1.457 + 1.011 + 0.11} = 174^\circ\text{C}$$

From Table 10,  $k_1 = 0.104$ ;  $k_2 = 0.066$ . Recalculating,

$$q_s = \frac{623}{\frac{0.2136 \ln(160.8 / 84.1)}{0.104} + \frac{0.2136 \ln(213.6 / 160.8)}{0.066} + 0.11} = 264 \text{ W/m}^2$$

From Figure 9 at 264 W/m<sup>2</sup>,  $R_s = 0.11$ . The mean temperature of the diatomaceous silica is

$$\frac{0.2136 \ln(160.8 / 84.1)}{0.104} = 1.33; \frac{1.33}{2} = 0.665$$

$$650 - \frac{0.665 / 2.360}{623} = 474^\circ\text{C}$$

and the mean temperature of the calcium silicate is

$$\frac{0.2136 \ln(213.6 / 160.8)}{0.066} = 0.919; \frac{0.919}{2} = 0.46; 1.33 + 0.46 = 1.79$$

$$650 - \frac{1.79}{2.360}623 = 177^\circ\text{C}$$

<sup>a</sup>Calculations from ASTM C680; steel:  $k = 45.3 \text{ W/(m}^2 \cdot \text{K)}$ ;  $\varepsilon = 0.94$ .

<sup>b</sup>Losses per square metre of pipe for pipes larger than 600 mm can be considered the same as losses per square metre for 600 mm pipe.

From Table 10, at 474°C,  $k_1 = 0.104$ ; at 177°C,  $k_2 = 0.066$ . Since  $R_s$ ,  $k_1$ , and  $k_2$  do not change at 264 W/m<sup>2</sup>, this value is  $q_s$ . The heat flow per square metre of the inner surface of the insulation is

$$q_o = q_s(r_s / r_o) = 264(213.6 / 84.1) = 6701 \text{ W/m}^2$$

Because trial-and-error techniques are tedious, the computer programs previously described should be used to estimate heat flows per unit area of flat surfaces or per unit length of piping, and interface temperatures including surface temperatures.

Several methods can be used to determine the most effective thickness of insulation for piping and equipment. Table 13 shows the recommended insulation thicknesses for three different pipe and equipment insulations. Installed cost data can be developed using procedures described by the Federal Energy Administration (1976). Computer programs capable of calculating thickness information are available from several sources. Also, manufacturers of insulations offer computerized analysis programs for designers and owners to evaluate insulation requirements. For more information on determining economic insulation thickness, see Chapter 23.

Chapters 3 and 23 give guidance concerning process control, personnel protection, condensation control, and economics. For specific information on sizes of commercially available pipe insulation, see ASTM *Standard C 585* and consult with the North American Insulation Manufacturers Association (NAIMA) and its member companies.

### CALCULATING HEAT FLOW FOR BURIED PIPELINES

In calculating heat flow to or from buried pipelines, the thermal properties of the soil must be assumed. Table 7 gives the apparent thermal conductivity values of various soil types, and Figure 8 shows the typical trends of apparent soil thermal conductivity with moisture content for various soil types. Table 8 provides ranges of apparent thermal conductivity for various types of rock. Kernsten (1949) also discusses thermal properties of soils. Carslaw and Jaeger (1959) give methods for calculating the heat flow taking place between one or more buried cylinders and the surroundings.

**P**ROVIDING a comfortable and healthy indoor environment for building occupants is the primary concern of HVAC engineers. Comfort and indoor air quality (IAQ) depend on many factors, including thermal regulation, control of internal and external sources of pollutants, supply of acceptable air, removal of unacceptable air, occupants' activities and preferences, and proper operation and maintenance of building systems. Ventilation and infiltration are only part of the acceptable indoor air quality and thermal comfort problem. HVAC designers, occupants, and building owners must be aware of and address other factors as well. Choosing appropriate ventilation and infiltration rates to solve thermal comfort problems and to reduce energy consumption can affect indoor air quality and may be against code, so such procedures should be approached with care and be under the direction of a registered professional engineer with expertise in HVAC analysis and design.

HVAC design engineers and others concerned with building ventilation and indoor air quality should obtain a copy of *ASHRAE Standard 62*. This standard is reviewed regularly and contains ventilation design and evaluation requirements for commercial and residential buildings. In the design of a new building or the analysis of an existing building, the version of *Standard 62* that has been adopted by the local code authority must be determined. An existing building may be required to meet current code, or it may be grandfathered under an older code. If a project involves infiltration in residences, then *ASHRAE Standards 119* and *136* should be consulted. The last chapter of each year's *ASHRAE Handbook* (Chapter 39 of this volume) has a list of current standards.

This chapter focuses on commercial and institutional buildings, where ventilation concerns usually dominate, and on single- and multifamily residences, where infiltration is important. The basic concepts and terminology for both are presented before more advanced analytical and design techniques are given. Ventilation of industrial buildings is covered in Chapter 28 of the 1999 *ASHRAE Handbook—Applications*. However, many of the fundamental ideas and terminology covered in this chapter can also be applied to industrial buildings.

### BASIC CONCEPTS AND TERMINOLOGY

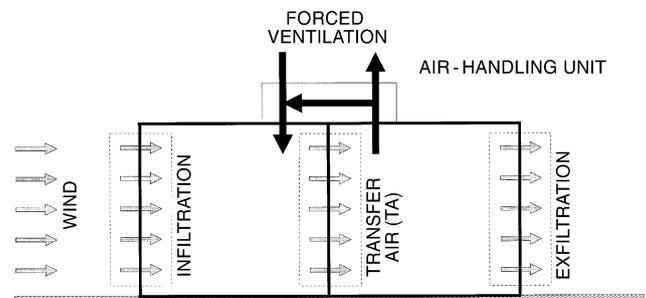

Outdoor air that flows through a building is often used to dilute and remove indoor air contaminants. However, the energy required to condition this outdoor air can be a significant portion of the total space-conditioning load. The magnitude of the outdoor airflow into the building must be known for proper sizing of the HVAC equipment and evaluation of energy consumption. For buildings without mechanical cooling and dehumidification, proper ventilation and infiltration airflows are important for providing comfort

for occupants. *ASHRAE Standard 55* specifies conditions under which 80% or more of the occupants in a space will find it thermally acceptable. Chapter 8 of this volume also addresses thermal comfort. Additionally, the flow of air into buildings and between zones will affect fires and the movement of smoke. Smoke management is addressed in Chapter 51 of the 1999 *ASHRAE Handbook—Applications*.

### Ventilation and Infiltration

**Air exchange** of outdoor air with the air already in a building can be divided into two broad classifications: ventilation and infiltration. **Ventilation air** is air used to provide acceptable indoor air quality. It may be composed of forced or natural ventilation, infiltration, suitably treated recirculated air, transfer air, or an appropriate combination (*ASHRAE Standard 62*). **Ventilation** includes the intentional introduction of air from the outside into a building; it is further subdivided into natural ventilation and forced ventilation. **Natural ventilation** is the flow of air through open windows, doors, grilles, and other planned building envelope penetrations, and it is driven by natural and/or artificially produced pressure differentials. **Forced ventilation**, shown in Figure 1, is the intentional movement of air into and out of a building using fans and intake and exhaust vents; it is also called **mechanical ventilation**.

**Infiltration** is the flow of outdoor air into a building through cracks and other unintentional openings and through the normal use of exterior doors for entrance and egress. Infiltration is also known as **air leakage** into a building. **Exfiltration**, depicted in Figure 1, is the leakage of indoor air out of a building through similar types of openings. Like natural ventilation, infiltration and exfiltration are driven by natural and/or artificial pressure differences. These forces are discussed in detail in the section on Driving Mechanisms for Ventilation and Infiltration. **Transfer air** is air that moves from one interior space to another, either intentionally or not.

**Fig. 1 Two-Space Building with Forced Ventilation, Infiltration, and Exfiltration**

The preparation of this chapter is assigned to TC 4.3, Ventilation Requirements and Infiltration.

These modes of air exchange differ significantly in how they affect energy consumption, air quality, and thermal comfort, and they can each vary with weather conditions, building operation, and use. Although one mode may be expected to dominate in a particular building, all must be considered for the proper design and operation of an HVAC system.

Modern commercial and institutional buildings are normally required to have forced ventilation and are usually pressurized somewhat to reduce or eliminate infiltration. Forced ventilation has the greatest potential for control of air exchange when the system is properly designed, installed, and operated; it should provide acceptable indoor air quality and thermal comfort when ASHRAE *Standard 62* and *Standard 55* requirements are followed. Forced ventilation equipment and systems are described in Chapters 1, 2, and 9 of the 2000 *ASHRAE Handbook—Systems and Equipment*.

In commercial and institutional buildings, natural ventilation, such as through operable windows, may not be desirable from the point of view of energy conservation and comfort. In commercial and institutional buildings with mechanical cooling and forced ventilation, an air- or water-side economizer cycle may be preferable to operable windows for taking advantage of cool outdoor conditions when interior cooling is required. Infiltration may be significant in commercial and institutional buildings, especially in tall, leaky, or partially pressurized buildings and in lobby areas.

In most of the United States, residential buildings typically rely on infiltration and natural ventilation to meet their ventilation needs. Neither is reliable for ventilation purposes, because they depend on weather conditions, building construction, and maintenance. However, natural ventilation, usually through operable windows, is more likely to allow occupants to control airborne contaminants and interior air temperature, but it can have a substantial energy cost if used while the residence's heating or cooling equipment is operating.

In place of operable windows, small exhaust fans may be provided for localized venting in residential spaces such as kitchens and bathrooms. Not all local building codes require that the exhaust be vented to the outside. Instead, the code may allow the air to be treated and returned to the space or to be discharged to an attic space. Poor maintenance of these treatment devices can make nonducted vents ineffective for ventilation purposes. Condensation in attics should be avoided. In northern Europe and in Canada, some building codes require general forced ventilation in residences, and heat recovery heat exchangers are popular for reducing the energy impact. Residential buildings with low rates of infiltration and natural ventilation require forced ventilation at rates given in ASHRAE *Standard 62*.

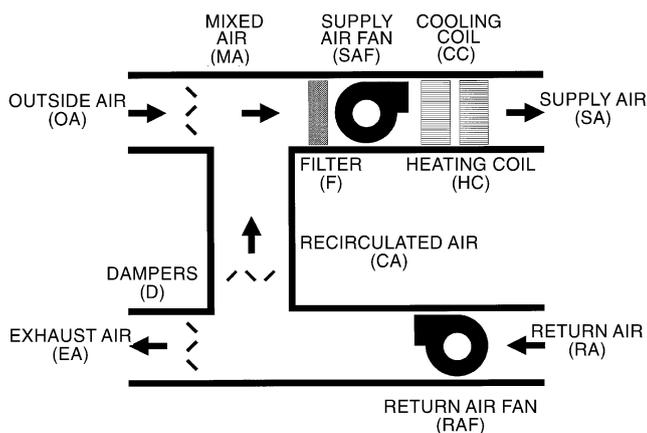

Fig. 2 Simple All-Air Air-Handling Unit with Associated Airflows

## Forced-Air Distribution Systems

Figure 2 shows a simple **air-handling unit** (AHU) or **air-handler** that conditions air for a building. Air brought back to the air handler from the conditioned space is **return air** (ra). The portion of the return air that is discharged to the environment is **exhaust air** (ea), and the part of the return air that is reused is **recirculated air** (ca). Air brought in intentionally from the environment is **outdoor** or **outside air** (oa). Because outside air may need treatment to be acceptable for use in a building, it should not be called “fresh air.” The outside air and the recirculated air are combined to form **mixed air** (ma), which is then conditioned and delivered to the thermal zone as **supply air** (sa). Any portion of the mixed air that intentionally or unintentionally circumvents conditioning is **bypass air** (ba). Due to the wide variety of air-handling systems, the airflows shown in Figure 2 may not all be present in a particular system as defined here. Also, more complex systems may have additional airflows.

## Outside Air Fraction

The outside airflow being introduced to a building or zone by an air-handling unit can also be described by the **outside air fraction**  $X_{oa}$ , which is the ratio of the volumetric flow rate of outside air brought in by the air handler to the total supply airflow rate:

$$X_{oa} = \frac{Q_{oa}}{Q_{sa}} = \frac{Q_{oa}}{Q_{ma}} = \frac{Q_{oa}}{Q_{oa} + Q_{ca}} \quad (1)$$

When expressed as a percentage, the outside air fraction is called the **percent outside air**. The design outside airflow rate for a building's or zone's ventilation system is found through evaluating the requirements of ASHRAE *Standard 62*. The supply airflow rate is that required to meet the thermal load. The outside air fraction and percent outside air then describe the degree of recirculation, where a low value indicates a high rate of recirculation, and a high value shows little recirculation. Conventional all-air air-handling systems for commercial and institutional buildings have approximately 10 to 40% outside air.

**100% outside air** means no recirculation of return air through the air-handling system. Instead, all the supply air is treated outside air, also known as **makeup air** (ka), and all return air is discharged directly to the outside as **relief air** (la), or exhausted by separate exhaust fans. An air-handling unit that provides 100% outside air to offset air that is exhausted is typically called a **makeup air unit** (MAU).

When outside air via forced ventilation is used to provide ventilation air (as is common in commercial and institutional buildings), this outside air is delivered to spaces as all or part of the supply air. With a variable air volume (VAV) system, the outside air fraction of the supply air may need to be increased when the flow rate of the supply air is reduced to meet a particular thermal load.

## Room Air Movement

Air movement within spaces affects the diffusion of ventilation air and therefore indoor air quality and comfort. Two distinct flow patterns are commonly used to characterize air movement in rooms: displacement flow and entrainment flow. **Displacement flow**, shown in Figure 3, is the movement of air within a space in a piston- or plug-type motion. No mixing of the room air occurs in ideal displacement flow, which is desirable for removing pollutants generated within a space. A laminar flow air distribution system that sweeps air across a space may produce displacement flow.

**Entrainment flow**, shown in Figure 4, is also known as **conventional mixing**. Systems with ceiling-based supply air diffusers and return air grilles are common examples of air distribution systems that produce entrainment flow. Entrainment flow with very poor mixing within the room has been called short-circuiting flow

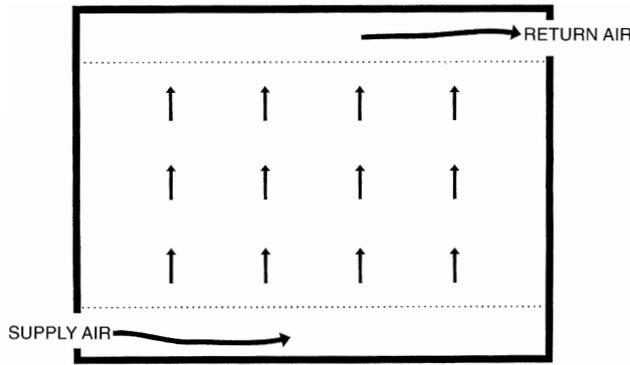

Fig. 3 Displacement Flow Within a Space

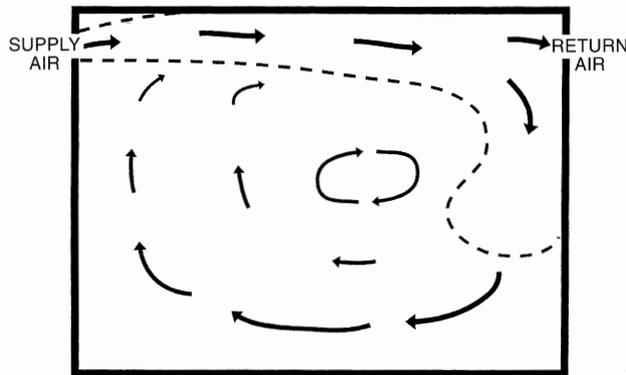

Fig. 4 Entrainment Flow Within a Space

because much of the supply air leaves the room without mixing with the room air. There is little evidence that properly designed, installed, and operated air distribution systems exhibit short-circuiting behavior. There is some evidence that poorly designed, installed, or operated systems can exhibit short-circuiting behavior, especially ceiling-based systems in the heating mode (Offermann and Int-Hout 1989).

**Perfect mixing** occurs when supply air is instantly and evenly distributed throughout a space. Perfect mixing is also known as **complete** or **uniform mixing**; the air may be called **well stirred** or **well mixed**. This theoretical performance is approached by entrainment flow systems that have good mixing and by displacement flow systems that allow too much mixing (Rock et al. 1995). The outdoor air requirements given in Table 2 of ASHRAE *Standard 62* assume delivery of ventilation air with perfect mixing within spaces. For more detailed information on space air diffusion, see Chapter 32.

The supply air that enters a space through a diffuser is also known as **primary air**. A **jet** is formed as this primary air leaves the diffuser. **Secondary air** is the room air entrained into the jet. **Total air** is the combination of primary air and secondary air at a specific point in a jet. The term primary air is also used to describe the supply air provided to fan-powered mixing boxes by a central air-handling unit.

### Air Exchange Rate

The **air exchange rate**  $I$  compares airflow to volume and is

$$I = \frac{Q}{V} \quad (2)$$

where

- $Q$  = volumetric flow rate of air into space,  $m^3/s$
- $V$  = interior volume of space,  $m^3$

The air exchange rate has units of 1/time. When the time unit is hours, the air exchange rate is also called **air changes per hour (ACH)**. The air exchange rate may be defined for several different situations. For example, the air exchange rate for an entire building or zone served by an air-handling unit compares the amount of outside air brought into the building or zone to the total interior volume. This **nominal air exchange rate**  $I_N$  is

$$I_N = \frac{Q_{oa}}{V} \quad (3)$$

where  $Q_{oa}$  is the outdoor airflow rate including ventilation and infiltration. The nominal air exchange rate describes the outside air ventilation rate entering a building or zone. It does not describe recirculation or the distribution of the ventilation air to each space within a building or zone.

For a particular space, the **space air exchange rate**  $I_S$  compares the supply airflow rate  $Q_{sa}$  to the volume of that space:

$$I_S = \frac{Q_{sa}}{V} \quad (4)$$

The space air exchange rate for a particular space or zone includes recirculated as well as outside air in the supply air, and it is used frequently in the evaluation of supply air diffuser performance and space air mixing.

### Time Constants

**Time constants**  $\tau$ , which have units of time (usually in hours or seconds), are also used to describe ventilation and infiltration. One time constant is the time required for one air change in a building, zone, or space if ideal displacement flow existed. It is the inverse of the air exchange rate:

$$\tau = \frac{1}{I} = \frac{V}{Q} \quad (5)$$

The **nominal time constant** compares the interior volume of a building or zone to the volumetric outdoor airflow rate:

$$\tau_N = \frac{V}{Q_{oa}} \quad (6)$$

Like the nominal air exchange rate, the nominal time constant does not describe recirculation of air within a building or zone. It also does not characterize the distribution of the outside air to individual spaces within a building or zone.

The **space time constant** compares the interior volume of a particular space to the total supply airflow rate to that space. The space time constant is the inverse of the space air exchange rate:

$$\tau_S = \frac{V}{Q_{sa}} \quad (7)$$

The space time constant includes the effect of recirculated air, if present, as well as that of outside air introduced to the space through the supply air. If infiltration is significant in a space, then the infiltration flow rate should be included when determining both the space air exchange rate and the space time constant.

### Averaging Time-Varying Ventilation

When assessing time-varying ventilation in terms of controlling indoor air quality, the quantity of interest is often the temporal average rather than the peak. The concept of **effective ventilation** (Sherman and Wilson 1986, Yuill 1986, and Yuill 1991) describes the

proper ventilation rate averaging process. In this concept, the average (effective) rate is the steady-state rate that would yield the same average contaminant concentration over the period of interest in the occupied space as does the actual sequence of time-varying discrete ventilation rates over the same period and in the same space. This effective rate is only equal to the simple arithmetic average rate when the discrete ventilation rates are constant over the period of interest and the contaminant concentration has reached its steady-state value. Simple arithmetic averaging of instantaneous ventilation rates or concentrations cannot generally be used to determine these averages due to the nonlinear response of indoor concentrations to the ventilation rate variations.

An important constraint in the effective ventilation concept is that the contaminant source strength  $F$  must be constant over the period of interest or must be uncorrelated with the ventilation rate. These conditions are satisfied in many residential and commercial buildings because the emission rates of many contaminants that are controlled by whole-building ventilation vary slowly. Sherman and Wilson (1986) describe how to deal with pollutants that have stepwise constant emission rates. Pollutants such as carbon monoxide, radon, and formaldehyde, whose emission rates can be affected by ventilation, cannot be analyzed with this concept and require more complex analyses.

For constant source-strength pollutants, the relationship between effective air exchange rate, effective ventilation rate, volumetric flow, source strength, average concentration, and time-averaged effective turnover time is given by

$$I_m = \frac{\bar{Q}}{V} = \frac{F}{V\bar{C}} = \frac{1}{\bar{\tau}_e} \quad (8)$$

The time-averaged effective turnover time  $\bar{\tau}_e$  in Equation (8) represents the characteristic time for the concentration in the occupied space to approach steady state over the period of interest. It can be determined from a sequence of discrete instantaneous ventilation air change rates  $I_i$  using the following (Sherman and Wilson 1986):

$$\bar{\tau}_e = \frac{1}{N} \sum_{i=1}^N \tau_{e,i} \quad (9)$$

$$\text{for } I_i > 0, \tau_{e,i} = \frac{1 - \exp(-I_i \Delta t)}{I_i} + \tau_{e,i-1} \exp(-I_i \Delta t) \quad (10)$$

$$\text{for } I_i = 0, \tau_{e,i} = \Delta t + \tau_{e,i-1} \quad (11)$$

where

$\Delta t$  = length of each discrete time period

$\bar{\tau}_e$  = time-averaged effective turnover time

$\tau_{e,i}$  = instantaneous turnover time in period  $i$

$\tau_{e,i-1}$  = instantaneous turnover time in previous period

ASHRAE *Standard* 136 provides a set of factors to assist in calculating the annual effective air exchange rate for houses. These factors were determined using Equations (9) through (11).

### Age of Air

The **age of air**  $\theta_{age}$  (Sandberg 1981) is the length of time that some quantity of outside air has been in a building, zone, or space. The “youngest” air is at the point where outside air enters the building by forced or natural ventilation or through infiltration (Grieve 1989). The “oldest” air may be at some location in the building or in the exhaust air. When the characteristics of the air distribution system are varied, a longer age of air suggests poorer outside air delivery compared to a shortage of air for the same location. The age of

air has units of time, usually in seconds or minutes, so it is not a true “efficiency” or “effectiveness” measure. The age of air concept, however, has gained wide acceptance in Europe and is used increasingly in North America.

The age of air can be evaluated for existing buildings using tracer gas methods. Using either the decay (step-down) or the growth (step-up) tracer gas method, the zone average or **nominal age of air**  $\theta_{age,N}$  can be determined by taking concentration measurements in the exhaust air. The **local age of air**  $\theta_{age,L}$  is evaluated through tracer gas measurements at any desired point in a space, such as at a worker’s desk. Once time-dependent data of tracer gas concentration are available, the age of air can be calculated from

$$\theta_{age} = \int_{\theta=0}^{\infty} \frac{C_{in} - C}{C_{in} - C_o} d\theta \quad (12)$$

where  $C_{in}$  = concentration of tracer gas being injected.

Because evaluation of the age of air requires integration to infinite time, an exponential tail is usually added to the known concentration data (Farrington et al. 1990).

### Air Change Effectiveness

**Ventilation effectiveness** is a description of an air distribution system’s ability to remove internally generated pollutants from a building, zone, or space. **Air change effectiveness** is a description of an air distribution system’s ability to deliver ventilation air to a building, zone, or space. The HVAC design engineer does not have knowledge or control of actual pollutant sources within buildings, so Table 2 of ASHRAE *Standard* 62 defines outdoor air requirements for typical, expected building uses. For most projects, therefore, the air change effectiveness is of more relevance to HVAC system design than the ventilation effectiveness. Various definitions for air change effectiveness have been proposed. The specific measure that meets the local code requirements must be determined, if any is needed at all.

Air change effectiveness measures  $\epsilon_I$  are nondimensional gages of ventilation air delivery. One common definition of air change effectiveness is the ratio of a time constant to an age of air:

$$\epsilon_I = \frac{\tau}{\theta_{age}} \quad (13)$$

The **nominal air change effectiveness**  $\epsilon_{I,N}$  shows the effectiveness of outside air delivery to the entire building, zone, or space:

$$\epsilon_{I,N} = \frac{\tau_N}{\theta_{age,N}} \quad (14)$$

where the nominal time constant  $\tau_N$  is usually calculated from measured airflow rates.

The **local air change effectiveness**  $\epsilon_{I,L}$  shows the effectiveness of outside air delivery to one specific point in a space:

$$\epsilon_{I,L} = \frac{\tau_N}{\theta_{age,L}} \quad (15)$$

where  $\tau_N$  is found either through airflow measurements or from tracer gas concentration data. An  $\epsilon_{I,L}$  value of 1.0 indicates that the air distribution system delivers air equivalent to that of a system with perfectly mixed air in the spaces. A value less than 1.0 shows less than perfect mixing with some degree of stagnation. A value of  $\epsilon_{I,L}$  greater than 1.0 suggests that a degree of plug or displacement flow is present at that point (Rock 1992).

Currently, the HVAC design engineer must assume that a properly designed, installed, operated, and maintained air distribution

system provides an air change effectiveness of about 1. Therefore, the Table 2 values of ASHRAE *Standard 62* are appropriate for the design of commercial, institutional, and residential buildings when the Ventilation Rate Procedure is used. If the Indoor Air Quality Procedure of *Standard 62* is used, then actual pollutant sources and the air change effectiveness must be known for the successful design of HVAC systems that have fixed ventilation airflow rates.

ASHRAE *Standard 129* describes a method for measuring air change effectiveness of mechanically vented spaces and buildings with limited air infiltration, exfiltration, and air leakage with surrounding indoor spaces.

### DRIVING MECHANISMS FOR VENTILATION AND INFILTRATION

Natural ventilation and infiltration are driven by pressure differences across the building envelope caused by wind and air density differences due to temperature differences between indoor and outdoor air (buoyancy, or the stack effect). Mechanical air-moving systems also induce pressure differences across the envelope due to the operation of appliances, such as combustion devices, leaky forced-air thermal distribution systems, and mechanical ventilation systems. The indoor-outdoor pressure difference at a location depends on the magnitude of these driving mechanisms as well as on the characteristics of the openings in the building envelope (i.e., their locations and the relationship between pressure difference and airflow for each opening).

#### Stack Pressure

Stack pressure is the hydrostatic pressure caused by the weight of a column of air located inside or outside a building. It can also occur within a flow element such as a duct or chimney that has vertical separation between its inlet and outlet. The hydrostatic pressure in the air depends on density and the height of interest above a reference point.

Air density is a function of local barometric pressure, temperature, and humidity ratio, as described by Chapter 6. As a result, standard conditions should not be used to calculate the density. For example, a building site at 1500 m has an air density that is about 20% less than if the building were at sea level. An air temperature increase from -30 to 20°C causes a similar air density difference. Combined, these elevation and temperature effects reduce the air density about 45%. Moisture effects on density are generally negligible, so the dry air density can be used instead, except in hot, humid climates when the air is hot and close to saturation. For example, saturated air at 40°C has a density about 5% greater than that of dry air.

Assuming temperature and barometric pressure are constant over the height of interest, the stack pressure decreases linearly as the separation above the reference point increases. For a single column of air, the stack pressure can be calculated as

$$p_s = p_r - \rho gH \quad (16)$$

where

- $p_s$  = stack pressure, Pa
- $p_r$  = stack pressure at reference height, Pa
- $g$  = gravitational constant, 9.81 m/s<sup>2</sup>
- $\rho$  = indoor or outdoor air density, kg/m<sup>3</sup>
- $H$  = height above reference plane, m

For tall buildings or when significant temperature stratification occurs indoors, Equation (16) should be modified to include the density gradient over the height of the building.

Temperature differences between indoors and outdoors cause stack pressure differences that drive airflows across the building envelope. Sherman (1991) showed that any single-zone building can be treated as an equivalent box from the point of view of stack

effect, if its leaks follow the power law. The building is then characterized by an effective stack height and neutral pressure level (NPL) or leakage distribution (see the section on Neutral Pressure Level). Once calculated, these parameters can be used in physical, single-zone models to estimate infiltration.

Neglecting vertical density gradients, the stack pressure difference for a horizontal leak at any vertical location is given by

$$\begin{aligned} \Delta p_s &= (\rho_o - \rho_i)g(H_{NPL} - H) \\ &= \rho_o \left( \frac{T_o - T_i}{T_i} \right) g(H_{NPL} - H) \end{aligned} \quad (17)$$

where

- $T_o$  = outdoor temperature, K
- $T_i$  = indoor temperature, K
- $\rho_o$  = outdoor air density, kg/m<sup>3</sup>
- $\rho_i$  = indoor air density, kg/m<sup>3</sup>
- $H_{NPL}$  = height of neutral pressure level above reference plane without any other driving forces, m

Chastain and Colliver (1989) showed that when there is stratification, the average of the vertical distribution of temperature differences is more appropriate to use in Equation (17) than the localized temperature difference near the opening of interest.

By convention, stack pressure differences are positive when the building is pressurized relative to outdoors, which causes flow out of the building. Therefore, in the absence of other driving forces and assuming no stack effect is within the flow elements themselves, when the indoor air is warmer than outdoors, the base of the building is depressurized and the top is pressurized relative to outdoors; when the indoor air is cooler than outdoors, the reverse is true.

In the absence of other driving forces, the location of the NPL is influenced by leakage distribution over the building exterior and by interior compartmentation. As a result, the NPL is not necessarily located at the mid-height of the building nor is it necessarily unique. NPL location and leakage distribution are described later in the section on Combining Driving Forces.

For a penetration through the building envelope for which (1) there is a vertical separation between its inlet and outlet and (2) the air inside the flow element is not at the indoor or outdoor temperature, such as in a chimney, more complex analyses than Equation (17) are required to determine the stack effect at any location on the building envelope.

#### Wind Pressure

When wind impinges on a building, it creates a distribution of static pressures on the building's exterior surface that depends on the wind direction, wind speed, air density, surface orientation, and surrounding conditions. Wind pressures are generally positive with respect to the static pressure in the undisturbed airstream on the windward side of a building and negative on the leeward sides. However, pressures on these sides can be negative or positive, depending on wind angle and building shape. Static pressures over building surfaces are almost proportional to the velocity pressure of the undisturbed airstream. The wind pressure or velocity pressure is given by the Bernoulli equation, assuming no height change or pressure losses:

$$p_w = C_p \rho \frac{U^2}{2} \quad (18)$$

where

- $p_w$  = wind surface pressure relative to outdoor static pressure in undisturbed flow, Pa
- $\rho$  = outside air density, kg/m<sup>3</sup> (about 1.2)
- $U$  = wind speed, m/s
- $C_p$  = wind surface pressure coefficient, dimensionless

$C_p$  is a function of location on the building envelope and wind direction. Chapter 16 provides additional information on the values of  $C_p$ .

Most pressure coefficient data are for winds normal to building surfaces. Unfortunately, for a real building, this fixed wind direction rarely occurs, and when the wind is not normal to the upwind wall, these pressure coefficients do not apply. A harmonic trigonometric function was developed by Walker and Wilson (1994) to interpolate between the surface average pressure coefficients on a wall that were measured with the wind normal to each of the four building surfaces. This function was developed for low-rise buildings three stories or less in height. For each wall of the building,  $C_p$  is given by

$$C_p(\phi) = \frac{1}{2} \{ [C_p(1) + C_p(2)](\cos^2\phi)^{1/4} + [C_p(1) - C_p(2)](\cos\phi)^{3/4} + [C_p(3) + C_p(4)](\sin^2\phi)^2 + [C_p(3) - C_p(4)]\sin\phi \} \quad (19)$$

where

- $C_p(1)$  = pressure coefficient when wind is at  $0^\circ$
- $C_p(2)$  = pressure coefficient when wind is at  $180^\circ$
- $C_p(3)$  = pressure coefficient when wind is at  $90^\circ$
- $C_p(4)$  = pressure coefficient when wind is at  $270^\circ$
- $\phi$  = wind angle measured clockwise from the normal to Wall 1

The measured data used to develop the harmonic function from Akins et al. (1979) and Wren (1985) show that typical values for the pressure coefficients are  $C_p(1) = 0.6$ ,  $C_p(2) = -0.3$ ,  $C_p(3) = C_p(4) = -0.65$ . Because of the geometry effects on flow around a building, the application of this interpolation function is limited to low-rise buildings that are of rectangular plan form (i.e., not L-shaped) with the longest wall less than three times the length of the shortest wall. For less regular buildings, simple correlations are inadequate and building-specific pressure coefficients are required. Chapter 16 discusses wind pressures for complex building shapes and for high-rise buildings in more detail.

The wind speed most commonly available for infiltration calculations is the wind speed measured at the local weather station, typically the nearest airport. This wind speed needs to be corrected for reductions due to the difference between the height where the wind speed is measured and the height of the building and reductions due to shelter effects.

The reference wind speed used to determine pressure coefficients is usually the wind speed at the eaves height for low-rise buildings and the building height for high-rise buildings. However, meteorological wind speed measurements are made at a different height (typically 10 m) and at a different location. The difference in terrain between the measurement station and the building under study must also be accounted for. Chapter 16 shows how to calculate the effective wind speed  $U_H$  from the reference wind speed  $U_{met}$  using boundary layer theory and estimates of terrain effects.

In addition to the reduction in wind pressures due to the reduction in wind speed, the effects of local shelter also act to reduce wind pressures. The shielding effects of trees, shrubbery, and other buildings within several building heights of a particular building produce large-scale turbulence eddies that not only reduce effective wind speed but also alter wind direction. Thus, meteorological wind speed data must be reduced carefully when applied to low buildings.

Ventilation rates measured by Wilson and Walker (1991) for a row of houses showed reductions in ventilation rates of up to a factor of three when the wind changed direction from perpendicular to parallel to the row. They recommended estimating wind shelter for winds perpendicular to each side of the building and then using the

interpolation function in Equation (20) to find the wind shelter for intermediate wind angles:

$$s = \frac{1}{2} \left\{ [s(1) + s(2)]\cos^2\phi + [s(1) - s(2)]\cos\phi + [s(3) + s(4)]\sin^2\phi + [s(3) - s(4)]\sin\phi \right\} \quad (20)$$

where

- $s$  = shelter factor for the particular wind direction  $\phi$
- $s(i)$  = shelter factor when wind is normal to Wall  $i$   
( $i = 1$  to  $4$ , for four sides of a building)

Although the above method gives a realistic variation of wind shelter effects with wind direction, estimates for the numerical values of wind shelter factor  $s$  for each of the four cardinal directions must be provided. Table 11 in the section on Residential Calculation Examples lists typical shelter factors. The wind speed used in Equation (18) is then given by

$$U = sU_H \quad (21)$$

The magnitude of the pressure differences found on the surfaces of buildings varies rapidly with time because of turbulent fluctuations in the wind (Grimsrud et al. 1979, Etheridge and Nolan 1979). However, the use of average wind pressures to calculate pressure differences is usually sufficient to calculate average infiltration values.

## Mechanical Systems

The operation of mechanical equipment, such as supply or exhaust systems and vented combustion devices, affects pressure differences across the building envelope. The interior static pressure adjusts such that the sum of all airflows through the openings in the building envelope plus equipment-induced airflows balance to zero. To predict these changes in pressure differences and airflow rates caused by mechanical equipment, the location of each opening in the envelope and the relationship between pressure difference and airflow rate for each opening must be known. The interaction between mechanical ventilation system operation and envelope airtightness has been discussed for low-rise buildings (Nylund 1980) and for office buildings (Tamura and Wilson 1966, 1967b; Persily and Grot 1985a).

Air exhausted from a building by a whole-building exhaust system must be balanced by increasing the airflow into the building through other openings. As a result, the airflow at some locations changes from outflow to inflow. For supply fans, the situation is reversed and envelope inflows become outflows. Thus, the effects a mechanical system has on a building must be considered. Depressurization caused by an improperly designed exhaust system can increase the rate of radon entry into a building and interfere with the proper operation of combustion device venting or other exhaust systems. Depressurization can also force moist outdoor air through the building envelope; for example, during the cooling season in hot humid climates, moisture may condense within the building envelope. A similar phenomenon, but in reverse, can occur during the heating season in cold climates if the building is depressurized.

The interaction between mechanical systems and the building envelope also pertains to systems serving zones of buildings. The performance of zone-specific exhaust or pressurization systems is affected by the leakage in zone partitions as well as in exterior walls.

Mechanical systems can also create infiltration-driving forces in single-zone buildings. Specifically, some single-family houses with central forced-air duct systems have multiple supply registers, yet only a central return register. When internal doors are closed in these houses, large positive indoor-outdoor pressure differentials are created for rooms with only supply registers, whereas the room

with the return duct tends to depressurize relative to outside. This is caused by the resistance of internal door undercuts to flow from the supply register to the return (Modera et al. 1991). The magnitudes of the indoor-outdoor pressure differentials created have been measured to average 3 to 6 Pa (Modera et al. 1991).

Building envelope airtightness and interzonal airflow resistance can also affect the performance of mechanical systems. The actual airflow rate delivered by these systems, particularly ventilation systems, depends on the pressure they work against. This effect is the same as the interaction of a fan with its associated ductwork, which is discussed in Chapter 34 of this volume and Chapter 18 of the 2000 *ASHRAE Handbook—Systems and Equipment*. The building envelope and its leakage must be considered part of the ductwork in determining the pressure drop of the system.

Duct leakage can cause similar problems. Supply leaks to the outside will tend to depressurize the building; return leaks to the outside will tend to pressurize it.

**Combining Driving Forces**

The pressure differences due to wind pressure, stack pressure, and mechanical systems are considered in combination by adding them together and then determining the airflow rate through each opening due to this total pressure difference. The air flows must be determined in this manner, as opposed to adding the airflow rates due to the separate driving forces, because the airflow rate through each opening is not linearly related to pressure difference.

For uniform indoor air temperatures, the total pressure difference across each leak can be written in terms of a reference wind parameter  $P_U$  and stack effect parameter  $P_T$  common to all leaks:

$$P_U = \rho_o \frac{U^2}{2} \tag{22}$$

$$P_T = g\rho_o \left( \frac{T_o - T_i}{T_i} \right) \tag{23}$$

where  $T$  = air temperature, K.

The pressure difference across each leak (with positive pressures for flow into the building) is then given by

$$\Delta p = s^2 C_p P_U + H P_T + \Delta p_l \tag{24}$$

where  $\Delta p_l$  = pressure that acts to balance inflows and outflows (including mechanical system flows). Equation (24) can then be applied to every leak for the building with the appropriate values of  $C_p$ ,  $s$ , and  $H$ . Thus, each leak is defined by its pressure coefficient, shelter, and height. Where indoor pressures are not uniform, more complex analyses are required.

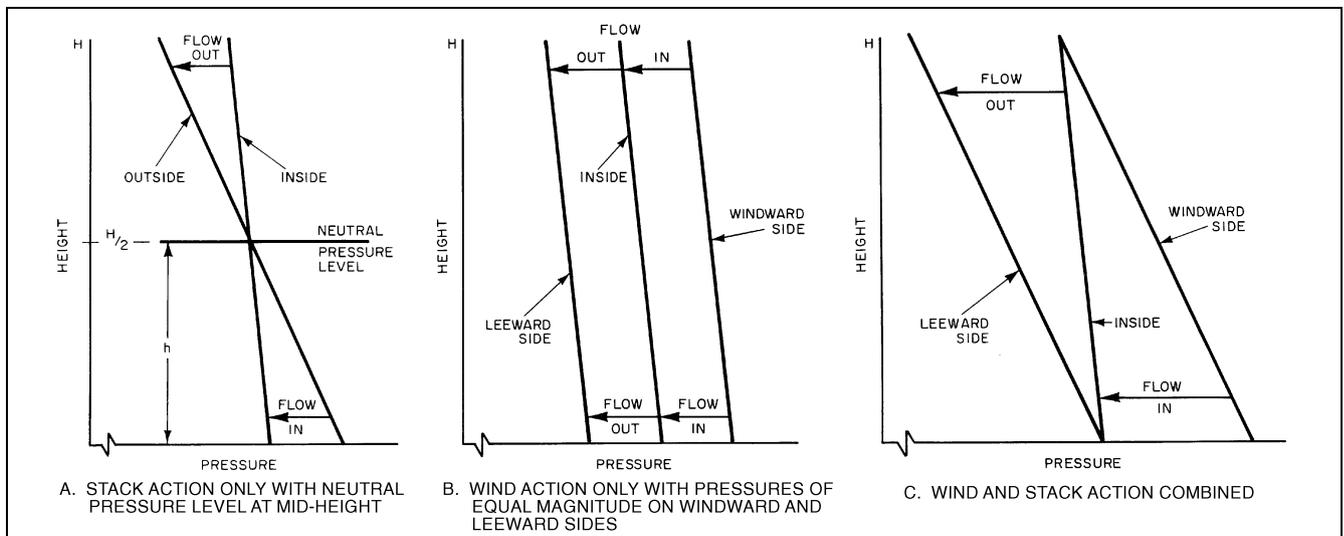

**Neutral Pressure Level**

The neutral pressure level (NPL) is that location or locations in the building envelope where there is no pressure difference. Internal partitions, stairwells, elevator shafts, utility ducts, chimneys, vents, operable windows, and mechanical supply and exhaust systems complicate the analysis of NPL location. An opening with a large area relative to the total building leakage causes the NPL to shift toward the location of the opening. In particular, chimneys and openings at or above roof height raise the NPL in small buildings. Exhaust systems increase the height of the NPL; outdoor air supply systems lower it.

Figure 5 qualitatively shows the addition of driving forces for a building with uniform openings above and below mid-height and without significant internal resistance to airflow. The slopes of the pressure lines are a function of the densities of the indoor and outdoor air. In Figure 5A, with inside air warmer than outside and pressure differences caused solely by thermal forces, the NPL is at mid-height, with inflow through lower openings and outflow through higher openings. Direction of flow is always from the higher to the lower pressure region.

Figure 5B presents qualitative uniform pressure differences caused by wind alone, with opposing effects on the windward and leeward sides. When the temperature difference and wind effects both exist, the pressures due to each are added together to determine the total pressure difference across the building envelope. In Figure 5B, there is no NPL because no locations on the building envelope have zero pressure difference. Figure 5C shows the combination, where the wind force of Figure 5B has just balanced the thermal force of Figure 5A, causing no pressure difference at the top windward or bottom leeward side.

The relative importance of the wind and stack pressures in a building depends on building height, internal resistance to vertical airflow, location and flow resistance characteristics of envelope

**Fig. 5** Distribution of Inside and Outside Pressures over Height of Building

openings, local terrain, and the immediate shielding of the building. The taller the building is and the smaller its internal resistance to airflow, the stronger the stack effect will be. The more exposed a building is, the more susceptible it will be to wind. For any building, there will be ranges of wind speed and temperature difference for which the building's infiltration is dominated by the stack effect, the wind, or the driving pressures of both (Sinden 1978a). These building and terrain factors determine, for specific values of temperature difference and wind speed, in which regime the building's infiltration lies.

The effect of mechanical ventilation on envelope pressure differences is more complex and depends on both the direction of the ventilation flow (exhaust or supply) and the differences in these ventilation flows among the zones of the building. If mechanically supplied outdoor air is provided uniformly to each story, the change in the exterior wall pressure difference pattern is uniform. With a nonuniform supply of outdoor air (for example, to one story only), the extent of pressurization varies from story to story and depends on the internal airflow resistance. Pressurizing all levels uniformly has little effect on the pressure differences across floors and vertical shaft enclosures, but pressurizing individual stories increases the pressure drop across these internal separations. Pressurization of the ground level is often used in tall buildings to reduce the stack pressures across entries.

Available data on the NPL in various kinds of buildings are limited. The NPL in tall buildings varies from 0.3 to 0.7 of total building height (Tamura and Wilson 1966, 1967a). For houses, especially houses with chimneys, the NPL is usually above mid-height. Operating a combustion heat source with a flue raises the NPL further, sometimes above the ceiling (Shaw and Brown 1982).

### Thermal Draft Coefficient

Compartmentation of a building also affects the NPL location. Equation (17) provides a maximum stack pressure difference, given no internal airflow resistance. The sum of the pressure differences across the exterior wall at the bottom and at the top of the building, as calculated by these equations, equals the total theoretical draft for the building. The sum of the actual top and bottom pressure differences, divided by the total theoretical draft pressure difference, equals the **thermal draft coefficient**. The value of the thermal draft coefficient depends on the airflow resistance of the exterior walls relative to the airflow resistance between floors. For a building without internal partitions, the total theoretical draft is achieved across the exterior walls (Figure 6A), and the thermal draft coefficient equals 1. In a building with airtight separations at each floor, each story acts independently, its own stack effect being unaffected by that of any other floor (Figure 6B). The theoretical draft is minimized in this case, and each story has an NPL.

Real multistory buildings are neither open inside (Figure 6A), nor airtight between stories (Figure 6B). Vertical air passages, stairwells, elevators, and other service shafts allow airflow between floors. Figure 6C represents a heated building with uniform openings in the exterior wall, through each floor, and into the vertical shaft at each story. Between floors, the slope of the line representing the inside pressure is the same as that shown in Figure 6A, and the discontinuity at each floor (Figure 6B) represents the pressure difference across it. Some of the pressure difference maintains flow through openings in the floors and vertical shafts. As a result, the pressure difference across the exterior wall at any level is less than it would be with no internal flow resistance.

Maintaining airtightness between floors and from floors to vertical shafts is a means of controlling indoor-outdoor pressure differences due to the stack effect and therefore infiltration (Lovaett and Wilson 1994). Good separation is also conducive to the proper operation of mechanical ventilation and smoke management systems. However, care is needed to avoid pressure differences that could prevent door opening in an emergency. Tamura and Wilson (1967b) showed that when vertical shaft

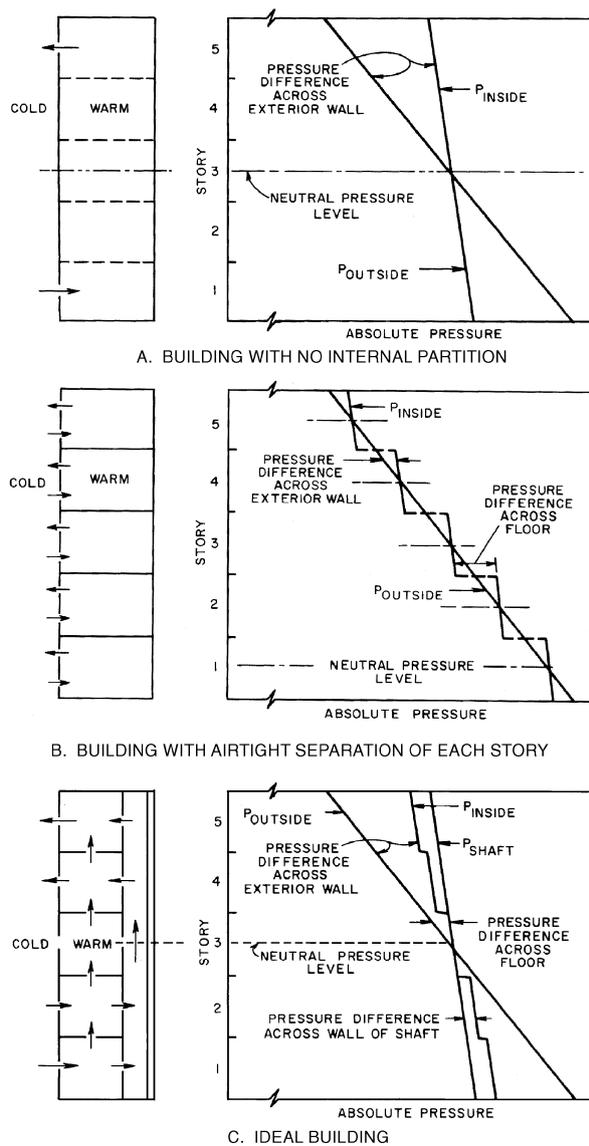

Fig. 6 Compartmentation Effect in Buildings

leakage is at least two times the envelope leakage, the thermal draft coefficient is almost one and the effect of compartmentation is negligible. Measurements of pressure differences in three tall office buildings by Tamura and Wilson (1967a) indicated that the thermal draft coefficient ranged from 0.8 to 0.9 with the ventilation systems off.

### ASHRAE Standard 62

ASHRAE Standard 62 provides guidance on ventilation and indoor air quality and includes two alternative procedures for determining design ventilation rates. In the **Ventilation Rate Procedure**, indoor air quality is assumed to be acceptable if (1) the concentrations of six pollutants in the incoming outdoor air meet the U.S. EPA national ambient air quality standards (EPA 1986), and (2) the outdoor air ventilation rates meet or exceed values (which depend on the space type) provided in a table.

The minimum outside air ventilation per person for any type of space is 8 L/s. This minimum rate will maintain the indoor  $CO_2$  concentration within 0.07% (700 parts per million) of the outdoor concentration, assuming a typical  $CO_2$  generation rate per occupant

(Janssen 1989). This minimum outside air ventilation rate was based, in part, on research by Berg-Munch et al. (1986), Yaglou et al. (1936), Iwashita et al. (1989), and Cain et al. (1993) that indicated that 8 L/s was required to satisfy the odor perceptions of 80% or more of visitors.

The other design approach in ASHRAE *Standard 62* is the **Indoor Air Quality Procedure**. In this procedure, acceptable indoor air quality is achieved through the control of indoor contaminant concentrations. Such control can be realized through source control, air cleaning, and ventilation. It allows for either or both improved indoor air quality and reduced energy consumption. Chapter 24 of the 2000 ASHRAE *Handbook—Systems and Equipment* has information on air cleaning.

A combination of source control and local exhaust, as opposed to dilution with ventilation air, is the method of choice in industrial environments. Industrial ventilation is discussed in Chapters 28 and 29 of the 1999 ASHRAE *Handbook—Applications* and in *Industrial Ventilation: A Manual of Recommended Practice* (ACGIH 1998).

### INDOOR AIR QUALITY

Outdoor air requirements for acceptable indoor air quality (IAQ) have long been debated, and different rationales have produced radically different ventilation standards (Grimsrud and Teichman 1989, Janssen 1989, Klaus et al. 1970, Yaglou et al. 1936, Yaglou and Witheridge 1937). Historically, the major considerations have included the amount of outdoor air required to control moisture, carbon dioxide (CO<sub>2</sub>), odors, and tobacco smoke generated by occupants. These considerations have led to prescriptions of a minimum rate of outdoor air supply per occupant. More recently, the maintenance of acceptable indoor concentrations of a variety of additional pollutants that are not generated primarily by occupants has been a major concern. Information on contaminants can be found in Chapter 12, and odors are covered in Chapter 13.

Indoor pollutant concentrations depend on the strength of pollutant sources and the total rate of pollutant removal. Pollutant sources include the outdoor air; indoor sources such as occupants, furnishings, and appliances; and the soil adjacent to the building. Pollutant removal processes include dilution with outside air, local exhaust ventilation, deposition on surfaces, chemical reactions, and air-cleaning processes. If (1) general building ventilation is the only significant pollutant removal process, (2) the indoor air is thoroughly mixed, and (3) the pollutant source strength and ventilation rate have been stable for a sufficient period; then the steady-state indoor pollutant concentration is given by

$$C_i = C_o + S/Q_{oa} \quad (25)$$

where

$$\begin{aligned} C_i &= \text{steady-state indoor concentration, } \mu\text{g}/\text{m}^3 \\ C_o &= \text{outdoor concentration, } \mu\text{g}/\text{m}^3 \\ S &= \text{total pollutant source strength, } \mu\text{g}/\text{s} \\ Q_{oa} &= \text{ventilation rate, } \text{m}^3/\text{s} \end{aligned}$$

Variation in pollutant source strengths (rather than variation in ventilation rate) is considered the largest cause of building-to-building variation in the concentrations of pollutants that are not generated by occupants. Turk et al. (1989) found that a lack of correlation between average indoor respirable particle concentrations and whole-building outdoor ventilation rate indicated that source strength, high outdoor concentrations, building volume, and removal processes are important. Because pollutant source strengths are highly variable, maintenance of minimum ventilation rates does not ensure acceptable indoor air quality in all situations. The lack of health-based concentration standards for many indoor air pollutants, primarily due to the lack of health data, makes the specification of minimum ventilation rates even more difficult.

In cases of high contaminant source strengths, impractically high rates of ventilation are required to control contaminant levels, and other methods of control are more effective. Removal or reduction of contaminant sources is a very effective means of control. Controlling a localized source by means of local exhaust, such as range hoods or bathroom exhaust fans, can also be effective.

Particles can be removed with various types of air filters. Gaseous contaminants with higher relative molecular mass can be controlled with activated carbon or alumina pellets impregnated with a substance such as potassium permanganate. Chapter 24 of the 2000 ASHRAE *Handbook—Systems and Equipment* has information on air cleaning.

### THERMAL LOADS

Outdoor air introduced into a building constitutes a large part of the total space-conditioning (heating, cooling, humidification, and dehumidification) load, which is one reason to limit air exchange rates in buildings to the minimum required. Air exchange typically represents 20 to 50% of a building's thermal load. Chapter 28 and Chapter 29 cover thermal loads in more detail.

Air exchange increases a building's thermal load in three ways. First, the incoming air must be heated or cooled from the outdoor air temperature to the indoor or supply air temperature. The rate of energy consumption due to this sensible heating or cooling is given by

$$q_s = Q\rho c_p \Delta t = 1200Q\Delta t \quad (26)$$

where

$$\begin{aligned} q_s &= \text{sensible heat load, W} \\ Q &= \text{airflow rate, } \text{m}^3/\text{s} \\ \rho &= \text{air density, } \text{kg}/\text{m}^3 \text{ (about 1.2)} \\ c_p &= \text{specific heat of air, } \text{J}/(\text{kg}\cdot\text{K}) \text{ (about 1000)} \\ \Delta t &= \text{temperature difference between indoors and outdoors, K} \end{aligned}$$

Second, air exchange modifies the moisture content of the air in a building. The rate of energy consumption associated with these latent loads (neglecting the energy associated with any condensate) is given by

$$q_l = Q\Delta W[4775 + 1.998\Delta t] \quad (27)$$

where

$$\begin{aligned} q_l &= \text{latent heat load, W} \\ \Delta W &= \text{humidity ratio difference between indoors and outdoors,} \\ &\quad \text{mass water/unit mass dry air (kg/kg)} \end{aligned}$$

Finally, air exchange can change a building's thermal load by altering the performance of the envelope insulation system. Airflow through the insulation can decrease the thermal load due to heat exchange between infiltrating or exfiltrating air and the thermal insulation. Conversely, air moving in and out of the insulation from outside can increase the thermal load. Experimental and numerical studies have demonstrated that significant thermal coupling can occur between air leakage and insulation layers, thereby modifying the heat transmission in building envelopes. In particular, a number of researchers (Wolf 1966; Berlad et al. 1978; Bankvall 1987; Lecompte 1987) have shown that convective airflow through air-permeable insulation in an envelope assembly may degrade its effective thermal resistance. This R-value degradation occurs when outside air moves through and/or around the insulation within the wall cavity and returns to the outdoors without reaching the conditioned space. A literature review by Powell et al. (1989) summarized the findings about air movement effects on the effective thermal resistance of porous insulation under various conditions. The effect of such airflow on insulation system performance is difficult to quantify but should be considered. Airflow

within the insulation system can also decrease the system's performance due to moisture condensation in and on the insulation.

Even if air flows only through cracks instead of through the insulation, the actual heating/cooling load due to the combined effect of conduction and airflow heat transfer can be lower than the heating/cooling load calculated by Equation (26). This reduction in total heating/cooling load is a consequence of the thermal coupling between conduction and convection heat transfer and is called **infiltration heat recovery (IHR)**. This effect appears to be significant in building envelopes, based on preliminary laboratory and numerical work under controllable conditions by several investigators.

Using a computer simulation, Kohonen et al. (1987) found that the conduction/infiltration thermal interaction reduced total heating load by 15%. Several experimental studies by Claridge et al. (1988), Claridge and Bhattacharyya (1990), Liu and Claridge (1992a, 1992b, 1992c, 1995), Timusk et al. (1992), and others using a test cell under both steady-state and dynamic conditions found that the actual energy attributed to air infiltration can be 20 to 80% of the values given by Equation (27). Judkoff et al. (1997) measured heat recovery using a mobile home under steady-state conditions. They found that up to 40% heat recovery occurs during exfiltration through the envelope of the mobile home. Buchanan and Sherman (2000) carried out two- and three-dimensional computational fluid dynamics simulations to study the fundamental physics of the IHR process and developed a simple macro-scale mathematical model based on the steady-state one-dimensional convection-diffusion equation to predict a heat recovery factor. Their results show that the traditional method may overpredict the infiltration energy load.

### Infiltration Degree-Days

Heating and cooling degree-days are a simple way to characterize the severity of a particular climate. Heating and cooling degree-day values are based on sensible temperature data, but infiltration loads are both sensible and latent. **Infiltration degree days (IDDs)** more fully describe a climate and can be used to estimate heat loss or gain due to infiltration in residences (Sherman 1986). Total infiltration degree-days is the sum of the heating and cooling infiltration degree-days and is calculated from hour-by-hour weather data and base conditions using weather weighted by infiltration rate. The selection of base conditions is an important part of the calculation of the IDDs. ASHRAE *Standard* 119 lists IDDs for many locations with a particular set of base conditions.

## NATURAL VENTILATION

Natural ventilation is the flow of outdoor air due to wind and thermal pressures through intentional openings in the building's shell. Under some circumstances, it can effectively control both temperature and contaminants in mild climates, but it is not considered practical in hot and humid climates or in cold climates. Temperature control by natural ventilation is often the only means of providing cooling when mechanical air conditioning is not available. The arrangement, location, and control of ventilation openings should combine the driving forces of wind and temperature to achieve a desired ventilation rate and good distribution of ventilation air through the building. However, intentional openings cannot always guarantee adequate temperature and humidity control or indoor air quality because of the dependence on natural (wind and stack) effects to drive the flow (Wilson and Walker 1992).

### Natural Ventilation Openings

Natural ventilation openings include (1) windows, doors, dormer (monitor) openings, and skylights; (2) roof ventilators; (3) stacks connecting to registers; and (4) specially designed inlet or outlet openings.

**Windows** transmit light and provide ventilation when open. They may open by sliding vertically or horizontally; by tilting on horizontal pivots at or near the center; or by swinging on pivots at the top, bottom, or side. The type of pivoting used is important for weather protection and affects airflow rate.

**Roof ventilators** provide a weather-resistant air outlet. Capacity is determined by the ventilator's location on the roof; the resistance to airflow of the ventilator and its ductwork; the ventilator's ability to use kinetic wind energy to induce flow by centrifugal or ejector action; and the height of the draft.

Natural-draft or gravity roof ventilators can be stationary, pivoting, oscillating, or rotating. Selection criteria include ruggedness, corrosion resistance, stormproofing features, dampers and operating mechanisms, noise, cost, and maintenance. Natural ventilators can be supplemented with power-driven supply fans; the motors need only be energized when the natural exhaust capacity is too low. Gravity ventilators can have manual dampers or dampers controlled by thermostat or wind velocity.

A natural-draft roof ventilator should be positioned so that it receives the full, unrestricted wind. Turbulence created by surrounding obstructions, including higher adjacent buildings, impairs a ventilator's ejector action. The ventilator inlet should be conical or bell mounted to give a high flow coefficient. The opening area at the inlet should be increased if screens, grilles, or other structural members cause flow resistance. Building air inlets at lower levels should be larger than the combined throat areas of all roof ventilators.

**Stacks or vertical flues** should be located where wind can act on them from any direction. Without wind, stack effect alone removes air from the room with the inlets.

### Required Flow for Indoor Temperature Control

The ventilation airflow rate required to remove a given amount of heat from a building can be calculated from Equations (26) and (27) if the quantity of heat to be removed and the indoor-outdoor temperature difference are known.

### Airflow Through Large Intentional Openings

The relationship describing the airflow through a large intentional opening is based on the Bernoulli equation with steady, incompressible flow. The general form that includes stack, wind, and mechanical ventilation pressures across the opening is

$$Q = C_D A \sqrt{2\Delta p / \rho} \quad (28)$$

where

$Q$  = airflow rate, m<sup>3</sup>/s

$C_D$  = discharge coefficient for opening, dimensionless

$A$  = cross-sectional area of opening, m<sup>2</sup>

$\rho$  = air density, kg/m<sup>3</sup>

$\Delta p$  = pressure difference across opening, Pa

The discharge coefficient  $C_D$  is a dimensionless number that depends on the geometry of the opening and the Reynolds number of the flow.

### Flow Caused by Wind Only

Factors due to wind forces that affect the ventilation rate include average speed, prevailing direction, seasonal and daily variation in speed and direction, and local obstructions such as nearby buildings, hills, trees, and shrubbery. Liddament (1988) reviewed the relevance of wind pressure as a driving mechanism. A multiflow path simulation model was developed and used to illustrate the effects of wind on air exchange rate.

Wind speeds may be lower in summer than in winter; directional frequency is also a function of season. Natural ventilation systems are often designed for wind speeds of one-half the seasonal average. The following equation shows the rate of air forced

through ventilation inlet openings by wind or determines the proper size of openings to produce given airflow rates:

$$Q = C_vAU \tag{29}$$

where

- $Q$  = airflow rate, m<sup>3</sup>/s
- $C_v$  = effectiveness of openings ( $C_v$  is assumed to be 0.5 to 0.6 for perpendicular winds and 0.25 to 0.35 for diagonal winds)
- $A$  = free area of inlet openings, m<sup>2</sup>
- $U$  = wind speed, m/s

Inlets should face directly into the prevailing wind. If they are not advantageously placed, flow will be less than that predicted by Equation (29); if the inlets are unusually well placed, flow will be slightly more. Desirable outlet locations are (1) on the leeward side of the building directly opposite the inlet, (2) on the roof, in the low-pressure area caused by a flow discontinuity of the wind, (3) on the side adjacent to the windward face where low-pressure areas occur, (4) in a dormer on the leeward side, (5) in roof ventilators, or (6) by stacks. Chapter 16 gives a general description of the wind pressure distribution on a building. The inlets should be placed in the exterior high-pressure regions; the outlets should be placed in the exterior low-pressure regions.

**Flow Caused by Thermal Forces Only**

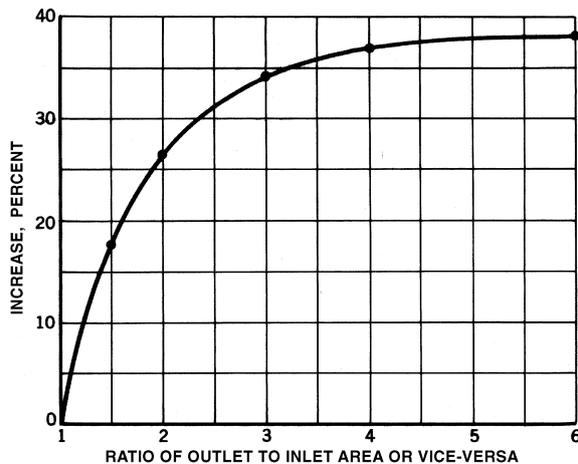

If building internal resistance is not significant, the flow caused by stack effect can be expressed by

$$Q = C_D A \sqrt{2g\Delta H_{NPL}(T_i - T_o)/T_i} \tag{30}$$

where

- $Q$  = airflow rate, m<sup>3</sup>/s
- $C_D$  = discharge coefficient for opening
- $\Delta H_{NPL}$  = height from midpoint of lower opening to NPL, m
- $T_i$  = indoor temperature, K
- $T_o$  = outdoor temperature, K

Equation (30) applies when  $T_i > T_o$ . If  $T_i < T_o$ , replace  $T_i$  in the denominator with  $T_o$ , and replace  $(T_i - T_o)$  in the numerator with  $(T_o - T_i)$ . An average temperature should be used for  $T_i$  if there is thermal stratification. If the building has more than one opening, the outlet and inlet areas are considered equal. The discharge coefficient  $C_D$  accounts for all viscous effects such as surface drag and interfacial mixing.

**Fig. 7 Increase in Flow Caused by Excess Area of One Opening over the Other**

Estimation of  $\Delta H_{NPL}$  is difficult for naturally ventilated buildings. If one window or door represents a large fraction (approximately 90%) of the total opening area in the envelope, then the NPL is at the mid-height of that aperture, and  $\Delta H_{NPL}$  equals one-half the height of the aperture. For this condition, flow through the opening is bidirectional (i.e., air from the warmer side flows through the top of the opening, and air from the colder side flows through the bottom). Interfacial mixing occurs across the counterflow interface, and the orifice coefficient can be calculated according to the following equation (Kiel and Wilson 1986):

$$C_D = 0.40 + 0.0045|T_i - T_o| \tag{31}$$

If enough other openings are available, the airflow through the opening will be unidirectional, and mixing cannot occur. A discharge coefficient of  $C_D = 0.65$  should then be used. Additional information on stack-driven airflows for natural ventilation can be found in Foster and Down (1987).

Greatest flow per unit area of openings is obtained when inlet and outlet areas are equal; Equations (30) and (31) are based on this equality. Increasing the outlet area over inlet area (or vice versa) increases airflow but not in proportion to the added area. When openings are unequal, use the smaller area in Equation (30) and add the increase as determined from Figure 7.

**Natural Ventilation Guidelines**

Several general guidelines should be observed in designing for natural ventilation. Some of these may conflict with other climate-responsive strategies (such as using orientation and shading devices to minimize solar gain) or other design considerations.

1. In hot, humid climates, use mechanical cooling. If mechanical cooling is not available, air velocities should be maximized in the occupied zones. In hot, arid climates, consider evaporative cooling. Airflow throughout the building should be maximized for structural cooling, particularly at night when the temperature is low.
2. Topography, landscaping, and surrounding buildings should be used to redirect airflow and give maximum exposure to breezes. Vegetation can funnel breezes and avoid wind dams, which reduce the driving pressure differential around the building. Site objects should not obstruct inlet openings.
3. The building should be shaped to expose maximum shell openings to breezes.
4. Architectural elements such as wing walls, parapets, and overhangs should be used to promote airflow into the building interior.
5. The long facade of the building and the majority of the door and window openings should be oriented with respect to the prevailing summer breezes. If there is no prevailing direction, openings should be sufficient to provide ventilation regardless of wind direction.
6. Windows should be located in opposing pressure zones. Two openings on opposite sides of a space increase the ventilation flow. Openings on adjacent sides force air to change direction, providing ventilation to a greater area. The benefits of the window arrangement depend on the outlet location relative to the direction of the inlet airstream.
7. If a room has only one external wall, better airflow is achieved with two widely spaced windows.
8. If the openings are at the same level and near the ceiling, much of the flow may bypass the occupied level and be ineffective in diluting contaminants there.
9. Vertical distance between openings is required to take advantage of the stack effect; the greater the vertical distance, the greater the ventilation.

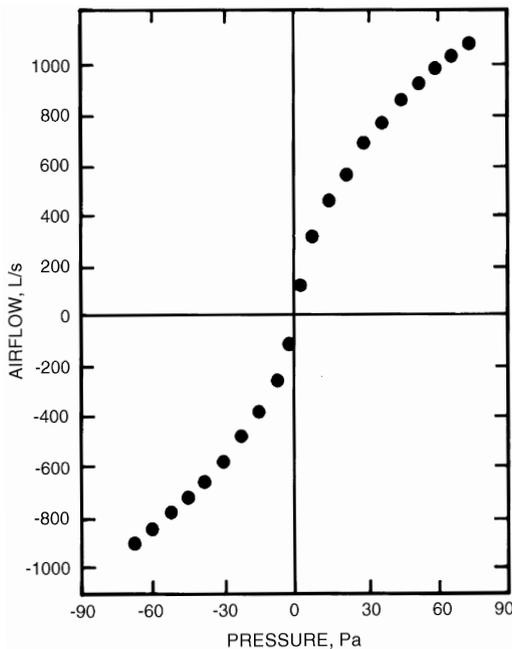

10. Openings in the vicinity of the NPL are least effective for thermally induced ventilation. If the building has only one large opening, the NPL tends to move to that level, which reduces the pressure across the opening.
11. Greatest flow per unit area of total opening is obtained by inlet and outlet openings of nearly equal areas. An inlet window smaller than the outlet creates higher inlet velocities. An outlet smaller than the inlet creates lower but more uniform airspeed through the room.
12. Openings with areas much larger than calculated are sometimes desirable when anticipating increased occupancy or very hot weather.
13. Horizontal windows are generally better than square or vertical windows. They produce more airflow over a wider range of wind directions and are most beneficial in locations where prevailing wind patterns shift.
14. Window openings should be accessible to and operable by occupants.
15. Inlet openings should not be obstructed by indoor partitions. Partitions can be placed to split and redirect airflow but should not restrict flow between the building's inlets and outlets.
16. Vertical airshafts or open staircases can be used to increase and take advantage of stack effects. However, enclosed staircases intended for evacuation during a fire should not be used for ventilation.

**RESIDENTIAL AIR LEAKAGE**

Most infiltration in residential buildings in the U.S. is dominated by envelope leakage. However, trends in new construction are towards tighter envelopes such that envelope leakage is reduced in newer housing.

**Envelope Leakage Measurement**

Envelope leakage of a building can be measured with **pressurization testing** (commonly called a **blower-door test**). Fan pressurization is relatively quick and inexpensive, and it characterizes building envelope airtightness independent of weather conditions.

**Fig. 8 Airflow Rate Versus Pressure Difference Data from Whole-House Pressurization Test**

In this procedure, a large fan or blower is mounted in a door or window and induces a large and roughly uniform pressure difference across the building shell (ASTM *Standard E 779*, ASTM *Standard E 1827*, ISO *Standard 9972*, and CGSB *Standard 149.10*). The airflow required to maintain this pressure difference is then measured. The leakier the building is, the more airflow is necessary to induce a specific indoor-outdoor pressure difference. The airflow rate is generally measured at a series of pressure differences ranging from about 10 Pa to 75 Pa.

The results of a pressurization test, therefore, consist of several combinations of pressure difference and airflow rate data. An example of typical data is shown in Figure 8. These data points characterize the air leakage of a building and are generally converted to a single value that serves as a measure of the building's airtightness. There are several different measures of airtightness, most of which involve fitting the data to a curve describing the relationship between the airflow  $Q$  through an opening in the building envelope and the pressure difference  $\Delta p$  across it. This relationship is called the **leakage function** of the opening. The form of the leakage function depends on the geometry of the opening. Background theoretical material relevant to leakage functions may be found in Hopkins and Hansford (1974), Etheridge (1977), Kronvall (1980), Chastain et al. (1987), and Walker et al. (1997).

The openings in a building envelope are not uniform in geometry and, generally, the flow never becomes fully developed. Each opening in the building envelope can be described by Equation (32), commonly called the **power law equation**:

$$Q = c(\Delta p)^n \tag{32}$$

where

- $c$  = flow coefficient,  $m^3/(s \cdot Pa^n)$
- $n$  = pressure exponent, dimensionless

Sherman (1992b) showed how the power law can be developed analytically by looking at developing laminar flow in short pipes. Equation (32) only approximates the relationship between  $Q$  and  $\Delta p$ . Measurements of single cracks (Honma 1975, Krieth et al. 1957) have shown that  $n$  can vary if  $\Delta p$  changes over a wide range. Additional investigation of pressure/flow data for simple cracks by Chastain et al. (1987) further indicated the importance of adequately characterizing the three-dimensional geometry of openings and the entrance and exit effects. Walker et al. (1997) showed that for the arrays of cracks in a building envelope over the range of pressures acting during infiltration,  $n$  is constant. A typical value for  $n$  is about 0.65.  $c$  and  $n$  can be determined for a building using fan pressurization techniques.

**Airtightness Ratings**

In some cases, the predicted airflow rate is converted to an equivalent or effective air leakage area as follows:

$$A_L = 10\,000 Q_r \frac{\sqrt{\rho/2\Delta p_r}}{C_D} \tag{33}$$

where

- $A_L$  = equivalent or effective air leakage area,  $cm^2$
- $Q_r$  = predicted airflow rate at  $\Delta p_r$  (from curve fit to pressurization test data),  $m^3/s$
- $\rho$  = air density,  $kg/m^3$
- $\Delta p_r$  = reference pressure difference, Pa
- $C_D$  = discharge coefficient

All the openings in the building shell are combined into an overall opening area and discharge coefficient for the building when the equivalent or effective air leakage area is calculated. Some users of the leakage area approach set  $C_D = 1$ . Others set  $C_D \approx 0.6$  (i.e., the discharge coefficient for a sharp-edged orifice). The air leakage area

of a building is, therefore, the area of an orifice (with an assumed value of  $C_D$ ) that would produce the same amount of leakage as the building envelope at the reference pressure.

An airtightness rating, whether based on an air leakage area or a predicted airflow rate, is generally normalized by some factor to account for building size. Normalization factors include floor area, exterior envelope area, and building volume.

With the wide variety of possible approaches to normalization and reference pressure difference, and the use of the air leakage area concept, many different airtightness ratings are being used. Reference pressure differences include 4, 10, 25, 50, and 75 Pa. Reference pressure differences of 4 and 10 Pa are advocated because they are closer to the pressure differences that actually induce air exchange and, therefore, better model the flow characteristics of the openings. While this may be true, they are outside the range of measured values in the test; therefore, the predicted airflow rates at 4 and 10 Pa are subject to significant uncertainty. The uncertainty in these predicted airflow rates and the implications for quantifying airtightness are discussed in Persily and Grot (1985b), Chastain (1987), and Modera and Wilson (1990). Round robin tests by Murphy et al. (1991) to determine the repeatability and reproducibility of fan pressurization devices found that subtle errors in fan calibration or operator technique are greatly exaggerated when extrapolating the pressure versus flow curve out to 4 Pa, with errors as great as  $\pm 40\%$ , mainly due to the fan calibration errors at low flow.

Some common airtightness ratings include the effective air leakage area at 4 Pa assuming  $C_D = 1.0$  (Sherman and Grimsrud 1980); the equivalent air leakage area at 10 Pa assuming  $C_D = 0.611$  (CGSB *Standard* 149.10); and the airflow rate at 50 Pa, divided by the building volume to give units of air changes per hour (Blomsterberg and Harje 1979).

### Conversion Between Ratings

Air leakage areas at one reference pressure difference can be converted to air leakage areas at an other reference pressure difference according to:

$$A_{r,2} = A_{r,1} \left( \frac{C_{D,1}}{C_{D,2}} \right) \left( \frac{\Delta p_{r,2}}{\Delta p_{r,1}} \right)^{n-0.5} \quad (34)$$

where

- $A_{r,1}$  = air leakage area at reference pressure difference  $\Delta p_{r,1}$ ,  $\text{cm}^2$
- $A_{r,2}$  = air leakage area at reference pressure difference  $\Delta p_{r,2}$ ,  $\text{cm}^2$
- $C_{D,1}$  = discharge coefficient used to calculate  $A_{r,1}$
- $C_{D,2}$  = discharge coefficient used to calculate  $A_{r,2}$
- $n$  = pressure exponent from Equation (32)

An air leakage area at one reference pressure difference can be converted to an airflow rate at some other reference pressure difference according to

$$Q_{r,2} = \frac{C_{D,1} A_{r,1}}{10\,000} \sqrt{\frac{2}{\rho}} (\Delta p_{r,1})^{0.5-n} (\Delta p_{r,2})^n \quad (35)$$

where  $Q_{r,2}$  = airflow rate at reference difference  $\Delta p_{r,2}$ ,  $\text{m}^3/\text{s}$ .

The flow coefficient  $c$  in Equation (32) may be converted to an air leakage area according to

$$A_L = \frac{10\,000 c}{C_D} \sqrt{\frac{2}{\rho}} \Delta p_r^{(n-0.5)} \quad (36)$$

Finally, an air leakage area may be converted to the flow coefficient  $c$  in Equation (32) according to

$$c = \frac{C_D A_L}{10\,000} \sqrt{\frac{2}{\rho}} (\Delta p_r)^{0.5-n} \quad (37)$$

Equations (34) through (37) require the assumption of a value of  $n$ , unless it is reported with the measurement results. When whole-building pressurization test data are fitted to Equation (32), the value of  $n$  generally lies between 0.6 and 0.7. Therefore, using a value of  $n$  in this range is reasonable.

### Building Air Leakage Data

Fan pressurization measures a building property that ideally varies little with time and weather conditions. In reality, unless the wind and temperature differences during the measurement period are sufficiently mild, the pressure differences they induce during the test will interfere with the test pressures and cause measurement errors. Persily (1982) and Modera and Wilson (1990) studied the effects of wind speed on pressurization test results. Several experimental studies have also shown variations on the order of 20 to 40% over a year in the measured airtightness in homes (Persily 1982, Kim and Shaw 1986, Warren and Webb 1986).

Figure 9 summarizes envelope leakage measured North American housing (Sherman and Dickerhoff 1998) and from several European and Canadian sources (AIVC 1994). This figure shows the large range of measured envelope tightness but can still be used to illustrate typical and extreme values in the housing stock.

ASHRAE *Standard* 119 establishes air leakage performance levels for residential buildings. These levels are in terms of the normalized leakage area  $A_n$ :

$$A_n = 0.1 \left( \frac{A_L}{A_f} \right) \left( \frac{H}{H_o} \right)^{0.3} \quad (38)$$

where

- $A_n$  = normalized leakage area, dimensionless
- $A_L$  = effective leakage area at 4 Pa ( $C_D = 1.0$ ),  $\text{cm}^2$
- $A_f$  = gross floor area (within exterior walls),  $\text{m}^2$
- $H$  = building height, m
- $H_o$  = reference height of one-story building = 2.5 m

### Air Leakage of Building Components

The fan pressurization procedure discussed in the section on Envelope Leakage Measurement enables the measurement of whole-building air leakage. The location and size of individual openings in building envelopes are extremely important because they influence the air infiltration rate of a building as well as the heat and moisture transfer characteristics of the envelope. Additional test procedures exist for pressure-testing individual building components such as windows, walls, and doors; they are discussed in ASTM *Standards* E 283 and E 783 for laboratory and field tests, respectively.

### Leakage Distribution

Dickerhoff et al. (1982) and Harje and Born (1982) studied the air leakage of individual building components and systems. The following points summarize the percentages of whole-building air leakage area associated with various components and systems. The values in parentheses include the range determined for each component and the mean of the range.

**Walls** (18 to 50%; 35%). Both interior and exterior walls contribute to the leakage of the structure. Leakage between the sill plate and the foundation, cracks below the bottom of the gypsum wall-board, electrical outlets, plumbing penetrations, and leaks into the attic at the top plates of walls all occur.

**Ceiling details** (3 to 30%; 18%). Leakage across the top ceiling of the heated space is particularly insidious because it reduces the effectiveness of insulation on the attic floor and contributes to infil-

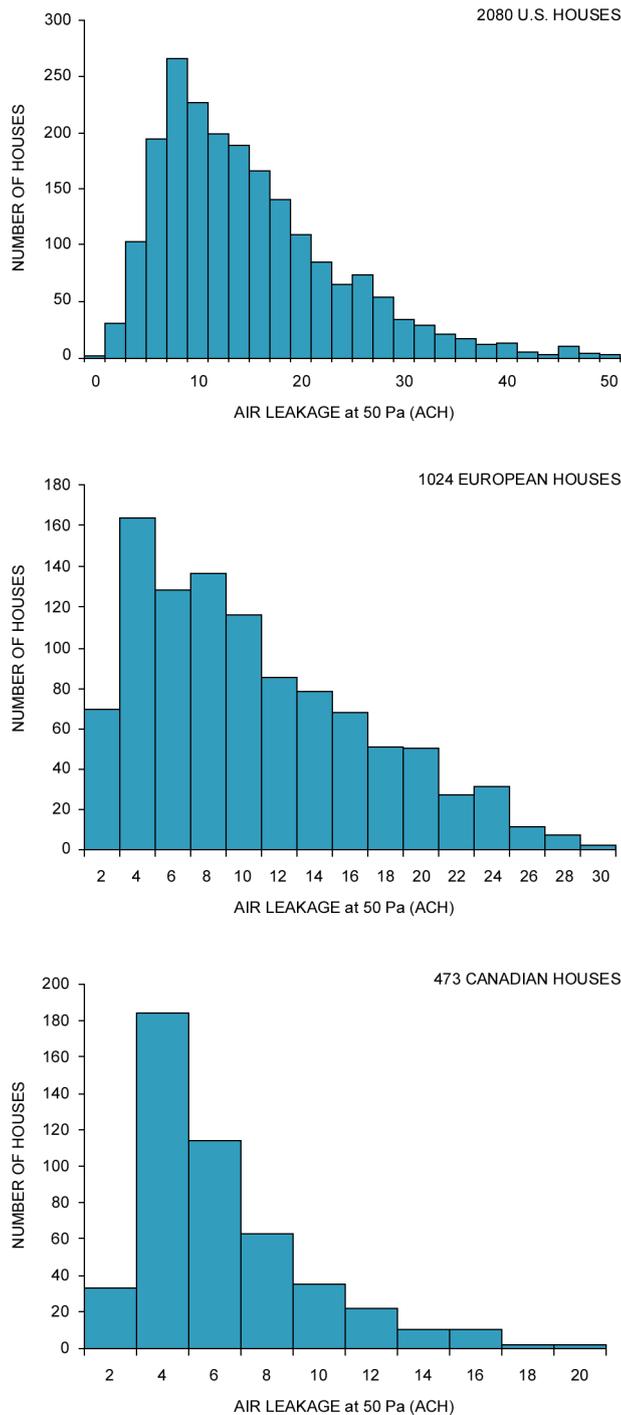

Fig. 9 Envelope Leakage Measurements

tration heat loss. Ceiling leakage also reduces the effectiveness of ceiling insulation in buildings without attics. Recessed lighting, plumbing, and electrical penetrations leading to the attic are some particular areas of concern.

**Forced-air heating and/or cooling systems (3 to 28%; 18%).** The location of the heating or cooling equipment, air handler, or ductwork in conditioned or unconditioned spaces; the venting arrangement of a fuel-burning device; and the existence and location of a combustion air supply all affect leakage. Modera et al. (1991) and Robison and Lambert (1989), among others, have shown

that the variability of leakage in ducts passing through unconditioned spaces is high, the coefficient of variation being on the order of 50%. Field studies have also shown that in-situ repairs can eliminate one-quarter to two-thirds of the observed leakage (Cummings and Tooley 1989, Cummings et al. 1990, Robison and Lambert 1989, Jump et al. 1996). The 18% contribution of ducts to total leakage significantly underestimates their impact because during system operation, the pressure differentials across the duct leaks are approximately ten times higher than typical pressure differences across the envelope leaks (Modera 1989, Modera et al. 1991) and result in large (factors of two to three) changes in ventilation rate (Walker 1999, Walker et al. 1999, Cummings et al. 1990).

**Windows and doors (6 to 22%; 15%).** More variation in window leakage is seen among window types (e.g., casement versus double-hung) than among new windows of the same type from different manufacturers (Weidt et al. 1979). Windows that seal by compressing the weather strip (casements, awnings) show significantly lower leakage than windows with sliding seals.

**Fireplaces (0 to 30%; 12%).** When a fireplace is not in use, poorly fitting dampers allow air to escape. Glass doors reduce excess air while a fire is burning but rarely seal the fireplace structure more tightly than a closed damper does. Chimney caps or fireplace plugs (with signs that warn they are in place) effectively reduce leakage through a cold fireplace.

**Vents in conditioned spaces (2 to 12%; 5%).** Exhaust vents in conditioned spaces frequently have either no dampers or dampers that do not close properly.

**Diffusion through walls (<1%).** Diffusion, in comparison to infiltration through holes and other openings in the structure, is not an important flow mechanism. At 5 Pa, the permeability of building materials produces an air exchange rate of less than 0.01 ACH by wall diffusion in a typical house.

**Component leakage areas.** Table 1 shows effective air leakage areas for a variety of residential building components at 4 Pa with  $C_D$  assumed equal to 1 (Colliver et al. 1992). The values in the table present results in terms of air leakage area per unit component. Per unit component means per component, per unit surface area, or per unit length of crack or sash, whichever is appropriate. These air leakage areas may be converted to air leakage areas at other reference pressures, airflow rates, or flow coefficients using Equations (34) through (37). Table 1 can be used to estimate the air leakage area of the building if test data are not available. To obtain the building's total air leakage area, multiply the overall dimensions or number of occurrences of each building component by the appropriate table entry. The sum of the resulting products is the total building air leakage area. Table 2 gives the result of an example calculation of the effective air leakage area of a residence. Each leakage component is identified in the first column and described in the second. The length, area, or number of the component is in the third column. The fourth column contains the air leakage area per unit component, from Table 1, and the fifth contains the total air leakage area associated with that component. The sum of the terms in the last column is the total air leakage area of the building, in this case 848  $\text{cm}^2$ . Klote and Milke (1992) describe a method for estimating airflows through gaps such as those found around doors.

### Multifamily Building Leakage

Leakage distribution is particularly important in multifamily apartment buildings. These buildings often cannot be treated as single zones due to the internal resistance between apartments. Moreover, the leakage between apartments varies widely, tending to be small in modern construction, and ranging as high as 60% of the total apartment leakage in turn-of-the-century brick walk-up apartment buildings (Modera et al. 1991, Diamond et al. 1986). Little information on interzonal leakage has been reported because of the difficulty and expense of these measurements.

**Table 1 Effective Air Leakage Areas (Low-Rise Residential Applications Only)**

	Units (see note)	Best Estimate	Mini- mum	Maxi- mum		Units (see note)	Best Estimate	Mini- mum	Maxi- mum

### Controlling Air Leakage

**New Buildings.** It is much easier to build a tight building than to tighten an existing building. Elmroth and Levin (1983), Eyre and Jennings (1983), Marbek Resource Consultants (1984), and Nelson et al. (1985) provide information and construction details on airtight building design for houses.

A continuous air infiltration retarder is one of the most effective means of reducing air leakage through walls, around window and door frames, and at joints between major building elements. Particular care must be taken to ensure its continuity at all wall, floor, and ceiling joints; at window and door frames; and at all penetrations of the retarder, such as electrical outlets and switches, plumbing connections, and utility service penetrations. Joints in the **air-vapor retarder** must be lapped and sealed. Plastic vapor retarders installed in the ceiling should be tightly sealed with the vapor retarder in the outside walls and should be continuous over the partition walls. A seal at the top of the partition walls prevents leakage into the attic; a plate on top of the studs generally gives a poor seal. The air infiltration retarder can be installed either on the inside of the wall framing, in which case it usually functions as a vapor retarder as well, or on the outside of the wall framing, in which case it should have a permeance rating high enough to permit diffusion of water vapor from the wall. For a discussion of moisture transfer in building envelopes, see Chapter 23 and Chapter 24.

A continuous air infiltration retarder installed on the outside of wall framing can cover many difficult construction details associated with the installation of continuous air-vapor retarders. Interior air-vapor retarders must be lapped and sealed at electrical outlets and switches, at joints between walls and floors and between walls and ceilings, and at plumbing connections penetrating the wall's interior finish. The exterior air infiltration retarder can cover these problem areas continuously. Joints in the air infiltration retarder should be lapped and sealed or taped. Exterior air infiltration retarders are generally made of a material stronger than plastic film and are more likely to withstand damage during construction. Sealing the wall against air leakage at the exterior of the insulation also cuts down on convection currents within the wall cavity, allowing insulation to retain more of its effectiveness.

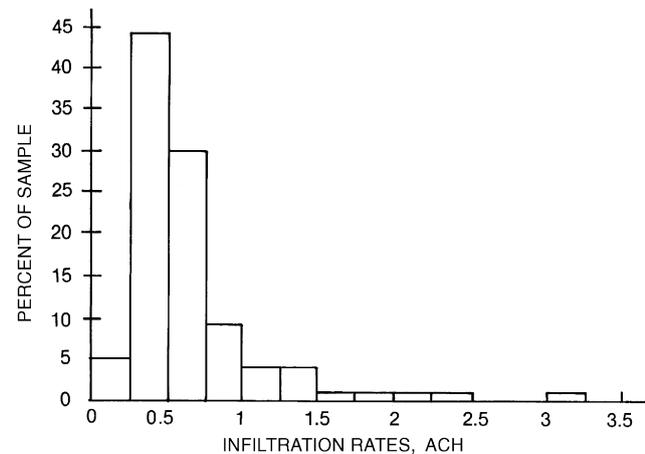

**Existing Buildings.** The air leakage sites must first be located in order to tighten the envelope of an existing building. As discussed earlier, air leakage in buildings is due not only to windows and doors, but to a wide range of unexpected and unobvious construction defects. Many important leakage sites can be very difficult to find. A variety of techniques developed to locate leakage sites are described in ASTM *Standard E 1186* and Charlesworth (1988).

Once leakage sites are located, they can be repaired with materials and techniques appropriate to the size and location of the leak. Harrje et al. (1979), Diamond et al. (1982), and Energy Resource Center (1982) include information on airtightening in

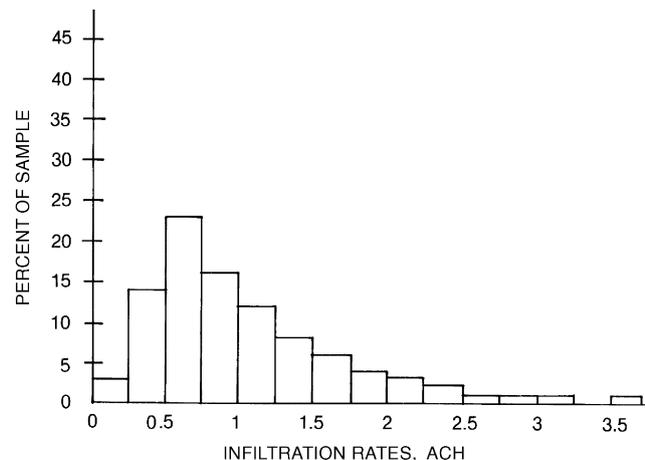

existing residential buildings. With these procedures, the air leakage of residential buildings can be reduced dramatically. Depending on the extent of the tightening effort and the experience of those doing the work, residential buildings can be tightened anywhere from 5% to more than 50% (Blomsterberg and Harrje 1979, Harrje and Mills 1980, Jacobson et al. 1986, Verschoor and Collins 1986, Giesbrecht and Proskiw 1986). Much less information is available for airtightening large, commercial buildings, but the same general principles apply (Parekh et al. 1991, Persily 1991).

### RESIDENTIAL VENTILATION

Typical infiltration values in housing in North America vary by a factor of about ten, from tightly constructed housing with seasonal average air exchange rates of about 0.2 air changes per hour (ACH) to loosely constructed housing with air exchange rates as great as 2.0 ACH. Figure 10 and Figure 11 show histograms of infiltration rates measured in two different samples of North American housing (Grimmsrud et al. 1982, Grot and Clark 1979). Figure 10 shows the average seasonal infiltration of 312 houses located in different areas in North America. The median infiltration value of this sample is 0.5 ACH. Figure 11 represents measurements in 266 houses located in 16 cities in the United States. The median value of this sample is 0.9 ACH. The group of houses contained in the Figure 10 sample is biased toward new, energy-efficient houses, while the group in Figure 11 represents older, low-income housing in the United States.

**Fig. 10 Histogram of Infiltration Values—New Construction**

**Fig. 11 Histogram of Infiltration Values—Low-Income Housing**

Additional studies have found average values for houses in regional areas. Palmiter and Brown (1989) and Parker et al. (1990) found a heating season average of 0.40 ACH (range: 0.13 to 1.11 ACH) for 134 houses in the Pacific Northwest. In a comparison of 292 houses incorporating energy-efficient features (including measures to reduce air infiltration and provide ventilation heat recovery) with 331 control houses, Parker et al. (1990) found an average of about 0.25 ACH (range: 0.02 to 1.63 ACH) for the energy-efficient houses versus 0.49 (range: 0.05 to 1.63 ACH) for the control. Ek et al. (1990) found an average of 0.5 ACH (range: 0.26 to 1.09) for 93 double-wide manufactured homes also in the Pacific Northwest. Canadian housing stock has been characterized by Yuill and Comeau (1989) and Riley (1990). While these studies do not represent random samples of North American housing, they indicate the distribution of infiltration rates expected in a group of buildings.

Occupancy influences have not been measured directly and vary widely. Desrochers and Scott (1985) estimated that they add an average of 0.10 to 0.15 ACH to unoccupied values. Kvisgaard and Collet (1990) found that in 16 Danish dwellings, the users on average provided 63% of the total air exchange rate.

Ventilation air requirements for houses in the U.S. have traditionally been met on the assumption that the building envelope is leaky enough that infiltration will suffice. Possible difficulties with this approach include low infiltration when natural forces (temperature difference and wind) are weak, unnecessary energy consumption when such forces are strong, drafts in cold climates, lack of control of ventilation rates to meet changing needs, poor humidity control, potential for interstitial condensation from exfiltration in cold climates or infiltration in hot humid climates, and lack of opportunity to recover the energy used to condition the ventilation air. The solution to these concerns is to have a reasonably tight building envelope and a properly designed and operated mechanical ventilation system.

ASHRAE *Standard* 119 and the National Building Code of Canada (NRCC 1995) encourage the transition to tighter envelope construction. Hamlin (1991) shows a 30% increase in airtightness of tract-built Canadian houses between 1982 and 1989. Also, 82% of the newer houses had natural air exchange rates below 0.3 ACH in March. Yuill (1991) derived a procedure to show the extent to which infiltration contributes toward meeting ventilation air requirements. As a result, the National Building Code of Canada has requirements for mechanical ventilation capability in all new dwelling units.

ASHRAE *Standard* 62 gives ventilation air requirements for houses, essentially 0.35 ACH with at least 8 L/s per occupant. Canadian Standards Association (CSA) *Standard* F326 expands the requirements for residential mechanical ventilation systems to cover air distribution within the house, thermal comfort, minimum temperatures for equipment and ductwork, system controls, pressurization and depressurization of the dwelling, installation requirements, and verification of compliance. Verification can be by design or by test, but the total rate of outside air delivery must be measured.

Mechanical ventilation is being used in houses, especially in energy-efficient housing demonstration programs (Riley 1990, Palmiter et al. 1991). Possible systems can be characterized as local or central; exhaust, supply, or balanced; with forced-air or radiant/ hydronic heating/cooling systems; with or without heat recovery; and with continuous operation or controlled by occupants, demand (i.e., by pollutant sensing), timers or humidity. Note that not all combinations are viable. Various options are described by Fisk et al. (1984), Hekmat et al. (1986), Sibbitt and Hamlin (1991), Palmiter et al. (1991), Yuill et al. (1991), Holton et al. (1997), Sherman and Matson (1997), Reardon and Shaw (1997), and Lubliner et al. (1997).

The simplest systems use bathroom and kitchen fans to augment infiltration. Noise, installed capacity, durability under continuous operation, distribution to all rooms (especially bedrooms), envelope moisture, combustion safety, and energy efficiency issues need to be

addressed. Many present bath and kitchen fans are ineffective ventilators because of poor installation and design. However, properly specified and installed exhaust fans can form part of good whole-house ventilation systems and are so specified in some Canadian building codes.

Some central supply systems use a central air-handling unit blower to induce air from the outdoors and distribute it. However, the blower operates intermittently if thermostatically controlled and provides little ventilation in mild weather. Continuous blower operation increases energy consumption. If the blower operates continuously when the heat source is off, the combination of lower mixed air temperature and high air speed can cause cold air drafts. To offset these problems, some systems use electronically commutated blower motors, which allow efficient continuous operation at lower speeds. Some others use a timer to cycle the blower when thermostat demands are inadequate to cause the blower to operate when needed for ventilation (Rudd 1998).

Central exhaust systems use leakage sites and, in some cases, intentional and controllable openings in the building envelope as the supply. Such systems are suitable for retrofit in existing houses. Energy can be recovered from the exhaust airstream with a heat pump to supplement domestic hot water and/or space heating.

For new houses with tightly constructed envelopes, balanced ventilation with passive heat recovery (air-to-air heat exchangers or heat recovery ventilators) can be appropriate in some climates. Fan-induced supply and exhaust air flows at nearly equal rates over a heat exchanger, where heat and sometimes moisture is transferred between the airstreams. This reduces the energy required to condition the ventilation air by typically 60 to 80% (Cutter 1987). It also reduces the thermal comfort problem that occurs when untempered air is introduced directly into the house. Airflow balance, leakage between streams, biological contamination of wet surfaces, frosting, and first cost are concerns associated with these systems.

The type of ventilation system can be selected based on house leakage class as defined in ASHRAE *Standard* 119. Balanced air-to-air systems with heat recovery are optimal for tight houses (leakage classes A–C). The leakier the house is, the larger is the contribution from infiltration and the less effective is heat recovery ventilation. Tightening the envelope beyond the level of ASHRAE *Standard* 119 may be warranted in extreme climates to better use the heat recovery effect (Sherman and Matson 1997). In mild climates, these systems can also effectively be used in leakage classes D–F. Central exhaust systems should not be used for leakage classes A–C unless special provisions are made for air inlets; otherwise their operation may depressurize the house enough to cause backdrafting through fossil-fueled appliances. Unbalanced systems (either supply or exhaust) are optimal for leakage classes D–F. Ventilation systems are normally not needed for leakage classes G–J, but for those cases in which they are, an unbalanced system is usually the best choice.

### Residential Ventilation Zones

For guidance in the selection of residential ventilation systems, Sherman (1995) developed four climatic zones for the United States. These zones are shown in Figure 12 for the continental United States. Alaska is in Zone 1, and Hawaii is in Zone 4.

Zone 1 includes the severe climates of the northern tier of states. A Zone 1 residence that meets airtightness and energy conservation standards probably cannot meet its ventilation needs through infiltration and will require forced (mechanical) ventilation. Zone 2 includes the moderate climates where careful design and construction may allow buildings to simultaneously meet energy standards and ventilation needs through infiltration and mechanical exhaust. The mild climates in Zone 3 allow residences to meet both ASHRAE *Standards* 119 and 62 over a substantial range of airtightness. Zone 4 residences have relatively small energy penalties associated

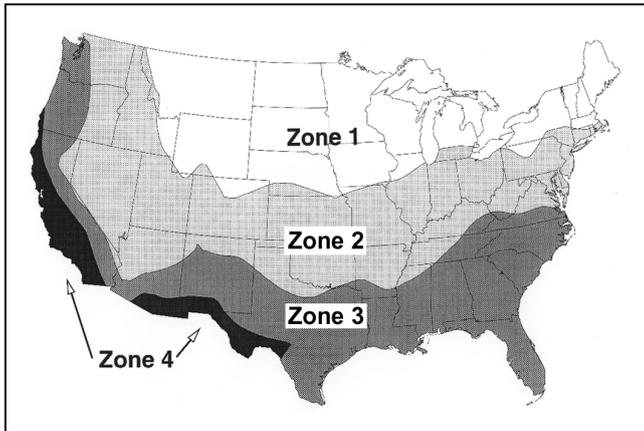

Fig. 12 Airtightness Zones for Residences in the United States (Sherman 1995)

with infiltration or ventilation. In this zone, natural ventilation is usually preferred to forced ventilation as a technique to supplement infiltration.

### RESIDENTIAL VENTILATION REQUIREMENTS

Traditionally, residential ventilation has been provided by natural ventilation and infiltration. Sherman and Matson (1997) showed that most of the older building stock is sufficiently leaky that infiltration alone can meet the minimum requirements of ASHRAE *Standard 62*. Houses built or retrofitted to new standards have substantially tighter envelopes and insufficient infiltration to meet ventilation standards. In most circumstances, concerns over safety, noise, comfort, air quality, and energy minimize occupant use of operable windows. As a result, these houses require supplemental mechanical ventilation to satisfy these standards.

Simply meeting the minimum residential ventilation rates is not always sufficient to adequately dilute all contaminants. For some buildings, such ventilation may not meet the requirements of individuals with allergies or chemical sensitivities or when there are unusual sources. In these cases, source control or extra ventilation is required to manage the contaminant levels. Therefore, especially in single-family dwellings, occupants must be responsible for introducing, monitoring, and controlling the sources in the indoor environment, as well as for operating the dwelling unit to meet their individual needs.

### Source Control

When considering how much whole-house ventilation should be supplied, typical and unusual significant sources of indoor pollution need to be controlled. This can be done either by mitigating the source itself or by using local exhaust to extract the contaminants before they can mix into the indoor environment. Typical sources that should be considered include the following:

**Clothes Dryers.** Clothes dryer exhaust is heavily laden with moisture and laundry by-products. Many moisture problems have been traced to clothes dryers vented indoors. Exhaust from clothes dryers, which is typically about 70 L/s, should be vented directly to the outdoors.

**Combustion.** Water and carbon dioxide are always emitted during combustion. Other more dangerous compounds can be emitted as well. All these by products should be vented directly outdoors. Venting of combustion appliances should meet all applicable codes, but for buildings with naturally aspirated combustion appliances within the pressure boundary, excessive depressurization due to

exhaust systems should be avoided. In addition, a depressurization safety test should be considered, such as described in ASTM *Standard E 1998* or CGSB *Standard 51.71*.

**Carbon monoxide** is one of the most pervasive indoor contaminants. It can come from virtually any source of combustion, including automobiles. Because even combustion appliances that meet manufacturers specifications can interact with the building and emit carbon monoxide, at least one carbon monoxide alarm meeting UL *Standard 2034* should be installed in each dwelling that has combustion appliances (including fireplaces) within the pressure boundary or attached garages.

**Garages.** Garages contain many sources of contaminants. Doors between garages and occupied space should be well sealed (with gaskets or weatherstripping) and possibly be self-closing. Depressurized sections of HVAC systems, such as air handlers or return ducts, should not be located in garages. If such sections must pass through garages, they should be well sealed.

**Particulates.** The ventilation system should be designed such that return and outdoor air is filtered before passing through the thermal conditioning components. Pressure drops associated with this filtration should be considered in the design of the air-handling system. Particulate filters or air cleaners should have a minimum efficiency of 60% for 3  $\mu$ m particles, which is equivalent to a MERV 6 designated filter according to ASHRAE *Standard 52.2*.

**Outdoor Air.** Outdoor air may contain unacceptably high levels of pollutants, including ozone, pollen, carbon monoxide, particulate matter, odors, etc. In such cases, it may be impossible to provide acceptable indoor air quality; increased ventilation rates can actually decrease indoor air quality. In areas in which this problem may be anticipated, controls should be provided to allow the occupants to temporarily reduce the ventilation rate. Air cleaning should be considered for sensitive individuals.

### Local Exhaust Ventilation

The single most important source control mechanism in dwellings apart from source elimination is local exhaust. All wet rooms and other spaces designed to allow specific contaminant release should be provided with local exhaust. These spaces include kitchens, utility rooms, bathrooms, and toilets. Workshops, recreation rooms, smoking areas, art studios, and hobby rooms may also require local ventilation and/or air cleaning to remove contaminants generated by the activities involved. If unvented combustion appliances must be used, then rooms with these appliances should meet the same general ventilation requirements for kitchens because such appliances generate significant amounts of moisture even when burning properly.

Mechanical ventilation is the preferred method of providing local ventilation. Normally, it is designed to operate intermittently to exhaust the contaminated air outside when the contaminant is being produced. However, in many circumstances, a continuous and lower-flow-rate exhaust can work as well.

**Continuous Local Mechanical Ventilation.** A continuously-operating mechanical exhaust is intended to operate without occupant intervention. This exhaust may be part of a balanced mechanical ventilation system. The system should be designed to operate during all hours in which the dwelling is occupied. Override control should be provided if needed. The minimum delivered ventilation should be at least that given in Table 3.

Table 3 Continuous Exhaust Airflow Rates

Application	Continuous Flow	Notes
Kitchen	5 ACH	Based on kitchen volume
Utility room	10 L/s	Not less than 2 room air changes per hour
Bathroom	10 L/s	
Toilet	10 L/s	

**Table 4 Intermittent Exhaust Airflow Rates**

Application	Continuous Flow	Notes
Kitchen	50 L/s	Vented range hood required if less than 5 kitchen air changes per hour
Utility room	25 L/s	Not less than 2 room air changes per hour
Bathroom	25 L/s	
Toilet	25 L/s	

**Table 5 Total Ventilation Air Requirements**

Area Based	Occupancy Based
0.10 L/s per square metre of floor space	8 L/s per person, based on normal occupancy

**Intermittent Local Mechanical Ventilation.** An intermittently operating local mechanical exhaust is intended to be operated as needed by the occupant and should be designed with this intent. Shut-off timers, occupancy controls, multiple speed fans, and switching integral with room lighting are helpful, provided they do not impede occupant control. The minimum airflow rating should be at least that given in Table 4, or as mandated by local codes.

**Alternative Local Ventilation.** Cleaning of recirculated air can sometimes be substituted for local ventilation, if it can be shown to be effective in removing contaminants of concern. Natural ventilation is not generally a suitable method for local ventilation in most climates and spaces. Use of natural ventilation can cause re-entrainment problems when air flows into rather than out of the space, and contaminated exfiltrating air reenters the building. In milder climates, it may be acceptable to use natural ventilation, when the contaminant of concern is related to odor rather than health or safety. Purpose-designed passive exhaust systems have shown acceptable ventilation in European settings and may be considered in lieu of mechanical systems.

**Whole-House Ventilation**

While control of significant sources of pollution in a dwelling is important, whole-house ventilation may still be needed. Each dwelling should be provided with outdoor air according to Table 5. The rate is the **sum** of the Area-Based and Occupancy-Based columns. Design occupancy can be based on the number of bedrooms as follows: first bedroom, two persons; each additional bedroom, one person.

**Natural whole-house ventilation** that relies on occupant operation should not be used to make up any part of the minimum total whole-house ventilation. However, because occupancy and sources vary significantly, the capacity to ventilate above minimum rates can be provided by operable openings such as doors and windows.

**Continuous whole-house mechanical ventilation** systems are intended to operate without occupant intervention. The ventilation effects of multiple local systems may be combined to meet whole-house requirements.

**Intermittent whole-house mechanical ventilation** systems are intended to be operated automatically and regularly, but not necessarily continuously. The system may consist of supply, exhaust, or balanced mechanical systems. It should be designed so that it can operate automatically based on a timer. A supplementary control mechanism such as a humidistat or indoor air quality sensor may be used.

The effective ventilation rate of an intermittent system is the product of its delivered capacity, its fractional on-time, and the temporal ventilation effectiveness from Table 6. Systems cycling at least once every 3 h may be assumed to have perfect ventilation effectiveness. Multiple systems may be combined, but the combination should only be supply or exhaust values and not both.

**Table 6 Ventilation Effectiveness for Intermittent Fans**

Fractional On-Time, <i>f</i>	Temporal Ventilation Effectiveness
$f \leq 35\%$	0.33
$35\% < f \leq 60\%$	0.50
$60\% < f \leq 80\%$	0.75
$80\% < f$	1.0

**Air Distribution**

Ventilation air should be provided to each habitable room through mechanical and natural air distribution. If a room does not have a balanced air supply (or inlet) and return (or exhaust), pathways for transfer air should be provided. These pathways may be door undercuts, transfer ducts with grilles, or simply grilles where ducts are not necessary.

In houses without central air handlers, special provisions to distribute outdoor air may be required. Rooms in which occupants spend many continuous hours, such as bedrooms, may require special consideration.

**Selection Principles for Ventilation Systems**

Determining the right ventilation approach is part of optimizing the entire building, and it can rarely be done without considering the building envelope, the climate, the needs of the users, and costs. For example, mechanical exhaust systems should not be used in hot, humid climates (because of possible condensation problems) when the building has or is likely to have air conditioning installed. Similarly, mechanical supply ventilation systems should not be used in very cold climates.

Occupant comfort, energy efficiency, ease of use, service life, first and life-cycle cost, value-added features, and indoor environmental quality should be considered when selecting a strategy and system. HVAC (and related) systems can be a potential cause of poor indoor air quality. For example, occupants may not use the ventilation systems as intended if operation results in discomfort (e.g., drafts) or excessive energy use. The resulting lack of ventilation might produce poor indoor air quality. Therefore, careful design, operation, and maintenance is necessary to provide optimum effectiveness.

All exhaust, supply, or air-handler fans have the potential to change the pressure of the living space relative to the outside. High-volume fans, such as the air handler and some cooking exhaust fans, can cause high levels of depressurization, particularly in tightly constructed homes. Considering these effects is essential in design. Depressurization of the living space relative to outside may cause backdrafting of combustion appliances and the migration of contaminants (such as radon or other soil gases, car exhaust, insulation particles, etc.) into the living space. Depressurization can also result in moisture intrusion into building cavities in warm, moist climates, which may cause structural damage and fungal growth. Pressurization of the living space can cause condensation in building cavities in cold climates, resulting in damage to the structural integrity of the home. Excess pressure can best be prevented by balanced ventilation systems and nonleaky duct systems. In addition, adequate pathways must be available for all return air to the air-handling devices.

Occupant activities and operation of fans that exhaust air from the home (including leaky ducts on air conditioners, furnaces, or heat pumps) may produce depressurization of the structure. Several options to address backdrafting concerns include

- Using combustion appliances with isolated (or sealed) combustion systems
- Locating combustion appliances in a ventilated room isolated from depressurized zones by well-sealed partitions
- Installing supply fans to balance or partially balance the exhaust from the zone
- Testing to ensure that depressurization will not be excessive

The system must be designed, built, operated, and maintained in a way that discourages the growth of biological contaminants. Typical precautions include sloping condensate drain pans toward the drain, keeping condensate drains free of obstructions, maintaining cooling coils free of dirt and other obstructions, and checking and eliminating any cause of moisture inside ducts.

### Selecting a Whole-House Ventilation System

Whole-house ventilation can be provided through mechanical or natural means or by a combination thereof. Regardless of the approach chosen, it is necessary to consider where the outdoor air comes from, how it enters the house, how it is distributed, and how it leaves the house. Systems that are uncomfortable, expensive to operate, unsafe, noisy, or in other ways unacceptable to the occupants are not likely to be used.

**Natural Ventilation.** The use of operable windows and other natural ventilation openings is rarely an acceptable means of providing base levels of whole-house ventilation (Wilson and Walker 1992), but when it is, it can be a cost-effective alternative. Operable windows allow the user to control the ventilation by the size of the opening. Windows are present for light and egress and can serve as a ventilation system; most detached dwellings have sufficient operable windows for natural ventilation. Environmental factors may inhibit effective occupant use of the windows. During cold periods, open windows can cause thermal discomfort. Noise or security issues may also reduce the desirability of opening windows. Finally, the uncontrolled nature of the natural ventilation may increase energy use in many climates, but it can be energy-efficient in some mild climates.

**Mechanical Ventilation.** Whole-house systems may run continuously or intermittently. Intermittent systems must supply more ventilation air and, thus, may cost more to temper the outside air and to run the fans. The system can consist of supply, exhaust, or a balanced combination of the two. Fans that are noisy are likely to be unacceptable to many occupants and will be disabled; noise should be reduced by using quiet fans or by remote mounting. Continuous ventilation requires less power if the system is designed with low-resistance ducting. The electrical energy required for operation should be calculated together with the energy required to temper the outside air introduced through ventilation.

**Supply Ventilation.** A supply ventilation system usually has a single intake for the ventilation air. This air is distributed through the house either by a dedicated duct system or by the thermal distribution system. The outdoor air may be filtered in a supply ventilation system to remove pollen and dust.

Envelope leakage, exhaust stacks, and flues provide pathways for exhaust air. Supply ventilation can result in indoor pressurization. This is generally unacceptable in very cold climates because the exfiltrating air can cause condensation in the building envelope. However, continuous supply ventilation systems can be designed in conjunction with specific building envelope features to account for this condensation.

Supply ventilation can mitigate radon entry or backdrafting problems and may reduce interstitial moisture problems in hot, humid climates. In temperate or severe climates, the supply air, if delivered directly to rooms without tempering, can cause thermal discomfort or draftiness. A dedicated duct system increases the cost of a supply ventilation system.

**Exhaust Ventilation.** An exhaust ventilation system usually has a central mechanical exhaust. Air enters the house through envelope leakage, open windows, or designed inlets. Because the air intake is dispersed, thermal discomfort is less than that with supply ventilation. An exhaust air heat pump can recover energy, but it may not be economical in many climates. The exhaust fan depressurizes the house, which can aggravate radon or backdrafting problems. Because of potential interstitial space moisture problems, exhaust

ventilation may be unacceptable in hot, moist climates when the indoor air is mechanically cooled.

Although air intake through building leaks reduces the particulate concentration somewhat, filtration of outdoor air is not generally possible with exhaust ventilation. In unusually tight houses, envelope leakage may be insufficient to provide enough supply air, so designed intakes may be needed.

**Balanced Ventilation.** In a balanced mechanical ventilation system, there is usually a mechanical exhaust either centrally located or ducted from locations likely to have high contaminant levels. There is a single outside air intake for the ventilation air, which is then dispersed through the house. The systems are designed to produce equal supply and exhaust flows. With equal flows, the system creates neither pressurization nor depressurization, so problems associated with house pressures are reduced. It is also possible to use slight positive pressurization to reduce infiltration. Filtration and tempering of the incoming air can be accomplished at the central unit.

Most balanced systems feature either sensible heat recovery or total heat recovery. Sensible heat recovery systems provide tempering of the incoming air using the exiting air as a source for heat (or cooling). Total heat recovery systems provide both sensible and latent tempering of the incoming air.

Because of its energy recovery properties, a balanced system becomes more attractive as total space-conditioning costs increase, such as in severe climates. The balanced system is initially the most costly of the three systems, but total operating costs may be less, particularly if high-efficiency fan/motor assemblies are used.

### Selecting a Local Ventilation System

The two most common methods for providing local ventilation to damp rooms are natural ventilation through an operable window and mechanical exhaust fans. These methods have the same design issues as whole-house systems. Balanced or supply-only systems should not be used for local ventilation to reduce spreading of moisture and contaminants through the house.

## SIMPLIFIED MODELS OF RESIDENTIAL VENTILATION AND INFILTRATION

This section describes several calculation procedures, ranging from simple estimation techniques to more physical models. Orme (1999) provides a more thorough review of simplified models. The air exchange rate of a building cannot be reliably deduced from the building's construction or age or from a simple visual inspection. Some measurement is necessary, such as a pressurization test of envelope airtightness or a detailed quantification of the leakage sites and their magnitude. The air exchange rate of a building may be calculated given (1) the location and leakage function for every opening in the building envelope and between major building zones, (2) the wind pressure coefficients over the building envelope, and (3) any mechanical ventilation airflow rates. These inputs are generally unavailable for all except very simple structures or extremely well studied buildings. Therefore, assumptions as to their values must be made. The appropriateness of these assumptions determines the accuracy of predictions of air exchange rates.

### Empirical Models

These models of residential infiltration are based on statistical fits of infiltration rate data for specific houses. They use pressurization test results to account for house airtightness and take the form of simple relations between infiltration rate, an airtightness rating, and, in most cases, weather conditions. Empirical models account for envelope infiltration only and do not deal with intentional ventilation. In one approach, the calculated air exchange rate at 50 Pa based on a pressurization test is simply divided by a constant approximately equal to 20 (Sherman 1987). This technique does not account for the effect of infiltration driving mechanisms on air

exchange. Empirical models that do account for weather effects have been developed by Reeves et al. (1979), Kronvall (1980), and Shaw (1981).

The latter two models account for building air leakage using the values of  $c$  and  $n$  from Equation (32). The only other inputs required are wind speed and temperature difference. Such empirical models predict long-term (one-week) infiltration rates very well in the houses from which they were developed; they do not, however, work as well in other houses due to the building-specific nature of leakage distribution, wind pressure, and internal partitioning. Persily and Linteris (1983) and Persily (1986) show comparisons between measured and predicted house infiltration rates for these and other models. The average long-term differences between measurements and predictions are generally on the order of 40%, although individual predictions can be off by 100% or more.

### Multizone Models

Multicell models of air exchange treat buildings as a series of interconnected zones and assume that the air within each zone is well mixed. Several such models have been developed by Allard and Herrlin (1989), Etheridge and Alexander (1980), Liddament and Allen (1983), Walton (1984, 1989), Herrlin (1985), and Feustel and Raynor-Hoosen (1990). They are all based on a mass balance for each zone of the building. These mass balances are used to solve for interior static pressures within the building by requiring that the inflows and outflows for each zone balance to zero. The models require the user to input a location and leakage function for every opening in the building envelope and in relevant interior partitions, a value for the wind pressure coefficient  $C_p$  at the location of each building envelope leakage site, temperatures for each zone, and any mechanical ventilation airflow rates. Such detailed information is difficult to obtain for a building. Wind pressure coefficient data in the literature, air leakage measurement results from the building or its components, and air leakage data from the literature can be used. These models not only solve for whole-building and individual zone air exchange rates, but also determine airflow rates and pressure differences between zones. These interzone airflow rates are useful for predicting pollutant transport within buildings with well mixed zones. Caution should be used when applying them to the prediction of smoke movement patterns in the event of a fire. Multizone models have the advantage of being able to model very complex representations of buildings by using personal computers; however, determining the correct inputs to these models is difficult. As a result of these uncertainties, multizone models are best used to bound a solution rather than determining an absolute solution. Monte Carlo simulation coupled with the multizone modeling is a useful technique to determine these bounds, if the probability distribution for the uncertain parameters can be defined.

### Single-Zone Models

Several procedures have been developed to calculate building air exchange rates that are based on physical models of the building interior as a single zone. These single-zone models are only appropriate to buildings with no internal resistance to airflow and are therefore inappropriate to large, multizone buildings. Models of this type have been developed by the Institute of Gas Technology (IGT) (Cole et al. 1980), the Building Research Establishment (Warren and Webb 1980), the Lawrence Berkeley National Laboratory (LBNL) (Sherman and Grimsrud 1980), and the University of Alberta (AIM-2) (Walker and Wilson 1998). These models have exhibited average errors on the order of 40% for many measurements on groups of houses and can be off by 100% in individual cases (Persily 1986, Walker and Wilson 1998). The following section on Residential Calculation Examples uses a basic model and an enhanced model (Walker and Wilson 1998, Palmiter and Bond 1994, Hamlin and Pushka 1994, CHBA 1994, Bradley 1993).

The **basic model** uses the effective air leakage area  $A_L$  at 4 Pa, which can be obtained from a whole-building pressurization test. If a test value is not available, the data in Table 1 can be used to estimate the air leakage area of the building. To obtain the building's total air leakage area, multiply the overall dimensions or number of occurrences of each building component by the appropriate table entry. The sum of the resulting products is the total building air leakage area. See Table 2 for an example.

The **enhanced model** uses pressurization test results to characterize house air leakage through the leakage coefficient  $c$  and the pressure exponent  $n$ . The enhanced model improves on the basic model by using a power law to represent the envelope leakage, including a flue as a separate leakage site, and having separate wind effects for houses with crawl spaces or slab/basement foundations.

For both models, the user must input wind speed, temperature difference, information on distribution of leakage over the building envelope, a wind shelter (or local shielding for the basic model) parameter, and a terrain coefficient. The predictive accuracy of the enhanced model can be very good, typically  $\pm 10\%$  when the parameters are well known for the building in question (Walker and Wilson 1998, Palmiter and Bond 1994, Sherman and Modera 1986). All these single-zone models are sensitive to the values of the inputs, which are quite difficult to determine.

### Superposition of Wind and Stack Effects

Simplified physical models of infiltration solve the problem of two natural driving forces (wind and stack) separately and then combine them in a process called **superposition**. Superposition is necessary because each physical process can affect the internal and external pressures on the structure, which can cause interactions between physical processes that are otherwise independent. An exact solution is impossible because detailed properties of all the building leaks are unknown and because leakage is a nonlinear process. For this reason, most modelers have developed a simplified superposition process to combine stack and wind effects. Sherman (1992a) compares various superposition procedures and derives a generalized superposition equation that involves some simple leakage distribution parameters. He shows that the result is always sub-additive. Typically only 35% of the infiltration due to the smaller effect can be added to the larger effect. Depending on the details, that percentage could go as high as 85% or as low as zero. Walker and Wilson (1993) compared several superposition techniques to measured data. Sherman, as well as Walker and Wilson, found quadrature [shown in Equation (39)] to be a robust superposition technique:

$$Q = \sqrt{Q_s^2 + Q_w^2} \quad (39)$$

The following sections discuss how this superposition is combined with the calculation of the wind and stack flows to determine the total flow.

### Residential Calculation Examples

**Basic Model.** The following calculations are based on the LBNL model (Sherman and Grimsrud 1980), which uses the effective air leakage area at 4 Pa. This leakage area can be obtained from a whole-building pressurization test. Using the effective air leakage area, the airflow rate due to infiltration is calculated according to

$$Q = \frac{A_L}{1000} \sqrt{C_s \Delta t + C_w U^2} \quad (40)$$

where

$$\begin{aligned} Q &= \text{airflow rate, m}^3/\text{s} \\ A_L &= \text{effective air leakage area, cm}^2 \\ C_s &= \text{stack coefficient, (L/s)}^2/(\text{cm}^4 \cdot \text{K}) \end{aligned}$$

$\Delta t$  = average indoor-outdoor temperature difference for time interval of calculation, K  
 $C_w$  = wind coefficient, (L/s)<sup>2</sup>/[cm<sup>4</sup> · (m/s)<sup>2</sup>]  
 $U$  = average wind speed measured at local weather station for time interval of calculation, m/s

$$I = (265 \text{ m}^3/\text{h})/340 \text{ m}^3$$

$$= 0.78 \text{ h}^{-1} = 0.78 \text{ ACH}$$

Table 7 presents values of  $C_s$  for one-, two-, and three-story houses. The value of the wind coefficient  $C_w$  depends on the local shelter class of the building (described in Table 8) and the building height. Table 9 presents values of  $C_w$  for one-, two-, and three-story houses in shelter classes 1 through 5. In calculating the values in Table 7 and Table 9, the following assumptions were made regarding input to the basic model:

- Terrain used for converting meteorological to local wind speeds is that of a rural area with scattered obstacles
- $R = 0.5$  (half of the building leakage in the walls)
- $X = 0$  (equal amounts of leakage in the floor and ceiling)
- Heights of one-, two-, and three-story buildings = 2.5, 5.0, and 7.5 m, respectively

**Example 1.** Estimate the infiltration at design conditions for a two-story house in Lincoln, Nebraska. The house has an effective air leakage area of 500 cm<sup>2</sup> and a volume of 340 m<sup>3</sup>, and the predominant wind is perpendicular to the street (shelter class 3). The indoor air temperature is 20°C.

**Solution:** The 99% design temperature for Lincoln is -19°C. Assume a design wind speed of 6.7 m/s. From Equation (40), with  $C_s = 0.000 290$  from Table 7 and  $C_w = 0.000 231$  from Table 9, the airflow rate due to infiltration is

$$Q = \frac{500}{1000} \sqrt{(0.000 290 \times 39) + (0.000 231 \times 6.7^2)}$$

$$= 0.0736 \text{ m}^3/\text{s} = 265 \text{ m}^3/\text{h}$$

From Equation (2), the air exchange rate  $I$  is equal to  $Q$  divided by the building volume:

**Table 7 Basic Model Stack Coefficient  $C_s$**

	House Height (Stories)		
	One	Two	Three
Stack coefficient	0.000 145	0.000 290	0.000 435

**Table 8 Local Shelter Classes**

Shelter Class	Description
1	No obstructions or local shielding
2	Typical shelter for an isolated rural house
3	Typical shelter caused by other buildings across the street from the building under study
4	Typical shelter for urban buildings on larger lots where sheltering obstacles are more than one building height away
5	Typical shelter produced by buildings or other structures that are immediately adjacent (closer than one house height): e.g., neighboring houses on the same side of the street, trees, bushes, etc.

**Table 9 Basic Model Wind Coefficient  $C_w$**

Shelter Class	House Height (Stories)		
	One	Two	Three
1	0.000 319	0.000 420	0.000 494
2	0.000 246	0.000 325	0.000 382
3	0.000 174	0.000 231	0.000 271
4	0.000 104	0.000 137	0.000 161
5	0.000 032	0.000 042	0.000 049

**Example 2.** Calculate the average infiltration during a one-week period in January for a one-story house in Portland, Oregon. During this period, the average indoor-outdoor temperature difference is 17 K, and the average wind speed is 2.7 m/s. The house has a volume of 255 m<sup>3</sup> and an effective air leakage area of 690 cm<sup>2</sup>, and it is located in an area with buildings and trees within 10 m in most directions (shelter class 4).

**Solution:** From Equation (40), the airflow rate due to infiltration is

$$Q = \frac{690}{1000} \sqrt{(0.000 145 \times 17) + (0.000 104 \times 2.7^2)}$$

$$= 0.0392 \text{ m}^3/\text{s} = 141 \text{ m}^3/\text{h}$$

The air exchange rate is therefore

$$I = 141/255 = 0.55 \text{ h}^{-1} = 0.55 \text{ ACH}$$

**Example 3.** Estimate the average infiltration over the heating season in a two-story house with a volume of 310 m<sup>3</sup> and the air leakage area calculated in Table 2 (848 cm<sup>2</sup>). The house is located on a lot with several large trees but no other close buildings (shelter class 3). The average wind speed during the heating season is 3.2 m/s, while the average indoor-outdoor temperature difference is 20 K.

**Solution:** From Equation (40), the airflow rate due to infiltration is

$$Q = \frac{848}{1000} \sqrt{(0.000 290 \times 20) + (0.000 231 \times 3.2^2)}$$

$$= 0.077 \text{ m}^3/\text{s} = 276 \text{ m}^3/\text{h}$$

The average air exchange rate is therefore

$$I = 276/310 = 0.89 \text{ h}^{-1} = 0.89 \text{ ACH}$$

**Enhanced Model.** This section presents a simple, single-zone approach to calculating air infiltration rates in houses based on the AIM-2 model (Walker and Wilson 1998). The airflow rate due to infiltration is calculated using

$$Q_s = cC_s \Delta t^n \tag{41}$$

$$Q_w = cC_w (sU)^{2n} \tag{42}$$

where

- $Q_s$  = stack airflow rate, m<sup>3</sup>/s
- $Q_w$  = wind airflow rate, m<sup>3</sup>/s
- $c$  = flow coefficient, m<sup>3</sup>/(s·Pa<sup>n</sup>)
- $C_s$  = stack coefficient, (Pa/K)<sup>n</sup>
- $C_w$  = wind coefficient, (Pa·s<sup>2</sup>/m<sup>2</sup>)<sup>n</sup>
- $s$  = shelter factor

In calculating the tabulated values of  $C_s$ ,  $C_w$ , and  $s$ , the following assumptions were made:

- Each story is 2.5 m high.
- The flue is 15 cm in diameter and reaches 2 m above the upper ceiling.
- The flue is unsheltered.
- Half of the envelope leakage (not including the flue) is in the walls and one-quarter each is at the floor and ceiling, respectively.
- $n = 0.67$

Using typical values for terrain factors, house height, and wind speed measurement height, the windspeed multiplier  $G$  (given in Table 10) uses a relationship based on equations found in Chapter 16.

**Example 4.** Estimate the infiltration at design conditions for a two-story slab-on-grade house with a flue in Lincoln, Nebraska. The house has

**Table 10 Enhanced Model Wind Speed Multiplier  $G$**

	House Height (Stories)		
	One	Two	Three
Wind speed multiplier $G$	0.48	0.59	0.67

**Table 11 Enhanced Model Shelter Factor  $s$**

Shelter Class	No Flue	One Story with Flue	Two Story with Flue	Three Story with Flue
1	1.00	1.10	1.07	1.06
2	0.90	1.02	0.98	0.97
3	0.70	0.86	0.81	0.79
4	0.50	0.70	0.64	0.61
5	0.30	0.54	0.47	0.43

**Table 12 Enhanced Model Stack and Wind Coefficients**

	One Story		Two Story		Three Story	
	No Flue	With Flue	No Flue	With Flue	No Flue	With Flue
$C_s$	0.054	0.069	0.078	0.089	0.098	0.107
$C_w$ for basement/slab	0.156	0.142	0.170	0.156	0.170	0.167
$C_w$ for crawl space	0.128	0.128	0.142	0.142	0.151	0.154

a flow coefficient of  $c = 0.051 \text{ m}^3/(\text{s} \cdot \text{Pa}^n)$  and a pressure exponent of  $n = 0.67$  (this corresponds to effective leakage area of  $500 \text{ cm}^2$  at 4 Pa). The building volume is  $340 \text{ m}^3$ . The 97.5% design temperature is  $-19^\circ\text{C}$ , and the design wind speed is 6.7 m/s.

**Solution:** For a slab-on-grade two-story house with a flue, Table 12 gives  $C_s = 0.089 \text{ (Pa/K)}^n$  and  $C_w = 0.156 \text{ (Pa} \cdot \text{s}^2/\text{m}^2)^n$ . The house is maintained at  $20^\circ\text{C}$  indoors. The building wind speed is determined by taking the design wind speed and multiplying by the wind speed multiplier  $G$  from Table 10:

$$U = GU_{met} = 0.59(6.7) = 3.95 \text{ m/s}$$

From Table 8, the shelter class for a typical urban house is 4. Table 11 gives the shelter factor for a two-story house with a flue and shelter class 4 as  $s = 0.64$ . The stack flow is calculated using Equation (41):

$$Q_s = (0.051)(0.089)[20 - (-19)]^{0.67} = 0.053 \text{ m}^3/\text{s}$$

The wind flow is calculated using Equation (42):

$$Q_w = (0.051)(0.156)(0.64 \times 3.95)^{1.34} = 0.027 \text{ m}^3/\text{s}$$

Substituting  $Q_s$  and  $Q_w$  into Equation (39) gives  $Q = 0.059 \text{ m}^3/\text{s} = 214 \text{ m}^3/\text{h}$ . From Equation (2), the air exchange rate  $I$  is equal to  $Q$  divided by the building volume:

$$I = (214 \text{ m}^3/\text{h})/340 \text{ m}^3 = 0.63 \text{ h}^{-1} = 0.63 \text{ ACH}$$

**Example 5.** Estimate the average infiltration over a one-week period for a single-story crawl space house in Redmond, Washington. The house has a flow coefficient of  $c = 0.078 \text{ m}^3/(\text{s} \cdot \text{Pa}^n)$  and a pressure exponent of  $n = 0.6$  (this corresponds to effective leakage area of  $690 \text{ cm}^2$  at 4 Pa). The building volume is  $255 \text{ m}^3$ . During this period, the average indoor-outdoor temperature difference is 16 K, and the wind speed is 2.7 m/s. The house is electrically heated and has no flue.

**Solution:** For a single-story house with no flue,  $C_s = 0.054 \text{ (Pa/K)}^n$ . For a crawl space,  $C_w = 0.128 \text{ (Pa} \cdot \text{s}^2/\text{m}^2)^n$ . From Table 10, for a one-story house,  $G = 0.48$ .

$$U = GU_{met} = 0.48(2.7) = 1.3 \text{ m/s}$$

Table 11 gives shelter factor  $s = 0.50$  for a house with no flue and shelter class 4. The stack flow is calculated using Equation (41):

$$Q_s = (0.078)(0.054)(16)^{0.6} = 0.022 \text{ m}^3/\text{s}$$

The wind flow is calculated using Equation (42):

$$Q_w = (0.078)(0.128)(0.50 \times 1.3)^{1.2} = 0.006 \text{ m}^3/\text{s}$$

Substituting  $Q_s$  and  $Q_w$  into Equation (39) gives  $Q = 0.023 \text{ m}^3/\text{s} = 83 \text{ m}^3/\text{h}$ . From Equation (2), the air exchange rate  $I$  is equal to  $Q$  divided by the building volume:

$$I = (83 \text{ m}^3/\text{h})/(255 \text{ m}^3) = 0.32 \text{ h}^{-1} = 0.32 \text{ ACH}$$

**Example 6.** Estimate the infiltration for a three-story house in San Francisco, California. The house has a flow coefficient of  $c = 0.102 \text{ m}^3/(\text{s} \cdot \text{Pa}^n)$  and a pressure exponent of  $n = 0.67$  (this corresponds to effective leakage area of  $1000 \text{ cm}^2$  at 4 Pa). The building volume is  $395 \text{ m}^3$ . The indoor-outdoor temperature difference is 5 K, and the wind speed is 4.47 m/s. The house has a flue and a crawl space foundation.

**Solution:** For a three-story house with a flue,  $C_s = 0.107 \text{ (Pa/K)}^n$ . For a crawl space,  $C_w = 0.154 \text{ (Pa} \cdot \text{s}^2/\text{m}^2)^n$ . From Table 10, for a three-story house,  $G = 0.67$ .

$$U = GU_{met} = 0.67(4.47) = 3.0 \text{ m/s}$$

The prevailing wind blows along the row of houses parallel to the street, so the house has a shelter class of 5. Table 11 gives the shelter factor for a three-story house with a flue and shelter class 5 as  $s = 0.43$ .

$$Q_s = (0.102)(0.107)(5)^{0.67} = 0.032 \text{ m}^3/\text{s}$$

$$Q_w = (0.102)(0.154)(0.43 \times 3.0)^{1.34} = 0.022 \text{ m}^3/\text{s}$$

Substituting  $Q_s$  and  $Q_w$  in Equation (39) gives  $Q = 0.039 \text{ m}^3/\text{s} = 140 \text{ m}^3/\text{h}$ .

$$I = (140 \text{ m}^3/\text{h})/395 \text{ m}^3 = 0.35 \text{ h}^{-1} = 0.35 \text{ ACH}$$

### Combining Residential Infiltration and Mechanical Ventilation

Significant infiltration and mechanical ventilation often occur simultaneously in residences. The pressure difference from Equation (24) can be used for each building leak, and the flow network (including mechanical ventilation) for the building can be solved to find the flow through all the leaks while accounting for the effect of the mechanical ventilation. However, for simplified models, the natural infiltration and mechanical ventilation are usually determined separately and require a superposition method to combine the flow rates.

Sherman (1992) compares various superposition procedures and derives a generalized superposition equation that involves some simple leakage distribution parameters. He shows that the result is always subadditive. For small unbalanced fans, typically only half the flow contributes to the total, but this fraction can be anywhere between 0% and 100% depending on the leakage distribution. When the fan flow becomes large, infiltration may be ignored.

In special cases when the leakage distribution is known and highly skewed, it may be necessary to work through the superposition method in more detail. For example, in a wind-dominated situation, a supply fan will have a much bigger effect than an exhaust fan on changing the total ventilation rate; the same situation holds for houses having high neutral levels in cold climates. For the general case, when the details are not known or can be assumed to be broad and typical, the following superposition gives good results:

$$Q_{comb} = Q_{bal} + \sqrt{Q_{unbal}^2 + Q_{infiltration}^2} \quad (43)$$

**NONRESIDENTIAL AIR LEAKAGE**

**Commercial Building Envelope Leakage**

There is currently only one industry standard for the measurement of envelope leakage in tall buildings: CGSB *Standard* 149.15. It utilizes the building's own air handlers. ASTM *Standard* E779 and CGSB *Standard* 149.10 are intended for small detached buildings such as houses and provide no guidelines for dealing with problems arising in tall buildings, such as stack and wind effects. Tall buildings require refinement and extensions of established procedures because of obstacles to accurate measurement not present in small buildings, including large envelope leakage area, interfloor leakage, vertical shafts, and large wind and stack pressures. Recent work by Bahnfleth et al. (1999) also shows how to deal with some of these issues.

The building envelopes of large commercial buildings are often thought to be quite airtight. The National Association of Architectural Metal Manufacturers specifies a maximum leakage per unit of exterior wall area of 300 cm<sup>3</sup>/(s·m<sup>2</sup>) at a pressure difference of 75 Pa exclusive of leakage through operable windows. Tamura and Shaw (1976a) found that, assuming a flow exponent *n* of 0.65 in Equation (32), air leakage measurements in eight Canadian office buildings with sealed windows ranged from 610 to 2440 cm<sup>3</sup>/(s·m<sup>2</sup>). Persily and Grot (1986) ran whole-building pressurization tests in large office buildings that showed that pressurization airflow rate divided by building volume is relatively low compared to that of houses. However, if these airflow rates are normalized by building envelope area instead of by volume, the results indicate envelope airtightness levels similar to those in typical American houses. In a study of eight U.S. office buildings, Persily and Grot (1986) found air leakage ranging from 1080 to 5220 cm<sup>3</sup>/(s·m<sup>2</sup>) at 75 Pa. This means that office building envelopes are leakier than expected. Typical air leakage values per unit wall area at 75 Pa are 500, 1500, and 3000 cm<sup>3</sup>/(s·m<sup>2</sup>) for tight, average, and leaky walls, respectively (Tamura and Shaw 1976a).

Grot and Persily (1986) also found that eight recently constructed office buildings had infiltration rates ranging from 0.1 to 0.6 ACH with no outdoor air intake. The infiltration rates of these buildings exhibited varying degrees of weather dependence, generally much lower than that measured in houses.

**Air Leakage Through Internal Partitions**

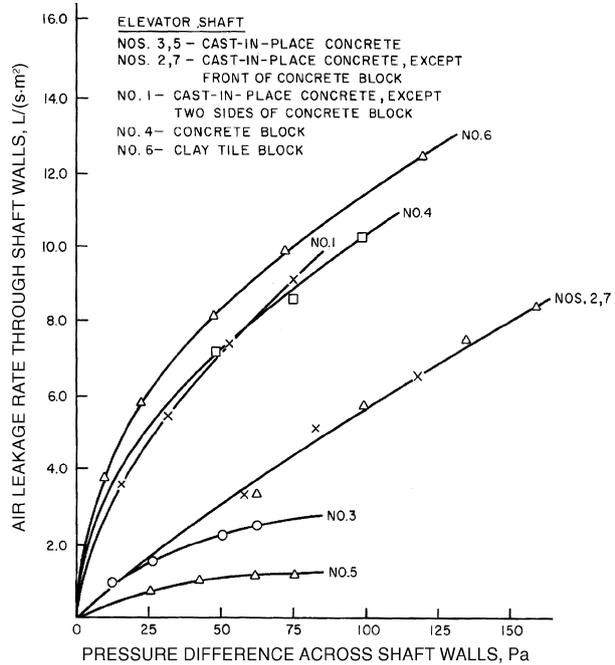

In large buildings, the air leakage associated with internal partitions becomes very important. Elevator, stair, and service shaft walls; floors; and other interior partitions are the major separations of concern in these buildings. Their leakage characteristics are needed to determine infiltration through exterior walls and airflow patterns within a building. These internal resistances are also important in the event of a fire to predict smoke movement patterns and evaluate smoke management systems.

Table 13 gives air leakage areas (calculated at 75 Pa with *C<sub>D</sub>* = 0.65) for different internal partitions of commercial buildings (Klote and Milke (1992)). Figure 13 presents examples of measured air leakage rates of elevator shaft walls (Tamura and Shaw (1976b)), the type of data used to derive the values in Table 13. Chapter 51 of the 1999

**Table 13 Air Leakage Areas for Internal Partitions in Commercial Buildings (at 75 Pa and *C<sub>D</sub>* = 0.65)**

Construction Element	Wall Tightness	Area Ratio
		<i>A<sub>L</sub></i> / <i>A<sub>w</sub></i>
Stairwell walls	Tight	0.14 × 10 <sup>-4</sup>
	Average	0.11 × 10 <sup>-3</sup>
	Loose	0.35 × 10 <sup>-3</sup>
Elevator shaft walls	Tight	0.18 × 10 <sup>-3</sup>
	Average	0.84 × 10 <sup>-3</sup>
	Loose	0.18 × 10 <sup>-2</sup>
		<i>A<sub>L</sub></i> / <i>A<sub>f</sub></i>
Floors	Average	0.52 × 10 <sup>-4</sup>

*A<sub>L</sub>* = air leakage area    *A<sub>w</sub>* = wall area    *A<sub>f</sub>* = floor area

**Fig. 13 Air Leakage Rates of Elevator Shaft Walls**

ASHRAE Handbook—Applications should be consulted for performance models and applications of smoke management systems.

Leakage openings at the top of elevator shafts are equivalent to orifice areas of 0.4 to 1.0 m<sup>2</sup>. Air leakage rates through stair shaft and elevator doors are shown in Figure 14 as a function of average crack width around the door. The air leakage areas associated with other openings within commercial buildings are also important for air movement calculations. These include interior doors and partitions, suspended ceilings in buildings where the space above the ceiling is used in the air distribution system, and other components of the air distribution system.

**Air Leakage Through Exterior Doors**

Door infiltration depends on the type of door, room, and building. In residences and small buildings where doors are used infrequently, the air exchange associated with a door can be estimated based on air leakage through cracks between the door and the frame. A frequently opened single door, as in a small retail store, has a much larger amount of airflow than a closed door.

**Air Leakage Through Automatic Doors**

Automatic doors are a major source of air leakage in buildings. They are normally installed in locations where large numbers of

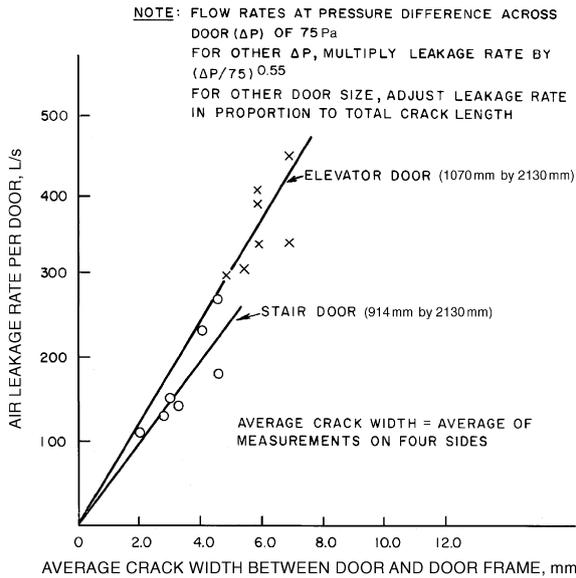

Fig. 14 Air Leakage Rate of Door Versus Average Crack Width

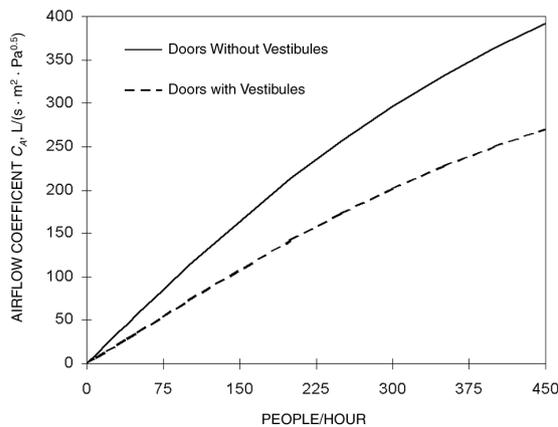

Fig. 15 Airflow Coefficient for Automatic Doors

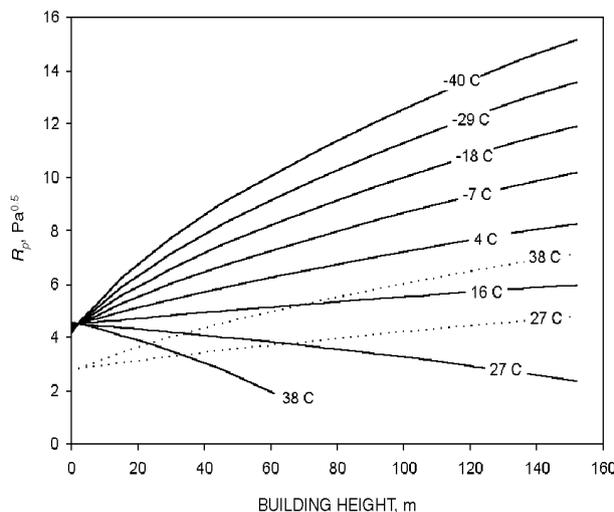

Fig. 16 Pressure Factor for Automatic Doors

people use the doors. They stay open longer with each use than manual doors. The air leakage through automatic doors can be reduced by the installation of a vestibule. However, pairs of automatic doors on the inside and outside of a vestibule normally have overlapping open periods, even when used by only one person at a time. Therefore, it is important that designers take into account the airflow through automatic doors when calculating the heating and cooling loads in the spaces next to them.

To calculate the average airflow rate through an automatic door, the designer must take into account the area of the door, the pressure difference across it, the discharge coefficient of the door when it is open, and the fraction of time that it is open. Obtaining the discharge coefficient is complicated by the fact that it changes as the door opens and closes.

To simplify this calculation, Figure 15 has been developed (Yuill 1996) to combine the discharge coefficients of doors as they open and close with the fraction of time that doors are open at a particular level of use. This figure presents an overall airflow coefficient as a function of the people using a door per hour. To obtain the average infiltration rate through an automatic door, the user must multiply this coefficient by the opening area of the door and by the square root of the pressure difference between the outdoor air and the indoor air at the location of the door. The pressure difference across a door in a building depends on the wind pressure on the building, the stack effect due to the indoor-outdoor temperature difference, and the effect of the operation of the air-handling system. It also depends on the leakage characteristics of the exterior walls of the building and of internal partitions.

Two simple methods are presented here. The first method uses simplifying assumptions to determine design values for  $R_p$ , the square root of the pressure difference across the automatic door, given in Figure 16. The second method requires explicit calculation of envelope pressures.

In Figure 16, the airflows shown for ambient temperatures of 27 and 38°C, represented by dotted lines, are outward flows. They intercept the vertical axis at a lower point than the other lines because the wind pressure coefficients on the downwind face of the building (where the greatest outward flows will occur) are lower than on the upward face. In many buildings, the pressure in the building is controlled by varying the flow rate through the return fan(s) or by controlling the relief air dampers. These systems are usually set to maintain a pressure above ambient in the lobby. Subtracting the interior pressure maintained in the lobby from the wind pressure gives the net pressure for estimating airflow through the door.

**Method 1.** For the first method, the infiltration rate through the automatic door is given by

$$Q = C_A A R_p \tag{44}$$

where

- $Q$  = airflow rate, L/s
- $C_A$  = airflow coefficient from Figure 15, L/(s · m<sup>2</sup> · Pa<sup>0.5</sup>)
- $A$  = area of the door opening, m<sup>2</sup>
- $R_p$  = pressure factor from Figure 16, (Pa)<sup>0.5</sup>

**Method 2.** The airflow  $Q$  is given by

$$Q = C_A A \sqrt{\Delta p} \tag{45}$$

where

- $Q$  = airflow rate, L/s
- $C_A$  = airflow coefficient from Figure 15, L/(s · m<sup>2</sup> · Pa<sup>0.5</sup>)
- $A$  = area of the door opening, m<sup>2</sup>
- $\Delta p$  = pressure difference across the door, Pa

To find  $\Delta p$ , it is necessary to find the pressure differential due to wind and that due to the stack effect. In order to give the largest possible pressure difference across the door, there are no interactions between the two natural pressures:

$$\Delta p = p_U - \Delta p_s \quad (46)$$

where

$p_U$  = wind-induced surface pressure relative to static pressure, Pa  
 $\Delta p_s$  = pressure difference due to stack effect, Pa

### Example Calculations

It is desired to find the maximum possible infiltration through an automatic door located on the ground floor of a 20-story building. The area of the door is  $0.91 \text{ m} \times 2.1 \text{ m} = 1.9 \text{ m}^2$ . Each floor is 4 m high. Approximately 300 people per hour pass through the door. The design wind conditions are 6.7 m/s, the indoor temperature is 21°C, and the outdoor temperature is -7°C. The airflow coefficient from Figure 15 (using the line for doors without vestibules) is approximately  $300 \text{ L}/(\text{s} \cdot \text{m}^2 \cdot \text{Pa}^{0.5})$ .

#### Method 1:

The pressure factor from Figure 16 is  $7.9 \text{ Pa}^{0.5}$ . Equation (44) gives the door flow as

$$Q = 300(1.9)7.9 = 4500 \text{ L/s}$$

#### Method 2:

The worst possible case for the wind surface pressure coefficient  $C_p$  at any point and in any position on the ground floor of the building is inferred from figures in Chapter 16 to be about 0.75. Using this in Equation (18), together with the specified wind speed, results in  $p_w = 20 \text{ Pa}$ . Assume that  $H$  is one-half the height of the door (1.1 m). In order to have the maximum pressure across the door, assume the neutral pressure plane is located halfway up the building such that

$$H_{\text{NPL}} = \frac{1}{2}(20 \text{ stories}) \frac{4 \text{ m}}{\text{story}} = 40 \text{ m}$$

Substituting these values into Equation (17) gives  $\Delta p_s = -47 \text{ Pa}$ . This is the maximum stack pressure difference given no internal resistance to airflow. To find the actual stack pressure difference, it is necessary to multiply this by a draft coefficient. We will assume that this coefficient is 0.9, which is the highest value that has been found for tall buildings. Therefore,  $\Delta p_s = 0.9(-47 \text{ Pa}) = -42 \text{ Pa}$ . The total pressure is then  $\Delta p = 20 - (-42) = 62 \text{ Pa}$ . Substituting into Equation (45),

$$Q = 306(1.9)\sqrt{62} = 4580 \text{ L/s}$$

If the building had a vestibule, the airflow coefficient would be read from Figure 15 using the line for doors with vestibules, and it would be approximately  $208 \text{ L}/(\text{s} \cdot \text{m}^2 \cdot \text{Pa}^{0.5})$ , reducing the airflow to 3100 L/s into the building.

## NONRESIDENTIAL VENTILATION

Commercial and institutional building ventilation systems are typically designed to provide a slight pressurization to minimize infiltration. This pressurization is achieved by having the outside or makeup airflow rate higher than the exhaust or relief airflow rate. In these buildings, infiltration is usually neglected except in areas such as lobbies, where infiltration can be important due to doors. As discussed in the section on Driving Mechanisms for Ventilation and Infiltration, wind and the stack effect can also cause significant infiltration and exfiltration. Ventilation airflow rates for commercial and institutional buildings are typically determined using procedures in ASHRAE *Standard* 62, Ventilation for Acceptable Indoor Air Quality. In these procedures for designing forced ventilation systems, no credit is given for infiltration. However, weather-driven pressure differentials may be significant and need to be considered when designing the ventilation system.

ASHRAE *Standard* 62 includes two procedures for obtaining acceptable indoor air quality: the Ventilation Rate Procedure and the Indoor Air Quality Procedure. The Ventilation Rate Procedure is by far the more commonly used.

## Ventilation Rate Procedure

In the Ventilation Rate Procedure, the design ventilation rate is determined based on a table of minimum ventilation requirements for different space types. These requirements are expressed as an outdoor airflow rate per occupant or per unit floor area, depending on the space type. These ventilation rates are based on air pollutants generated by people, activities, and building materials and furnishings.

The HVAC designer faces several challenges in designing an air distribution system to deliver outdoor air to the occupants of a building. The first is to determine whether the outdoor air is acceptable for use and to design a system for cleaning the air if it is not acceptable. A second goal is to design an air intake and distribution system that will deliver the required level of outdoor air to the occupied portions of the building. This outdoor air must be delivered not only at the design conditions, but throughout the year. The task is complicated by weather-related variations in indoor-outdoor pressure difference. Other complications include pressure variations due to building components such as exhaust fans or dirty filters, and probably most significantly by supply flow variations associated with the operation of variable air volume (VAV) systems (Mumma and Wong 1990, Janu et al. 1995). After the design level of outdoor air is brought into the building, it must then be delivered to the occupants. This issue is related to the discussion in the section on Air Change Effectiveness presented earlier in this chapter.

## TRACER GAS MEASUREMENTS

The only reliable way to determine the air exchange rate of an existing building is to measure it. Several tracer gas measurement procedures exist (including a standard test method: ASTM *Standard* E 741), all involving an inert or nonreactive gas used to label the indoor air (Hunt 1980; Sherman et al. 1980; Harje et al. 1981; Lagus and Persily 1985; Dietz et al. 1986; Charlesworth 1988; Persily 1988; Fisk et al. 1989; Lagus 1989; Sherman 1989a, 1989b; Fortmann et al. 1990; Harje et al. 1990; Persily and Axley 1990; Sherman 1990). The tracer is released into the building in a specified manner, and the concentration of the tracer within the building is monitored and related to the building's air exchange rate. A variety of tracer gases and associated concentration detection devices have been used. Desirable qualities of a tracer gas are detectability, non-reactivity, nontoxicity, neutral buoyancy, relatively low concentration in ambient air, and low cost (Hunt 1980).

All tracer gas measurement techniques are based on a mass balance of the tracer gas within the building. Assuming the outdoor concentration is zero and the indoor air is well mixed, this total balance takes the following form:

$$V \left( \frac{dC}{d\theta} \right) = F(\theta) - Q(\theta)C(\theta) \quad (47)$$

where

$V$  = volume of space being tested,  $\text{m}^3$   
 $C(\theta)$  = tracer gas concentration at time  $\theta$   
 $dC/d\theta$  = time rate of change of concentration,  $\text{s}^{-1}$   
 $F(\theta)$  = tracer gas injection rate at time  $\theta$ ,  $\text{m}^3/\text{s}$   
 $Q(\theta)$  = airflow rate out of building at time  $\theta$ ,  $\text{m}^3/\text{s}$   
 $\theta$  = time, s

In Equation (47), density differences between indoor and outdoor air are generally ignored for moderate climates; therefore,  $Q$  also refers to the airflow rate into the building. While  $Q$  is often referred to as the infiltration rate, any measurement includes both mechanical and natural ventilation in addition to infiltration. The ratio of  $Q$  to the volume  $V$  being tested has units of 1/time (often converted to ACH) and is the air exchange rate  $I$ .

Equation (47) is based on the assumptions that (1) no unknown tracer gas sources exist; (2) the airflow out of the building is the

dominant means of removing the tracer gas from the space (i.e., the tracer gas does not react chemically within the space and/or is not adsorbed onto or by interior surfaces), and (3) the tracer gas concentration within the building can be represented by a single value (i.e., the tracer gas is uniformly mixed within the space).

Three different tracer gas procedures are used to measure air exchange rates: (1) decay or growth, (2) constant concentration, and (3) constant injection.

### Decay or Growth

**Decay.** The simplest tracer gas measurement technique is the decay method (also known as the step-down method). A small amount of tracer gas is injected into the space and is allowed to mix with the interior air. After the injection,  $F = 0$  and then the solution to Equation (47) is

$$C(\theta) = C_o e^{-I\theta} \quad (48)$$

where  $C_o$  is the concentration of the tracer in the space at  $\theta = 0$ .

Equation (48) is generally used to solve for  $I$  by measuring the tracer gas concentration periodically during the decay and fitting the data to the logarithmic form of Equation (48):

$$\ln C(\theta) = \ln C_o - I\theta \quad (49)$$

Like all tracer gas techniques, the decay method has advantages and disadvantages. One advantage is that because logarithms of concentration are taken, only relative concentrations are needed, which can simplify the calibration of the concentration-measuring equipment. Also, the tracer gas injection rate need not be measured, although it must be controlled so that the tracer gas concentrations are within the range of the concentration-measuring device. The concentration-measuring equipment can be located on site, or building samples can be collected in suitable containers and analyzed elsewhere.

The most serious problem with the decay technique is imperfect mixing of the tracer gas with the interior air, both at initial injection and during the decay. Equations (47) and (48) employ the assumption that the tracer gas concentration within the building is uniform. If the tracer is not well mixed, this assumption is not appropriate and the determination of  $I$  will be subject to errors. It is difficult to estimate the magnitude of the errors due to poor mixing, and little analysis of this problem has been performed.

**Growth.** The growth or step-up method is similar to the decay method except that the initial tracer gas concentration is low and is increased during the test.

### Constant Concentration

In the constant concentration technique, the tracer gas injection rate is adjusted to maintain a constant concentration within the building. If the concentration is truly constant, then Equation (47) reduces to

$$Q(\theta) = F(\theta)/C \quad (50)$$

There is less experience with this technique than with the decay procedure, but an increasing number of applications exist (Kumar et al. 1979, Collet 1981, Bohac et al. 1985, Fortmann et al. 1990, Walker and Wilson 1998, Wilson and Walker 1993, Walker and Forst 1995).

Because the tracer gas injection is continuous, no initial mixing period is required. Another advantage is that the tracer gas injection into each zone of the building can be separately controlled; thus, the amount of outdoor air flowing into each zone can be determined. This procedure is best suited for longer term continuous monitoring of fluctuating infiltration rates. This procedure has the disadvantage

of requiring the measurement of absolute tracer concentrations and injection rates. Also, imperfect mixing of the tracer and the interior air causes a delay in the response of the concentration to changes in the injection rate.

### Constant Injection

In the constant injection procedure, the tracer is injected at a constant rate, and the solution to Equation (47) becomes

$$C(\theta) = (F/Q)(1 - e^{-I\theta}) \quad (51)$$

After sufficient time, the transient term reduces to zero, the concentration attains equilibrium, and Equation (51) reduces to

$$Q = F/C \quad (52)$$

Equation (52) is valid only when air exchange rate  $I$  and airflow rate  $Q$  are constant; thus, this technique is only appropriate for systems at or near equilibrium. It is particularly useful in spaces with mechanical ventilation or with high air exchange rates. Constant injection requires the measurement of absolute concentrations and injection rates.

Dietz et al. (1986) used a special case of the constant injection technique. This technique uses permeation tubes as a tracer gas source. The tubes release the tracer at an ideally constant rate into the building being tested. A sampling tube packed with an adsorbent collects the tracer from the interior air at a constant rate by diffusion. After a sampling period of one week or more, the sampler is removed and analyzed to determine the average tracer gas concentration within the building during the sampling period.

Solving Equation (47) for  $C$  and taking the time average gives

$$\langle C \rangle = \langle F/Q \rangle = F/\langle Q \rangle \quad (53)$$

where  $\langle \dots \rangle$  denotes time average. (Note that the time average of  $dC/d\theta$  is assumed to equal zero.)

Equation (53) shows that the average tracer concentration  $\langle C \rangle$  and the injection rate  $F$  can be used to calculate the average of the inverse airflow rate. The average of the inverse is less than the inverse of the actual average, with the magnitude of this difference depending on the distribution of airflow rates during the measurement period. Sherman and Wilson (1986) calculated these differences to be about 20% for one-month averaging periods. Differences greater than 30% have been measured when there were large changes in air exchange rate due to occupant airing of houses; errors from 5 to 30% were measured when the variation was due to weather effects (Bohac et al. 1987). Longer averaging periods and large changes in air exchange rates during the measurement periods generally lead to larger differences between the average inverse exchange rate and the inverse of the actual average rate.

### Multizone Air Exchange Measurement

Equation (47) is based on the assumption of a single, well-mixed enclosure, and the techniques described are for single-zone measurements. Airflow between internal zones and between the exterior and individual internal zones has led to the development of multizone measurement techniques (Harrje et al. 1985, Sherman and Dickerhoff 1989, Fortmann et al. 1990, Harrje et al. 1990). These techniques are important when considering the transport of pollutants from one room of a building to another. For a theoretical development, see Sinden (1978b). Multizone measurements typically use either multiple tracer gases for the different zones or the constant concentration technique. A proper error analysis is essential in all multizone flow determination (Charlesworth 1988, D'Ottavio et al. 1988).

## SYMBOLS

$A$  = area,  $m^2$  or  $cm^2$   
 $c$  = flow coefficient,  $m^3/(s \cdot Pa^n)$   
 $c_p$  = specific heat,  $J/(kg \cdot K)$  or  $kJ/(kg \cdot K)$   
 $\bar{C}$  = concentration  
 $\bar{C}$  = time averaged concentration  
 $C_A$  = airflow coefficient for automatic doors,  $L/(s \cdot m^2 \cdot Pa^{0.5})$   
 $C_D$  = discharge coefficient  
 $C_p$  = pressure coefficient  
 $C_s$  = stack flow coefficient,  $(L/s)^2/(cm^4 \cdot K)$  or  $(Pa/K)^n$   
 $C_v$  = effectiveness of openings  
 $C_w$  = wind flow coefficient,  $(L/s)^2/[cm^4 \cdot (m/s)^2]$  or  $[Pa/(m/s)^2]^n$   
 $F$  = tracer gas injection rate,  $m^3/s$   
 $\bar{F}$  = time-averaged contaminant source strength,  $m^3/s$   
 $f$  = fractional on-time  
 $g$  = wind speed reduction factor  
 $h$  = specific enthalpy,  $kJ/kg$   
 $H$  = height,  $m$   
 $i$  = hour of year  
 $I$  = air exchange rate,  $1/time$   
 $I_i$  = instantaneous air exchange rate,  $1/time$   
 $I_m$  = effective air exchange rate,  $1/time$   
 IDD = infiltration degree-days,  $K \cdot day$   
 $n$  = pressure exponent  
 $N$  = number of discrete time periods in period of interest  
 $p$  = pressure,  $Pa$   
 $P$  = parameter  
 $q$  = heat rate,  $W$   
 $\underline{Q}$  = volumetric flow rate,  $m^3/s$   
 $\bar{Q}$  = effective volumetric flow rate,  $m^3/s$   
 $s$  = shelter factor  
 $S$  = source strength,  $\mu g/s$   
 $t$  = relative temperature,  $^\circ C$   
 $T$  = absolute temperature,  $K$   
 $U$  = wind speed,  $m/s$   
 $V$  = volume,  $m^3$   
 $W$  = humidity ratio,  $kg/kg$   
 $\epsilon_f$  = air change effectiveness  
 $\phi$  = wind angle, degrees  
 $\rho$  = air density,  $kg/m^3$   
 $\theta$  = time  
 $\theta_{age}$  = age of air  
 $\tau$  = time constant

## Subscripts

$b$  = base  
 $ba$  = bypass air  
 $c$  = calculated  
 $ca$  = recirculated air  
 $e$  = effective  
 $ea$  = exhaust air  
 $f$  = floor  
 $i$  = indoor or time counter for summation (instantaneous)  
 $H$  = building height, eaves or roof  
 $ka$  = makeup air  
 $l$  = latent  
 $la$  = relief air  
 $L$  = leakage or local  
 $ma$  = mixed air  
 $met$  = meteorological station location  
 $n$  = normalized  
 $N$  = nominal  
 NPL = neutral pressure level  
 $o$  = outdoor, initial condition, or reference  
 $oa$  = outside air  
 $p$  = pressure  
 $r$  = reference  
 $s$  = sensible or stack  
 $sa$  = supply air  
 $S$  = space or source  
 $w$  = wind

#### BIBLIOGRAPHIC DATABASE

AIRBASE, a database of bibliographic references that contains abstracts in English of technical papers covering air infiltration in buildings, has been developed by the Air Infiltration and Ventilation Centre (AIVC 1992). Most of the articles are concerned with the prediction, measurement, and reduction of air infiltration and leakage rates. Abstracts are also included for selected papers relating to indoor air quality, occupant behavior, thermal comfort, ventilation efficiency, natural and mechanical ventilation, wind pressure and its influence on infiltration, energy-saving measures, and moisture and condensation.

# CLIMATIC DESIGN INFORMATION

<i>Climatic Design Conditions</i> .....	27.1
<i>Other Sources of Climatic Information</i> .....	27.4
<i>United States Design Conditions</i> .....	27.6
<i>Canadian Design Conditions</i> .....	27.22
<i>World Design Conditions</i> .....	27.27
<i>Selected Monthly Percentiles of Temperature and Humidity for United States Locations</i> .....	27.54

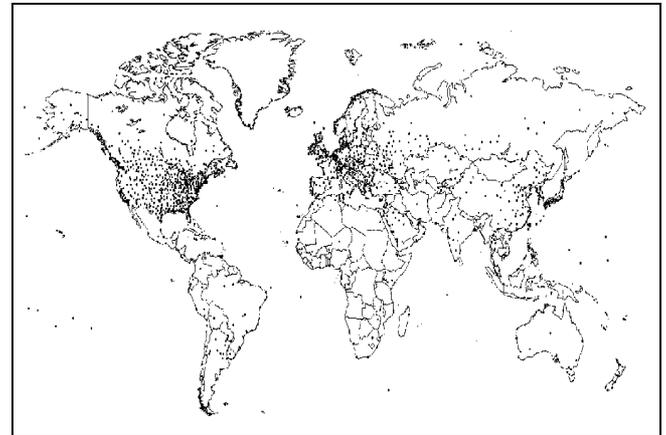

**T**HIS CHAPTER provides tables of climatic conditions for 1459 locations in the United States, Canada, and around the world. These summaries include values of dry-bulb, wet-bulb and dew-point temperature and wind speed with direction at various frequencies of occurrence. This information is commonly used for design, sizing, distribution, installation, and marketing of heating, ventilating, air-conditioning, and dehumidification equipment; as well as for other energy-related processes in residential, agricultural, commercial, and industrial applications. Sources of other information such as degree-days and typical weather years for energy calculations are also described.

The design information in this chapter was developed largely as part of a research project (ASHRAE 1997c, Colliver et al. 2000). The information includes design values of dry-bulb with mean coincident wet-bulb temperature, design wet-bulb with mean coincident dry-bulb temperature, and design dew-point with mean coincident dry-bulb temperature and corresponding humidity ratio. These data allow the designer to consider various operational peak conditions. Design values of wind speed (ASHRAE 1994, Lamming and Salmon 1998) allow for the design of smoke management systems in buildings.

The design conditions in this chapter are provided for those locations for which long-term hourly observations were available (at least 12 years of data). Consequently, many U.S. locations listed in previous versions (1993 and before) of this chapter are no longer listed because they lacked long-term data. The number of Canadian and international locations has increased significantly.

Warm-season temperature and humidity conditions correspond to annual percentile values of 0.4, 1.0, and 2.0. Cold-season conditions are based on annual percentiles of 99.6 and 99.0. The use of annual percentiles to define the design conditions ensures that they represent the same probability of occurrence anywhere, regardless of the seasonal distribution of extreme temperature and humidity. In the 1993 and earlier versions of this chapter, seasonal rather than annual percentiles were used to define the design conditions. As a result, the summer and winter months used for the calculation of design conditions varied depending on location. For instance, summer design conditions for the U.S. were calculated over the four-month period from June through September, whereas Canadian summer design conditions were based on only the month of July. The following sections describe how the annual percentiles were selected to yield design conditions that are similar to those previously calculated on a seasonal basis for most of the United States.

For a variety of reasons, such as seasonal variations in solar geometry, occupancy, or use of a building, there is sometimes a need for percentiles of temperature and humidity for specific months. New monthly tables for some U.S. locations have been added in this edition to meet this need.

**Fig. 1 Location of Weather Stations**

## CLIMATIC DESIGN CONDITIONS

Annual design conditions for the United States appear in Tables 1A and 1B, for Canada in Tables 2A and 2B, and for international locations in Tables 3A and 3B. Figure 1 is a world map showing locations.

Information on station location, period analyzed, heating design conditions, wind, mean annual extreme and standard deviation of minimum and maximum dry-bulb temperature, and mean daily temperature range is listed in Tables 1A, 2A, and 3A. Information on the design conditions for cooling and humidity control is provided in Tables 1B, 2B, and 3B.

The information provided in Tables 1A, 2A, and 3A in the indicated column numbers is

1. Name of the observing station as it appears in the data set from which it was abstracted, the World Meteorological Organization station number, latitude, longitude, elevation, standard pressure at elevation (see Chapter 6 for the equations used to calculate standard pressure), and the period analyzed
2. Dry-bulb temperature corresponding to 99.6% and 99.0% annual cumulative frequency of occurrence (cold)
3. Wind speed corresponding to 1.0%, 2.5% and 5.0% annual cumulative frequency of occurrence
4. Wind speed corresponding to the 0.4% and 1.0% cumulative frequency of occurrence for the coldest month (lowest average dry-bulb temperature), and the mean coincident dry-bulb temperature
5. Mean wind speed coincident with the 99.6% dry-bulb temperature in Column 2 and 0.4% dry-bulb temperature from Column 2 of Tables 1B, 2B, and 3B, and the wind direction most frequently occurring with the 99.6% and 0.4% dry-bulb

The preparation of this chapter is assigned to TC 4.2, Weather Information.

temperatures (direction is reported in degrees true: 360 represents a north wind, 90 east, etc.)

- Average of annual extreme maximum and minimum dry bulb temperatures and standard deviations

Information provided in Tables 1B, 2B, and 3B includes

- Station name
- Dry-bulb temperature corresponding to 0.4%, 1.0%, and 2.0% annual cumulative frequency of occurrence and the mean coincident wet-bulb temperature (warm)
- Wet-bulb temperature corresponding to 0.4%, 1.0%, and 2.0% annual cumulative frequency of occurrence and the mean coincident dry bulb temperature
- Dew-point temperature corresponding to 0.4%, 1.0%, and 2.0% annual cumulative frequency of occurrence and the mean coincident dry-bulb temperature and the humidity ratio (calculated for the dew-point temperature at the standard atmospheric pressure at the elevation of the station)
- Mean daily range, which is the mean of the difference between daily maximum and minimum dry-bulb temperatures for the warmest month (highest average dry-bulb temperature)

### Values of Cumulative Frequency of Occurrence Representing the Design Conditions

Values of ambient dry-bulb, dew-point, and wet-bulb temperature and wind speed corresponding to the various annual percentiles represent the value that is exceeded on average by the indicated percentage of the total number of hours in a year (8760). The 0.4%, 1.0%, 2.0%, and 5.0% values are exceeded on average 35, 88, 175, and 438 h per year, respectively, for the period of record.

The 99.0% and 99.6% (cold) values are defined in the same way but are usually viewed as the values for which the corresponding weather element is less than the design condition for 88 and 35 h, respectively.

Mean coincident values are the average of the indicated weather element occurring concurrently with the corresponding design value.

These design conditions were calculated from the frequency distribution analyzed from data sets observed over several years. Gaps due to missing data were filled as needed, as explained in the section on Calculation of Design Conditions. The design values occur more frequently than the corresponding nominal percentile in some years and less frequently in others.

### Data Sources

The following three primary sources of observational data sets were used for the calculation of design values:

- Hourly weather observations from Surface Airways Meteorological and Solar Observing Network (SAMSON) data from NCDC (National Climatic Data Center) for 239 United States observing locations from 1961 through 1990 (NCDC 1991)
- Hourly observational records in the DATSAV2 format (ASHRAE 1995b, Plantico and Lott 1995) for 538 United States locations for the period 1982 through 1993, including the 239 SAMSON locations, and for 860 international locations (most data for international locations consist of observations taken every 3 h)
- Hourly weather records for the period 1953 through 1993 for 145 Canadian locations from the Canadian Weather Energy and Engineering Data Sets (CWEEDS) produced by Environment Canada (1993b)

Two primary periods of record were used in the calculations. The values for the United States SAMSON and Canadian CWEEDS locations are generally based on the period from 1961 through 1993. DATSAV2 data were used for the 1991 through 1993 period for the SAMSON sites. The values for international locations and the rest

of the United States, whose data were analyzed from the DATSAV2 files, are based on the period 1982 through 1993. DATSAV2 is a comprehensive database containing hourly observations for locations around the world collected from global telecommunications circuits. It is quality-controlled and archived by the Air Force Combat Climatology Center at Asheville, NC. Tables 1A, 2A, and 3A indicate the period of record used for each location.

In summary, the data source for United States locations with the period identified as "6193" is SAMSON data supplemented with DATSAV2 data for the last 3 years. The source for United States locations with the period "8293" is DATSAV2.

### Calculation of Design Conditions

Details of the analysis procedures are available in ASHRAE (1997c) and Colliver et al. (2000), including the measures used to ensure that the number and distribution of missing data, both by month and by hour of the day, did not introduce significant biases into the analysis. Generally, the annual cumulative frequency distribution was constructed from the relative frequency distributions compiled for each month. Each individual month's data were included if they met screening criteria for completeness and unbiased distribution of missing data. Although the minimum period of record selected for this analysis was 12 years (1982 through 1993), some variation and gaps in observing programs meant that some months' data were unusable due to incompleteness.

A station's design conditions were included in this chapter only if there were data from at least 8 months that met the screening criteria from the period of record for each month of the year. For instance, there had to be 8 months each for January, February, March, etc. whose data met the completeness screening criteria.

Gaps of up to 5 h were filled. A month's data were included if the month was at least 85% complete after filling and the difference between the number of day and nighttime observations was less than 60.

### Relationship Between Design Conditions and Previously Published Design Temperatures

The design conditions in this chapter are calculated on a different basis from the design conditions published in the 1993 and previous editions of this Handbook. Previous design conditions were based on a 4-month summer period and a 3-month winter period in the United States, on the months of July and January in Canada, and on the warmest 4-month period and coldest 3-month period in international locations. Although generally suitable as design values, the different periods resulted in design temperatures representing different annual probabilities of occurrence, depending on the country; and within countries, on the distribution of temperature and humidity conditions throughout the year typical of regional climatic zones. The design conditions in this chapter explicitly represent the same annual probability of occurrence in any location, regardless of country or general climatic conditions.

The annual cumulative frequencies of occurrence representing the design dry-bulb temperatures generally correspond to the seasonal design temperatures in the following fashion for locations in the mid-latitude, continental locations (characterized by a hot summer and cold winter). The 0.4% annual value is about the same as the 1.0% summer design temperature in the 1993 *ASHRAE Handbook*. The 1.0% annual value is about 0.5 K lower than the 2.5% summer design temperature in the 1993 *ASHRAE Handbook*, and the 2.0% annual condition corresponds approximately to the 5.0% summer design temperature in the 1993 *ASHRAE Handbook*.

In Canadian continental locations, the 0.4% annual condition is about the same as the 2.5% July design temperature in the 1993 *ASHRAE Handbook*. In the United States for the Pacific region and southern coastal locations, where the extremes are generally more widely distributed throughout the year, the values in this chapter

represent more extreme conditions than the design temperatures in the 1993 *ASHRAE Handbook*.

Annual 99.6% and 99.0% design conditions represent a slightly colder condition than the previous cold season design temperatures, although there is considerable variability in this relationship from location to location.

Further details concerning differences between the design conditions in this Chapter and the 1993 and previous versions are described in ASHRAE (1997c) and Colliver et al. (2000).

### Applicability and Characteristics of the Design Conditions

The sets of design values in this chapter represent different psychrometric conditions. Design data based on dry-bulb temperature represent peak occurrences of the sensible component of ambient outdoor conditions. Design values based on wet-bulb temperature are related to the enthalpy of the outdoor air. Conditions based on dew point relate to the peaks of the humidity ratio. The designer, engineer, or other user must decide which set(s) of conditions and probability of occurrence apply to the design situation under consideration. The addition of the new psychrometric design conditions allows for several viewpoints of operational peak loads. Additional sources of information on the frequency and duration of extremes of temperature and humidity are provided later in the section on Other Sources of Climatic Information. Further information is available from Harriman et al. (1999).

**Heating Design Conditions.** The 99.6% and 99.0% design conditions in Column 2 of Tables 1A, 2A, and 3A are often used in the sizing of heating equipment. In cold spells, dry-bulb temperatures below the design conditions can last for a week or more.

Columns 4 and 5 of Tables 1A, 2A, and 3A provide information useful for estimating peak loads accounting for infiltration. Column 4 provides extreme wind speeds only for the coldest month, with the mean coincident dry-bulb temperature. Column 5 provides the mean wind speed and direction coincident to the corresponding percentile design dry-bulb temperature.

**Cooling and Dehumidification Design Conditions.** The 0.4%, 1.0%, and 2.0% dry-bulb temperatures and mean coincident wet-bulb temperatures in Column 2 of Tables 1B, 2B, and 3B often represent conditions on hot, mostly sunny days. These are useful for cooling applications, especially air-conditioning.

Design conditions based on wet-bulb temperature in Column 3 represent extremes of the total sensible plus latent heat of outdoor air. This information is useful for cooling towers, evaporative coolers, and fresh air ventilation system design.

The design conditions based on dew-point temperatures in Column 4 of Tables 1B, 2B, and 3B are directly related to extremes of humidity ratio, which represent peak moisture loads from the weather. Extreme dew-point conditions may occur on days with moderate dry-bulb temperatures resulting in high relative humidity. These values are especially useful for applications involving humidity control, such as desiccant cooling and dehumidification, cooling-based dehumidification, and fresh air ventilation systems. The values are also used as a check point when analyzing the behavior of cooling systems at part-load conditions, particularly when such systems are used for humidity control as a secondary function.

The humidity ratio values in Column 2 correspond to the combination of dew-point temperature and the mean coincident dry-bulb temperature calculated at the standard pressure at the elevation of the location.

**Wind.** Design wind speeds in Column 3 of Tables 1A, 2A, and 3A have been produced as a result of the requirement for the design of smoke management systems. Annual percentiles of 1.0, 2.5, and 5.0 have been determined appropriate for this application. The values for the United States SAMSON sites and Canadian locations have been taken from ASHRAE (1994), in which adjustments to the standard 10 m anemometer height were made. Wind speed values

for other locations are taken from ASHRAE (1997c), in which no adjustment for nonstandard anemometer height is made.

**Annual Extreme Temperatures.** Column 6 of Tables 1A, 2A, and 3A provides the mean and standard deviation of the annual extreme maximum and minimum dry-bulb temperatures. The probability of occurrence of very extreme conditions can be required for the operational design of equipment to ensure continuous operation and serviceability (regardless of whether the heating or cooling loads are being met). These values were calculated from the extremes of the hourly temperature observations. The true maximum and minimum temperatures for any day generally occur between hourly readings. Thus, the mean maximum and minimum temperatures calculated in this way will be about 0.5 K less extreme than the mean daily extreme temperatures observed with maximum and minimum thermometers.

Return period (or recurrence interval) is defined as the reciprocal of the annual probability of occurrence. For instance, the 50-year return period maximum dry-bulb temperature has a probability of occurring or being exceeded of 2.0% (i.e., 1/50) each year. This statistic does not indicate how often the condition will occur in terms of the number of hours each year (as in the design conditions based on percentiles) but describes the probability of the condition occurring at all in any year. The following method can be used to estimate the return period (recurrence interval) of extreme temperatures.

$$T_n = M + IFs \quad (1)$$

where

$T_n$  =  $n$ -year return period value of extreme dry-bulb temperature to be estimated, years

$M$  = mean of the annual extreme maximum or minimum dry-bulb temperatures, °C

$s$  = standard deviation of the annual extreme maximum or minimum dry-bulb temperatures, °C

$I$  = 1, if maximum dry-bulb temperatures are being considered  
= -1 if minimum extremes are being considered

$$F = -\frac{\sqrt{6}}{\pi} \left\{ 0.5772 + \ln \left[ \ln \left( \frac{n}{n-1} \right) \right] \right\}$$

For example, the 50-year return period extreme maximum dry-bulb temperature estimated for Terre Haute, Indiana is 40°C ( $M = 35.5^\circ\text{C}$ ,  $s = 1.8$ ,  $n = 50$ ,  $I = 1$ ). Similarly, the 100-year return period extreme minimum dry-bulb temperature for Winnipeg, Manitoba, is  $-44^\circ\text{C}$  ( $M = -36^\circ\text{C}$ ,  $s = 2.6$ ,  $n = 100$ ,  $I = -1$ ).

This calculation is based on the assumptions that the annual maxima and minima are distributed according to the Gumbel (Type 1 Extreme Value) distribution and are fitted with the method of moments (Lowery and Nash 1970). The uncertainty or standard error using this method increases with increasing standard deviation, increasing value of return period, and decreasing length of the period of record. It can be significant. For instance, the standard error in the 50-year return period maximum dry-bulb temperature estimated at a location with a 12-year period of record can be 3 K or more. Thus, the uncertainty of return-period values estimated in this way will be greater for locations from the DATSAV2 data sets than those from the longer SAMSON and CWEEDS data sets.

**Mean Daily Range.** The mean daily range is the mean difference between the daily maximum and minimum temperatures during the hottest month. These values are calculated from the extremes of the hourly temperature observations. The true daily temperature range is generally about 1 K greater, for the same reason as explained in the previous section.

### Monthly Tables

Selected monthly percentiles of temperature and humidity are provided in Tables 4A and 4B for 239 U.S. locations from the SAMSON data set. These monthly values are derived from the

same analysis that results in the design conditions in Tables 1A and 1B. These monthly summaries provide additional information when seasonal variations in solar geometry and intensity, building or facility occupancy, or building use patterns require consideration. In particular, these values can be used when determining air-conditioning loads during periods of maximum solar radiation.

Table 4A contains the location name and WMO station number and the 0.4%, 1.0%, and 2.0% value of the wet-bulb temperature and mean coincident dry-bulb temperature for the indicated month and annual period. The percentiles for the annual period are the same as those in Table 1B for the same location and are listed in Table 4A for convenience.

Table 4B contains the location name and WMO station number and the 0.4%, 1.0%, and 2.0% value of the dry-bulb temperature and mean coincident wet-bulb temperature for the indicated month and annual period. The percentiles for the annual period are the same as those in Table 1B for the same location and are listed in Table 4B for convenience.

For a 30-day month, the 0.4%, 1.0%, and 2.0% values of occurrence represent the value that occurs or is exceeded for a total of 3, 7, or 14 h, respectively, per month on average over the period of record.

Monthly percentile values of dry-bulb or wet-bulb temperature may be higher or lower than the design conditions corresponding to the same nominal percentile, depending on the month and the seasonal distribution of the parameter at that location. Generally, for the hottest or most humid months of the year, the monthly percentile value will exceed the design condition for the same element corresponding to the same nominal percentile. For instance, Table 1B shows that the 0.4% design dry-bulb temperature at Mobile, Alabama, is 34°C. Table 4B shows that the 0.4 monthly percentile dry-bulb temperature exceeds 34°C for the months of June, July, and August, with values of 35°C, 36°C, and 35°C, respectively.

It is essential to remember that the design conditions are based on an annual analysis. The 0.4% annual value represents a value occurring or exceeded 35 h on average every year over the period of record, whereas the 0.4% monthly value occurs or is exceeded 3 h on average for the month that it represents, over the period of record.

### Representativeness of Data and Sources of Uncertainty

The information in the tables was obtained by direct analysis of the observations from the indicated locations. The design values are provided and used as an estimate of the annual cumulative frequency of occurrence of the weather conditions at the recording station for several years into the future. Several sources of uncertainty affect the accuracy of using the design conditions to represent other locations or periods.

The most important of these factors is spatial representativeness. Most of the observed data for which design conditions were calculated were collected from airport observing sites, most of which are flat, grassy, open areas, away from buildings and trees or other local influences. Data representing the psychrometric conditions are generally properties of air masses, rather than local features, and tend to vary on regional scales. As a result, a particular value often may reasonably represent an area extending several kilometres. However, significant variations can occur with changes in local elevation, across large metropolitan areas, or in the vicinity of large bodies of water. Judgment must always be exercised in assessing the representativeness of the design conditions. It is especially important to note the elevation of locations because design conditions vary significantly for locations whose elevations differ by a few hundred metres or more. An applied climatologist should be consulted in estimating design conditions for locations not explicitly listed in this chapter.

Weather conditions vary from year to year and, to some extent, from decade to decade due to the inherent variability of climate. Similarly, values representing design conditions vary depending on

the period of record used in the analysis. Thus, due to short-term climatic variability, there is always some uncertainty in using the design conditions from one period to represent another period. Typically, the values of design dry-bulb temperature vary less than 1 K from decade to decade, but larger variations can occur. Differing periods used in the analysis can lead to differences in design conditions between nearby locations at similar elevations. Design conditions may show trends in areas of increasing urbanization or other regions experiencing extensive changes to land use. Longer term climatic change due to human or natural causes may also introduce trends into design conditions, but no conclusive evidence or consensus of opinion is available on the rapidity or nature of such changes.

Wind speed is very sensitive to local exposure features such as terrain and surface cover. Wind speed values in Columns 3, 4, and 5 of Tables 1A, 2A, and 3A are often representative of a flat, open exposure, such as at airports. Wind engineering methods, as described in Chapter 16, can be used to account for exposure differences between airport and building sites. This is a complex procedure, best undertaken by an experienced applied climatologist or wind engineer having knowledge of the exposure of the observing and building sites and surrounding regions.

## OTHER SOURCES OF CLIMATIC INFORMATION

### Joint Frequency Tables of Psychrometric Conditions

Most of the design values in this chapter were developed by a research project (ASHRAE 1997c, and Colliver et al. 2000). The joint frequency tables from this project provide the annual and monthly joint frequency of occurrence of various psychrometric combinations for each location in the tables. The complete set of joint frequency tables is available on CD (ASHRAE 1999)

The Engineering Weather Data (NCDC 1999) CD, an update of Air Force *Manual* 88-29, was compiled by the U.S. Air Force Combat Climatology Center. This CD contains several tabular and graphical summaries of temperature, humidity, and wind speed information for hundreds of locations in the United States and around the world. In particular, it contains detailed joint frequency tables of temperature and humidity for each month, binned at 1°F and 3-h local time-of-day intervals.

The International Station Meteorological Climate Summary (ISMCS) is a CD-ROM containing several tables of climatic summary information for over 7000 locations around the world (NCDC 1996). Only several hundred of these locations have observed hourly weather data. A table providing the joint frequency of dry-bulb temperature and wet-bulb temperature depression is provided for the locations with hourly observations. It can be used as an aid in estimating design conditions for locations for which no other information is available.

The monthly frequency distribution of dry-bulb temperatures and mean coincident wet-bulb temperatures is available for 134 Canadian locations from Environment Canada (1983-1987).

### Degree-Days and Climatic Normals

Degree-day summary information and climatic normals for the United States are available on CD-ROM in *The Climatology of the U.S.* (NCDC 1992a, 1992b, 1994); and, for Canada, in the *Canadian Climate Normals, 1961 to 1990* (Environment Canada 1993a).

### Typical Year Data Sets

Software exists to simulate the annual energy performance of buildings requiring a 1-year data set (8760 h) of weather conditions. Many data sets in different record formats have been developed to meet this requirement. The data represent a typical year from the viewpoint of weather-induced energy loads on a building. No

explicit effort was made to represent extreme conditions, so these files do not represent design conditions.

Weather Year for Energy Calculations Version 2 (WYEC2) for 52 U.S. and 5 Canadian locations is available from ASHRAE (ASHRAE 1997d). A user manual and software toolkit explains the development, format, and characteristics of this data and provides access and toolkit software.

Typical Meteorological Year Version 2 (TMY2) files are available for 239 U.S. locations from the National Renewable Energy Laboratory (Marion and Urban 1995). These were produced using an objective statistical algorithm to select the most typical month from the long-term record. These files were originally intended for the design of solar energy systems, so solar radiation values were weighted heavily.

Canadian Weather Year for Energy Calculation (CWEC) files for 47 Canadian locations were developed for use with the Canadian National Energy Code, using the TMY algorithm and software (Environment Canada 1993b).

Examples of the use of these files for energy calculations in both residential and commercial buildings, including the differences amongst the files, are available in Crawley (1998) and Huang (1998).

### Seasonal Percentiles of Dew-Point Temperature

Seasonal percentiles of dew-point temperature are available for 381 U.S. and Canadian locations in ASHRAE (1995a), with their development summarized in Colliver et al. (1995).

### Sequences of Extreme Temperature and Humidity Durations

Colliver et al. (1998) and ASHRAE (1997b) compiled extreme sequences of 1-, 3-, 5-, and 7-day duration for 239 U.S. (SAMSON data) and 144 Canadian (CWEEDS data) locations based independently on the following five criteria: high dry-bulb temperature, high dew-point temperature, high enthalpy, low dry-bulb temperature, and low wet-bulb depression. For the criteria associated with high values, the sequences are selected according to annual percentiles of 0.4, 1.0, and 2.0. For the criteria corresponding to low values, annual percentiles of 99.6, 99.0, and 98.0 are reported. The data included for each hour of a sequence are solar radiation, dry-bulb and dew-point temperature, atmospheric pressure, and wind speed and direction. Accompanying information allows the user to go back to the source SAMSON and CWEEDS data and obtain sequences with different characteristics (i.e., different probability of occurrence, windy conditions, low or high solar radiation, etc.). These extreme sequences are available on CD (ASHRAE 1997a).

These sequences were developed primarily to assist the design of heating or cooling systems having a finite capacity before regeneration is required or systems that rely on thermal mass to limit loads. The information is also useful where information on the hourly weather sequence during extreme episodes is required for design.

### Observational Data Sets

For detailed designs, custom analysis of the most appropriate long-term weather record is best. National weather services are generally the best source of long-term observational data. The WMO World Data Center A at the National Climate Data Center in Asheville, NC, collects and makes available a significant volume of archived weather observations from around the world.

The SAMSON and CWEEDS data sets provide long-term hourly data, including solar radiation values for the United States and Canada.

Increasingly, information about weather and climate services and data sets, as well as the data sets themselves, is becoming available through the Internet and World Wide Web. Information supplementary to this chapter may be posted from time to time on the ASHRAE Technical Committee 4.2 web site, the link to which is available from the ASHRAE web site ([www.ashrae.org](http://www.ashrae.org)).

MDB = mean coincident dry-bulb temp., °C      MWS = mean coincident wind speed, m/s      HR = humidity ratio, grams of moisture per kilogram of dry air  
MWB = mean coincident wet-bulb temp., °C      StdD = standard deviation, °C      A = airport      DP = dew-point temperature, °C

<i>General Procedure</i> .....	28.7	<i>PICKUP LOAD</i> .....	28.14

**T**HIS CHAPTER covers the engineering basis of modified residential load calculation procedures for the nonengineer. The procedures described in Chapter 29 may be used to calculate a heating or cooling load for residential buildings.

### RESIDENTIAL FEATURES

With respect to heating and cooling load calculation and equipment sizing, the unique features distinguishing residences from other types of buildings are the following:

- Unlike many other structures, residences are usually occupied and conditioned 24 h per day, virtually every day of the cooling and heating seasons.
- Residential system loads are primarily imposed by heat loss or gain through structural components and by air leakage or ventilation. Internal loads, particularly those from occupants and lights, are small in comparison to those in commercial or industrial structures.
- Most residences are conditioned as a single zone. Unit capacity cannot be redistributed from one area to another as loads change from hour to hour; however, exceptions do occur.
- Most residential cooling systems use units of relatively small capacity (about 5 to 18 kW cooling, 18 to 32 kW heating). Because loads are largely affected by outside conditions, and few days each season are design days, the unit operates at only partial load during most of the season; thus, an oversized unit is detrimental to good system performance, especially for cooling in areas of high wet-bulb temperature.
- Dehumidification occurs during cooling unit operation only, and space condition control is usually limited to use of room thermostats (sensible heat-actuated devices).
- Multifamily living units are similar to single-family detached houses, but the living units may not all have surfaces exposed in all directions. This affects load calculation.

### Categories of Residences

**Single-Family Detached.** A house in this category usually has exposed walls in four directions, often more than one story, and a roof. The cooling system is a single-zone, unitary system with a single thermostat. Two-story houses may have a separate cooling system for each floor. The rooms are reasonably open and generally have a centralized air return. In this configuration, both air and load from rooms are mixed, and a load-leveling effect, which requires a distribution of air to each room that is different from a pure commercial system, results. Because the amount of air supplied to each room is based on the load for that room, proper load calculation procedures must be used.

**Multifamily Buildings.** Unlike single-family detached units, multifamily units by definition do not have exposed surfaces facing in all directions. Rather, each unit has only one or two exposed surfaces and possibly a roof. Two exposed walls will be at right angles, and both east and west walls will not be exposed in a given living unit. Each living unit has a single unitary cooling system or a single fan-coil unit, and the rooms are relatively open to one another. This configuration does not have the same load-leveling effect as a single-family detached house, but it is not a commercial building. Therefore, a specific load calculation procedure is required.

**Other Categories.** Many buildings do not fall into either of the above categories. Critical to the designation of a single-family detached building is the exposure of both east and west walls. Therefore, some multifamily structures should be treated as single-family detached when the exposed surfaces are oriented in a particular way. Examples include duplexes or apartments with either exposed east, west, and south walls or exposed east, west, and north walls, with or without a roof; and apartments, town houses, or condominiums with only east and west or north and south exposed walls.

## COOLING LOAD

### LOAD COMPONENTS

A cooling load calculation determines total sensible cooling load due to heat gain (1) through structural components (walls, floors, and ceilings); (2) through windows; (3) caused by infiltration and ventilation; and (4) due to occupancy. The latent portion of the cooling load is evaluated separately. While the entire structure may be considered a single zone, equipment selection and system design should be based on a room-by-room calculation. For proper design of the distribution system, the amount of conditioned air required by each room must be known.

### Peak Load Computation

To select a properly sized cooling unit, the peak or maximum load (**block load**) for each zone must be computed. Because this procedure may vary considerably for different types of buildings, each building type has to be considered; the block load for a single-family detached house with one central system is the sum of all the room loads. If the house has a separate system for each zone, each zone block load (i.e., the sum of the loads for all rooms in each zone) is required. When a house is zoned with one central cooling system, the block load must be computed for the complete house as if it were one zone. In multifamily structures, each living unit has a zone load that equals the sum of the room loads. For apartments with separate systems, the block load for each unit establishes the system size. Apartment buildings with a central cooling system (i.e., a hydronic system with fan-coils in each apartment) require a block load calculation for the complete structure to size the central system; each unit

The preparation of this chapter is assigned to TC 4.1, Load Calculation Data and Procedures.

load establishes the size of the fan-coil and air distribution system for each apartment. One of the methods discussed in Chapter 29 may be used to calculate the block load.

**Indoor Temperature Swing**

For hour-by-hour load calculations, allowing for a swing in indoor temperature results in lower peak loads. Because the indoor temperature does swing, such an allowance gives a more reasonable equipment capacity. The tables in this section are based on an assumed indoor temperature swing of no more than 1.5 K on a design day, when the residence is conditioned 24 h per day and the thermostat is set at 24°C.

**Cooling Load Due to Heat Gain Through Structure**

The sensible cooling load due to heat gains through the walls, floor, and ceiling of each room is calculated using appropriate **cooling load temperature differences** (CLTDs) (Tables 1 and 2) and U-factors for summer conditions. For ceilings under naturally vented attics or beneath vented flat roofs, the combined U-factor for the roof, vented space, and ceiling should be used. The mass of the walls is a variable in Table 2 and is important in calculating energy use, but it is not used in Table 1 because of the averaging technique required to develop the CLTDs. Values in Tables 1 and 2 assume a dark color because color is an unpredictable variable in any residence.

Daily range (outdoor temperature swing on a design day) significantly affects the equivalent temperature difference. Tables 1 and 2 list daily temperature ranges classified as high, medium, and low. Tables 1, 2, and 3 in Chapter 27 list outdoor daily ranges of dry-bulb temperature for different locations.

**Cooling Load Due to Heat Gain Through Windows**

Direct application of procedures for calculating cooling load due to heat gain for flat glass (discussed in Chapters 29 and 30) results in unrealistically high cooling loads for residential installations. Window **glass load factors** (GLFs), modified for single- and multifamily residential cooling load calculations and including solar heat load plus air-to-air conduction, are given in Tables 3 and 4. Table 5 lists the **shading coefficients** (SCs) and U-factors used to compile Tables 3 and 4.

<sup>a</sup>Cooling load temperature differences (CLTDs) for single-family detached houses, duplexes, or multifamily, with both east and west exposed walls or only north and south exposed walls, K.

<sup>b</sup>L denotes low daily range, less than 9 K; M denotes medium daily range, 9 to 14 K; and H denotes high daily range, greater than 14 K.

In application, the area of each window is multiplied by the appropriate GLF. The effects of permanent outside shading devices should be considered separately in determining the cooling load. Shaded glass is considered the same as north-facing glass. The **shade line factor** (SLF) is the ratio of the distance a shadow falls beneath the edge of an overhang to the width of the overhang (Table 6). Therefore, assuming the overhang is at the top of the window, the shade line equals the SLF times the overhang width. The shaded and sunlit glass areas may then be computed separately. The tabulated values are the average of the shade line values for 5 h of maximum solar intensity on each wall orientation shown. Northeast- and northwest-facing windows are not effectively protected by roof overhangs; in most cases, they should not be considered shaded.

**Infiltration**

Natural air leakage in residential structures is less in summer than in winter, largely because wind velocities are lower in most localities. The data in Tables 7 and 8 showing space air changes per hour (ACH) apply to both single- and multifamily housing,

<sup>a</sup>Glass load factors (GLFs) for multifamily low-rise or single-family detached residences if zoned with separate temperature control for each zone, W/m<sup>2</sup>.

<sup>b</sup>Correct by +30% for latitude of 48° and by -30% for latitude of 32°. Use linear interpolation for latitude from 40 to 48 and from 40 to 32°.

To obtain GLF for other combinations of glass and/or inside shading:  $GLF_a = (SC_a/SC_t)(GLF_t - U_i D_i) + U_a D_i$ , where the subscripts *a* and *t* refer to the alternate and table values, respectively.  $SC_a$  and  $U_i$  are given in Table 5.  $D_i = (t_a - 24)$ , where  $t_a = t_o - (DR/2)$ ;  $t_o$  is the outdoor design temperature and DR is the daily range.

although most of the raw data were for single-family structures (McQuiston 1984). Construction may be defined as follows:

**Tight.** Good multifamily construction with close-fitting doors, windows, and framing is considered tight. New houses with full vapor retarder, no fireplace, well-fitted windows, weather-stripped doors, one story, and less than 140 m<sup>2</sup> floor area fall into this category.

**Medium.** Medium structures include new, two-story frame houses or one-story houses more than 10 years old with average maintenance, a floor area greater than 140 m<sup>2</sup>, average fit windows and doors, and a fireplace with damper and glass closure. Below-average multifamily construction falls in this category.

**Loose.** Loose structures are poorly constructed single- and multifamily residences with poorly fitted windows and doors. Examples include houses more than 20 years old, of average maintenance, having a fireplace without damper or glass closure, or having more than an average number of vented appliances. Average manufactured homes are in this category.

**Ventilation**

Residential air-conditioning systems may introduce outdoor air, although it is not a code requirement in most localities. Positive ventilation should be considered, however, if the anticipated infiltration is less than about 0.5 ACH. When positive means of introducing outdoor air are used, controls, either manual or automatic, should be provided, and an energy recovery device should be considered.

**Occupancy**

Even though occupant density is low, occupancy loads should be estimated. Sensible heat gain per sedentary occupant is assumed to be 67 W. To prevent gross oversizing, the number of occupants should not be overestimated. Recent census studies recommend that the total number of occupants be based on two persons for the first bedroom, plus one person for each additional bedroom. The occupancy load should then be distributed equally among the living areas because the maximum load occurs when most of the residents occupy these areas.

**Table 5 Shading Coefficients and U-Factors for Residential Windows**

Glass Type	Inside Shade					
	None		Drapery, Venetian Blind, or Translucent Roller Shade		Opaque Roller Shade	
	SC	U	SC	U	SC	U
Single	1.00	5.91	0.50	4.60	0.38	4.60
Double	0.88	3.46	0.45	3.12	0.36	3.12
Heat-absorbing	0.58	2.56	0.37	2.50	0.33	2.50
Triple	0.80	2.50	0.44	2.27	0.36	2.27

Note: U is in W/(m<sup>2</sup>·K).

**Table 6 Shade Line Factors (SLFs)**

Direction Window Faces	Latitude, Degrees N						
	24	32	36	40	44	48	52
East	0.8	0.8	0.8	0.8	0.8	0.8	0.8
SE	1.8	1.6	1.4	1.3	1.1	1.0	0.9
South	9.2	5.0	3.4	2.6	2.1	1.8	1.5
SW	1.8	1.6	1.4	1.3	1.1	1.0	0.9
West	0.8	0.8	0.8	0.8	0.8	0.8	0.8

Note: Shadow length below the overhang equals the shade line factor times the overhang width. Values are averages for the 5 h of greatest solar intensity on August 1.

**Household Appliances**

Appliance loads are concentrated mainly in the kitchen and laundry areas. Based on contemporary living conditions in single-family houses, a sensible load of 470 W should be divided between the kitchen and/or laundry and the adjoining room or rooms. A sensible utility load of 470 W may be added if the laundry room contains continuously operating appliances such as refrigerators and/or freezers. For multifamily units, the sensible heat gain values should be about 350 W. These values assume that the cooking range and clothes dryer are vented. Further allowances should be considered when unusual lighting intensities, computers, or other equipment is present.

**Air Distribution System—Heat Loss/Gain**

Whenever the air distribution system is outside the conditioned space (i.e., in attics, crawl spaces, or other unconditioned spaces) heat loss or gains to the ducts or pipes must be included in the calculated load and should be considered in equipment selection.

**Latent Heat Sources**

The latent cooling load has three main sources: outdoor air, occupants, and miscellaneous sources, such as cooking, laundry, and

**Table 7 Winter Air Exchange Rates (ACH) as Function of Airtightness**

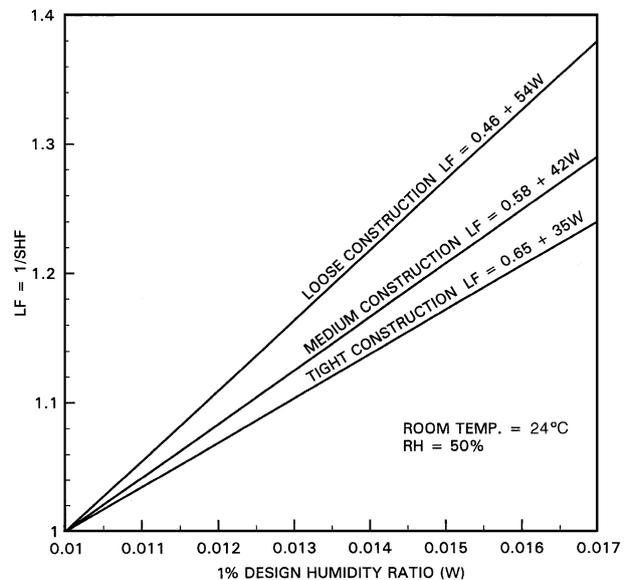

Class	Outdoor Design Temperature, °C									
	10	4	-1	-7	-12	-18	-23	-29	-34	-40
Tight	0.41	0.43	0.45	0.47	0.49	0.51	0.53	0.55	0.57	0.59

**Fig. 1 Effect of Infiltration on Latent Load Factor**

bathing. The miscellaneous latent loads are largely covered by outdoor air because most residences have exhaust fans and clothes dryers that vent most of the moisture from these sources. This vent air is accounted for in the infiltration calculation. McQuiston (1984) estimated latent load factors for typical houses located in geographic regions ranging from very dry to very wet using the transfer function method (Figure 1). A **latent factor** LF ( $LF = 1/SHF$ ) of 1.3 or a **sensible heat factor** SHF ( $SHF = \text{sensible load/total load}$ ) of 0.77 matches the performance of typical residential vapor compression cooling systems. Homes in almost all other regions of North America have cooling loads with an SHF greater than 0.77 and latent factors less than 1.3. Figure 1 may be used to estimate the total cooling load by reading LF as a function of the design humidity ratio and airtightness. Then  $q_{total} = (LF)q_{sensible}$ . If the humidity ratio is less than 0.01, set  $LF = 1.0$ .

**LOAD CALCULATION**

The cooling load calculation procedures are summarized in Table 9.

**Example 1.** A single-family detached house (Figure 2) is located in the south central United States at 36°N latitude.

*Roof construction.* Conventional roof-attic-ceiling combination, vented to remove moisture with 150 mm of fibrous batt insulation and vapor retarder [ $U = 0.28 \text{ W}/(\text{m}^2 \cdot \text{K})$ ].

*Wall construction.* Frame with 100 mm face brick, 90 mm fibrous batt insulation, 19 mm polystyrene sheathing, and 13 mm gypsum wall-board [ $U = 0.34 \text{ W}/(\text{m}^2 \cdot \text{K})$ ]. Ceiling height is 2.4 m throughout.

*Floor construction.* 100 mm concrete slab on grade.

*Fenestration.* Clear double glass, 3 mm thick, in and out. Assume closed, medium-color venetian blinds. The window glass has a 600 mm overhang at the top.

*Doors.* Solid core flush with all-glass storm doors [ $U = 1.82 \text{ W}/(\text{m}^2 \cdot \text{K})$ ].

*Outdoor design conditions.* Temperature of 36°C dry bulb with a 13 K daily range and a humidity ratio of 0.0136 kg vapor/kg dry air (23.7°C wet bulb).

*U-factors* for all external surfaces are based on a 3.4 m/s (12 km/h) wind velocity.

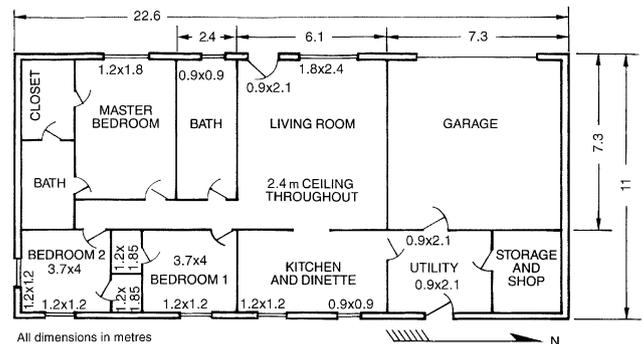

*Indoor design conditions.* Temperature of 24°C dry bulb and 50% rh.

*Occupancy.* Four persons, based on two for the master bedroom and one for each additional bedroom. Assign to the living room.

*Appliances and lights.* Assume 470 W for the kitchen, and assign 50% to the living room. Assume 470 W for the utility room, and assign 25% to the kitchen and 25% to the storage room.

The conditioning equipment is located in the garage, and the construction of the house is considered medium.

Find the sensible, latent, and total cooling load; size the cooling unit; and compute the air quantity for each room.

**Fig. 2 Floor Plan of Single-Family Detached House**

**Table 9 Summary of Procedures for Residential Cooling Load Calculations**

Load Source	Equation	Tables and Notes
Glass and window areas	$q = (GLF)A$	Glass load factors may be found in Tables 3 and 4 according to window orientation, type of glass, type of interior shading, and outdoor design temperature. The GLF includes effects of both transmission and solar radiation. Glass shaded by overhangs is treated as north glass. Table 6 gives shade line factors.
Doors	$q = U_d A (CLTD)$	Door CLTD values are in Tables 1 and 2 according to orientation, outdoor design temperature, and design daily temperature range.
Above-grade exterior walls	$q = U_w A (CLTD)$	Wall CLTD values are in Tables 1 and 2 based on the outdoor design temperature, daily range, and orientation.
Partitions to unconditioned space	$q = U_p A \Delta t$	Where $\Delta t$ is the temperature difference across the partition.
Ceilings and roofs	$q = U_r A (CLTD)$	Tables 1 and 2 for CLTD, based on outdoor design temperature and daily range.
Exposed floors	$q = U_f A (CLTD)$	Tables 1 and 2 for CLTD, based on outdoor design temperature and daily range.
Infiltration	$q = 1.2 Q \Delta t$ $Q = ACH \times (\text{room volume}) \times 1000/3600$	Air exchange rates are given in Tables 7 and 8.
Internal loads— People, appliances, lights	Plan 67 W per person.	Divide occupants evenly among rooms not used as bedrooms. If number of occupants is not known, assume two people for first bedroom and one person for each additional bedroom.  The appliance and light load of 470 W is divided between the kitchen and adjoining room and the laundry and adjoining room. Use 350 W for multifamily units.
Total loads	Total cooling load = $LF \times$ (Sum of individual sensible cooling load components)	Load factors are from Figure 1 according to outdoor design humidity ratio and airtightness classification.

$q$  = sensible cooling load, W  
 $\Delta t$  = design temperature difference between outside and inside air, K  
 $A$  = area of applicable surface,  $\text{m}^2$   
 $U$  = U-factors for appropriate construction,  $\text{W}/(\text{m}^2 \cdot \text{K})$

$Q$  = volumetric airflow rate, L/s  
 ACH = air changes per hour, 1/h  
 GLF = glass load factor,  $\text{W}/\text{m}^2$   
 CLTD = cooling load temperature difference, K  
 LF = latent load multiplier

**Solution:** The cooling load must be made on a room-by-room basis to determine the proper distribution of air. The calculations follow the procedure outlined in the section on Load Components.

*Walls, roof, windows, and doors.* The calculations for the living room and the kitchen, where  $q = UA(CLTD)$  for the walls, roof, and door and  $q = A(GLF)$  for the windows, are outlined in Table 10. The glass shaded by the overhang is treated as north-facing glass, with the shaded area computed using Table 6.

*Internal and infiltration sensible cooling loads.* Compute as follows.

*For the living room:*

Infiltration. Using Table 8,

$$Q = ACH (\text{room volume}) \times 1000/3600$$

$$Q = 0.5 \times 106.9 \times 1000/3600 = 14.85 \text{ L/s}$$

$$q = 1.2Q(t_o - t_i)$$

$$q = 1.2 \times 14.85(36 - 24) = 214 \text{ W}$$

Occupants. Assuming 67 W per person,

$$q = 67 \times (\text{persons})$$

$$q = 67 \times 4 = 268 \text{ W}$$

Appliances. Assuming that 50% of the kitchen appliance load is picked up in the living room,

$$q = 0.5 \times (\text{kitchen appliance load})$$

$$q = 0.5 \times 470 = 235 \text{ W}$$

*For the kitchen:*

Infiltration.

$$Q = 0.5 \times 54.2 \times 1000/3600 = 7.5 \text{ L/s}$$

$$q = 1.2 \times 7.5(36 - 24) = 108 \text{ W}$$

No occupants.

$$q = 0$$

Appliances. Assuming 25% of the utility appliance load is picked up in the kitchen,

$$q = (470/2) + (470/4) = 352.5 \text{ W}$$

Duct loss (10%)								0.58	
Outdoor ventilation air								0.47	
									Total 6.80 kW

For the total sensible cooling load for these two rooms and the cooling load for the remaining rooms, see Table 11. At this point, the sensible cooling load for the house is 5.75 kW. Depending on the design of the air distribution system, heat losses from the supply and return ducts may add to the cooling load. These may be more accurately estimated after designing the system; however, to size the cooling unit, duct losses should be included initially. If all ducts are in the attic space, a duct loss of 10% of the space sensible cooling load is reasonable. For a counterflow system, with ducts below the slab, a 5% loss is more reasonable.

An infiltration rate of 0.5 ACH may not be adequate for good indoor air quality, so some outdoor air should be introduced. This additional cooling load may be estimated in the same way as the infiltration load.

Assume that the entire duct system is in the attic; that is, the total sensible cooling load with a 10% duct loss is  $1.1 \times 5.75 = 6.33$  kW. Also, assume that additional outdoor air is needed to assure good indoor air quality, so the total infiltration and outdoor ventilation air is 0.75 ACH. This increases the infiltration rate by 50%, or about 0.47 kW. The total sensible cooling load is then increased to 6.80 kW (Table 11).

The total cooling load (sensible plus latent) may be estimated by applying the latent factor (LF) from Figure 1. For a design humidity ratio of 0.0136 kg vapor per kg dry air, LF = 1.15 for a house of medium construction. Hence, the total cooling load equals  $1.15 \times 6.80 = 7.82$  kW.

The load raises the temperature of the cooling air 9 to 12 K as it leaves the rooms. The total design flow from the air conditioner can be estimated by the following equation:

$$Q_{tot} = \frac{1000q}{1.2\Delta t} \tag{1}$$

where

$Q_{tot}$  = total airflow, L/s

$q$  = total sensible load, W

1.2 = density times specific heat of cooling air

$\Delta t$  = temperature difference of air entering and leaving room, K

For a temperature difference of 10 K, the total airflow is estimated from Equation (1) as

$$Q_{tot} = \frac{1000 \times 5.75}{1.2 \times 10} = 479 \text{ L/s}$$

The exact design flow can be determined only after the cooling unit has been selected. Then, the supply air quantities can be computed. Air should be supplied to each room on the basis of the room sensible cooling load:

$$Q_{rm} = Q_{tot}(q_{rm}/q)$$

where

$Q_{rm}$  = airflow to each room, L/s

$q_{rm}$  = room sensible cooling load, W

Thus, for the example,

$$Q_{rm} = (479/5.75)q_{rm}$$

If the living space in Example 1 were a multifamily unit (assume that the north, south, and east walls are not exposed surfaces), the calculation procedure would be the same, except that Table 2 would have been used for the CLTDs and Table 4 for the GLFs. Assumptions regarding infiltration, ventilation, and appliance loads are different for smaller multifamily units.

## HEATING LOAD

Calculating a residential heating load involves estimating the maximum (block) heat loss of each room or space to be heated and the simultaneous maximum (block) heat loss for the building, while maintaining a selected indoor air temperature during periods of design outdoor weather conditions. Heat losses are mainly

- Transmission losses or heat transferred through the confining walls, glass, ceiling, floor, or other surfaces
- Infiltration losses or energy required to warm outdoor air leaking in through cracks and crevices around doors and windows,

through open doors and windows, and through porous building materials

**GENERAL PROCEDURE**

To calculate a design heating load, prepare the following information about building design and weather data at design conditions.

1. Select outdoor design weather conditions: temperature, wind direction, and wind speed. Winter climatic data can be found in Chapter 27, or selected weather conditions and temperatures appropriate for the application may be used. Weather station data may differ significantly from values in Chapter 27.
2. Select the indoor air temperature to be maintained in each space during design weather conditions.
3. Temperatures in adjacent unheated spaces, attached garages, and attics can be estimated at the outdoor ambient temperature.
4. Select or compute heat transfer coefficients for outside walls and glass; for inside walls, nonbasement floors, and ceilings if these are next to unheated spaces; and for the roof if it is next to heated spaces.
5. Determine the net area of outside wall, glass, and roof next to heated spaces, as well as any cold walls, floors, or ceilings next to unheated spaces. These determinations can be made from building plans or from the actual building, using inside dimensions.
6. Compute transmission heat losses for each kind of wall, glass, floor, ceiling, and roof in the building by multiplying the heat transfer coefficient in each case by the area of the surface and the temperature difference between indoor air and outdoor air or adjacent lower temperature spaces.
7. Compute heat losses from basement or grade-level slab floors using the methods in this chapter.
8. Select unit values, and compute the energy associated with infiltration of cold air around outside doors, windows, porous building materials, and other openings. These unit values depend on the kind or width of crack, wind speed, and the temperature difference between indoor and outdoor air. An alternative method is to use air changes (see Chapter 26).
9. When positive ventilation using outdoor air is provided by an air-heating or air-conditioning unit, the energy required to warm the outdoor air to the space temperature must be provided by the unit. The principle for calculation of this load component is identical to that for infiltration. If mechanical exhaust from the space is provided in an amount equal to the outdoor air drawn in by the unit, the unit must also provide for natural infiltration losses. If no mechanical exhaust is used and the outdoor air supply equals or exceeds the amount of natural infiltration that can occur without ventilation, some reduction in infiltration may occur.
10. The sum of the coincidental transmission losses or heat transmitted through the confining walls, floor, ceiling, glass, and other surfaces, plus the energy associated with cold air entering by infiltration or the ventilation air required to replace mechanical exhaust, represents the total heating load.
11. Include the pickup loads that may be required in intermittently heated buildings using night thermostat setback. Pickup loads frequently require an increase in heating equipment capacity to bring the temperature of structure, air, and material contents to the specified temperature. See Figure 9.
12. Use materials and data in Chapters 25, 26, 27, and others as appropriate to the calculations. See Table 12.

**SELECTING HEATING DESIGN CONDITIONS**

The ideal solution to a basic heating system design is a plant with a maximum output capacity equal to the heating load that develops with the most severe local weather conditions. However,

**Table 12 Summary of Loads, Equations, and References for Calculating Design Heating Loads**

Heating Load	Equation	Reference, Table, Description
Roofs, ceilings, walls, glass	$q = U A \Delta t$	Chapter 24, Tables 1, 2, and 4 Temperature difference between inside and outside design dry bulbs, Chapter 26. For temperatures in unheated spaces, see Equation (2); for attic temperatures, see Equation (3). Area calculated from plans
Walls below grade	$q = U A \Delta t$	See Table 14. Use Figure 6 to assist in determining $\Delta t$ .
Floors Above grade	$q = U A \Delta t$	For crawl space temperatures, see Equation (4).
On grade	$q = F_2 P \Delta t$	See Table 16. See Equation (6). Perimeter of slab
Below grade	$q = U A \Delta t$	Use Figure 6 to assist in determining $\Delta t$ . See Table 15.
Infiltration and ventilation air Sensible	$q_s = 0.018 Q \Delta t$	Volume of outdoor air entering building. See Chapter 25 for estimating methods for infiltration.
Latent	$q_t = 80.7 Q \Delta W$	Humidity ratio difference, if humidification is to be added

this solution is usually uneconomical. Weather records show that severe weather conditions do not repeat annually. If heating systems were designed for maximum weather conditions, excess capacity would exist during most of the system’s operating life. In many cases, an occasional failure of a heating plant to maintain a preselected indoor design temperature during brief periods of severe weather is not critical.

**Outdoor Design Temperature**

Before selecting an outdoor design temperature from Chapter 27, the designer should consider the following for residential buildings:

- Is the structure heavy, medium, or light?
- Is the structure insulated?
- Is the structure exposed to high wind?
- Is the load from infiltration or ventilation high?
- Is there more glass area than normal?
- During what part of the day will the structure be used?
- What is the nature of occupancy?
- Will there be long periods of operation at reduced indoor temperature?
- What is the amplitude between local maximum and minimum daily temperatures?
- Are there local conditions that cause significant variation from temperatures reported by the weather service?
- What auxiliary heating devices will be in the building?

Before selecting an outdoor design temperature, the designer must keep in mind that, if the outdoor to indoor design temperature difference is exceeded, the indoor temperature may fall, depending on (1) the thermal mass of the structure and its contents, (2) whether the internal load was included in calculations, (3) the duration of the cold period, and (4) internal heat generated by appliances, etc.

The effect of wind on the heating requirements of any building should be considered because

- Wind movement increases the heat transmission of walls, glass, and roof, affecting poorly insulated walls to a much greater extent than well-insulated walls.
- Wind materially increases the infiltration of cold air through cracks around doors and windows and even through building materials themselves (see Chapter 26).

Theoretically, on a design basis, the most unfavorable combination of temperature and wind speed should be chosen. A building may require more heat on a windy day with a moderately low outdoor temperature than on a quiet day with a much lower outdoor temperature. The worst combination of wind and temperature varies by building because wind speed has a greater effect on buildings with relatively high infiltration rates. The building heating load may be calculated for several combinations of temperature and wind speed on record, and the worst combination may be selected; however, except for critical applications, designers generally find such a degree of refinement unnecessary. No correlation has been shown between the design temperatures in Chapter 27 and the simultaneous maximum wind speed. If a designer prefers the air change method for computing infiltration rates, such correlation is not important. Designers who use the crack method can use a leakage rate at a wind speed of 6.7 m/s (24 km/h), unless local experience has established that another speed is more appropriate. Abnormally high wind speeds may have an effect on infiltration and the U-factor of the building components (see Chapter 23).

### Indoor Design Temperature

The indoor temperature for comfort heating may vary depending on building use, type of occupancy, or code requirements. Chapter 8 and ASHRAE *Standards* 55 and 55a define the relationship between temperature and comfort.

### ESTIMATING TEMPERATURES IN ADJACENT UNHEATED SPACES

Heat loss from heated rooms to unheated rooms or spaces must be based on the estimated or assumed temperature in such unheated spaces. This temperature will be in between the indoor and outdoor temperatures. If the surface area adjacent to the heated room and that exposed to the outdoors are equal and if the heat transfer coefficients are equal, the temperature in the unheated space may be assumed equal to the mean of the indoor and outdoor design temperatures. If, however, the surface areas and coefficients are unequal, the temperature in the unheated space should be estimated by

$$t_u = [t_i(A_1U_1 + A_2U_2 + A_3U_3 + \text{etc.}) + t_o(\rho c_p Q_o + A_a U_a + A_b U_b + A_c U_c + \text{etc.})] \div (A_1U_1 + A_2U_2 + A_3U_3 + \text{etc.}) + \rho c_p Q_o + A_a U_a + A_b U_b + A_c U_c + \text{etc.} \quad (2)$$

where

- $\rho c_p$  = density times specific heat of air = 1.2 kJ/(m<sup>3</sup>·K) for standard air
- $t_u$  = temperature in unheated space, °C
- $t_i$  = indoor design temperature of heated room, °C
- $t_o$  = outdoor design temperature, °C
- $A_1, A_2, A_3, \text{etc.}$  = areas of surfaces of unheated space adjacent to heated spaces, m<sup>2</sup>
- $A_a, A_b, A_c, \text{etc.}$  = areas of surfaces of unheated space exposed to outdoors, m<sup>2</sup>
- $U_1, U_2, U_3, \text{etc.}$  = heat transfer coefficients of surfaces of  $A_1, A_2, A_3, \text{etc.}$ , W/(m<sup>2</sup>·K)
- $U_a, U_b, U_c, \text{etc.}$  = heat transfer coefficients of surfaces of  $A_a, A_b, A_c, \text{etc.}$ , W/(m<sup>2</sup>·K)
- $Q_o$  = rate of introduction of outside air into unheated space by infiltration and/or ventilation, L/s

**Example 2.** Calculate the temperature in an unheated space adjacent to a heated room with surface areas ( $A_1, A_2,$  and  $A_3$ ) of 9, 11, and 13 m<sup>2</sup> and overall heat transfer coefficients ( $U_1, U_2,$  and  $U_3$ ) of 0.8, 1.1, and 1.4 W/(m<sup>2</sup>·K), respectively. The surface areas of the unheated space exposed to the outdoors ( $A_a$  and  $A_b$ ) are 9 and 13 m<sup>2</sup>, respectively, and the corresponding overall heat transfer coefficients are 0.6 and 1.7 W/(m<sup>2</sup>·K). The sixth surface is on the ground and can be neglected for this example, as can the effect of introduction of outdoor air into the unheated space. Assume  $t_i = 21^\circ\text{C}$  and  $t_o = -23^\circ\text{C}$ .

**Solution:** Substituting into Equation (2),

$$t_u = [21(9 \times 0.8 + 11 \times 1.1 + 13 \times 1.4) + (-23)(9 \times 0.6 + 13 \times 1.7)] \div (9 \times 0.8 + 11 \times 1.1 + 13 \times 1.4) + 9 \times 0.6 + 13 \times 1.7$$

$$t_u = 155/65 = 2.4^\circ\text{C}$$

Temperatures in unheated spaces with large glass areas and two or more surfaces exposed to the outdoors (e.g., sleeping porches and sun parlors) are generally assumed to be the same as that of the outdoors.

### Attic Temperature

An attic is a space having an average distance of 0.3 m or more between a ceiling and the underside of the roof. Estimating attic temperature is a special case of estimating temperature in an adjacent unheated space and can be done using

$$t_a = \frac{A_c U_c t_c + t_o(\rho c_p A_c V_c + A_r U_r + A_w U_w + A_g U_g)}{A_c(U_c + \rho c_p V_c) + A_r U_r + A_w U_w + A_g U_g} \quad (3)$$

where

- $\rho c_p$  = air density times specific heat = 1.20 kJ/(m<sup>3</sup>·K) for standard air
- $t_a$  = attic temperature, °C
- $t_c$  = indoor temperature near top floor ceiling, °C
- $t_o$  = outdoor temperature, °C
- $A_c$  = area of ceiling, m<sup>2</sup>
- $A_r$  = area of roof, m<sup>2</sup>
- $A_w$  = area of net vertical attic wall surface, m<sup>2</sup>
- $A_g$  = area of attic glass, m<sup>2</sup>
- $U_c$  = heat transfer coefficient of ceiling, W/(m<sup>2</sup>·K), based on surface conductance of 12.5 W/(m<sup>2</sup>·K) (upper surface, see Table 2 in Chapter 25); 12.5 = reciprocal of one-half the air space resistance
- $U_r$  = heat transfer coefficient of roof, W/(m<sup>2</sup>·K), based on surface conductance of 12.5 W/(m<sup>2</sup>·K) (upper surface, see Table 2 in Chapter 25); 12.5 = reciprocal of one-half the air space resistance
- $U_w$  = heat transfer coefficient of vertical wall surface, W/(m<sup>2</sup>·K)
- $U_g$  = heat transfer coefficient of glass, W/(m<sup>2</sup>·K)
- $V_c$  = rate of introduction of outside air into the attic space by ventilation per square metre of ceiling area, L/(s·m<sup>2</sup>)

**Example 3.** Calculate the temperature in an unheated attic assuming  $t_c = 21^\circ\text{C}$ ;  $t_o = -12^\circ\text{C}$ ;  $A_c = 100 \text{ m}^2$ ;  $A_r = 120 \text{ m}^2$ ;  $A_w = 10 \text{ m}^2$ ;  $A_g = 1.0 \text{ m}^2$ ;  $U_r = 2.8 \text{ W}/(\text{m}^2 \cdot \text{K})$ ;  $U_c = 2.3 \text{ W}/(\text{m}^2 \cdot \text{K})$ ;  $U_w = 1.7 \text{ W}/(\text{m}^2 \cdot \text{K})$ ;  $U_g = 6.4 \text{ W}/(\text{m}^2 \cdot \text{K})$ ; and  $V_c = 2.5 \text{ L}/(\text{s} \cdot \text{m}^2)$ .

**Solution:** Substituting these values into Equation (3),

$$t_a = [(100 \times 2.3 \times 20) + (-12)(1.2 \times 100 \times 2.5 + 120 \times 2.8 + 10 \times 1.7 + 1.0 \times 6.4)] \div [100(2.3 + 1.2 \times 2.5) + 120 \times 2.8 + 10 \times 1.7 + 1.0 \times 6.4]$$

$$t_a = -3313/889 = -3.7^\circ\text{C}$$

Equation (3) includes the effect of air interchange that would take place through attic vents or louvers intended to preclude attic condensation. Test data from Joy et al. (1956), Joy (1958), and Rowley et al. (1940) indicate that a reduction in the temperature

difference between attic air and outside air is linear as attic ventilation rates increase from 0 to 2.5 L/(s·m<sup>2</sup>) of the ceiling area. When attic ventilation meets the requirements in Chapter 24, 2.5 L/(s·m<sup>2</sup>) is the approximate ventilation rate for design conditions. This reduction in temperature difference affects the overall heat loss of a residence with an insulated ceiling by only 1 or 2%.

Equation (3) does not consider factors such as heat exchange between chimney and attic or solar radiation to and from the roof. Because of these effects, attic temperatures are frequently higher than values calculated using Equation (3). However, Equation (3) can be used to calculate attic temperature because the resulting error is generally less than that introduced by neglecting the roof and assuming that the attic temperature is equal to the outdoor air temperature.

When relatively large louvers are installed (customary in southern regions of the United States), the attic temperature is often assumed to be the average of the indoor and outdoor air temperatures.

For an approximate method of calculating heat losses through attics, the combined ceiling and roof coefficient may be used (see Table 5 in Chapter 25).

### CALCULATING HEAT LOSS FROM CRAWL SPACES

A crawl space can be considered a half basement. To prevent ground moisture from evaporating and causing a condensation problem, sheets of vapor retarder (e.g., polyethylene film) are used to cover the ground surface (see Chapter 24). Most codes require crawl spaces to be adequately vented all year round. However, venting the crawl space in the heating season causes substantial heat loss through the floor.

The space may be insulated in several ways: the crawl space ceiling (floor above the crawl space) can be insulated, or the perimeter wall can be insulated either on the outside or on the inside. If the floor above is insulated, the crawl space vents should be kept open because the temperature of the crawl space is likely to be below the dew point of the indoor space. If the perimeter wall is insulated, the vents should be kept closed in the heating season and open the remainder of the year.

#### Crawl Space Temperature

The crawl space temperature depends on such factors as venting, heating ducts, and the heating plant. When the crawl space is well ventilated, its temperature is close to that of the ambient air temperature. When the crawl space vent is closed for the heating season, or if the space is used as a plenum (i.e., part of the forced-air heating system), the crawl space temperature approaches that of the indoor conditioned space. In the former case, the floor above the crawl space, the heating ductwork, and the utility pipes should be insulated similarly to the walls and ceiling of a house.

The following steady-state equation can be used to estimate the temperature of a crawl space.

$$q_f = q_p + q_g + q_a$$

where

- $q_f$  = heat loss through floor into crawl space, W
- $q_p$  = heat loss from crawl space through foundation walls and sill box, W
- $q_g$  = heat loss into ground, W
- $q_a$  = heat loss due to ventilation of crawl space, W

Latta and Boileau (1969) estimated the air exchange rate for an uninsulated basement at 0.67 ACH under winter conditions. In more detail, the above equation can be repeated as

$$U_f A_f (t_i - t_c) = U_p A_p (t_c - t_o) + U_g A_g (t_c - t_g) + 0.67 \rho c_p V_c (t_c - t_o) / 3.6 \quad (4)$$

where

- $t_i$  = indoor air temperature (i.e., air above ceiling of crawl space), °C
- $t_o$  = outdoor air temperature, °C
- $t_g$  = ground temperature (constant), °C
- $t_c$  = crawl space temperature, °C
- $A_f$  = area of floor above, m<sup>2</sup>
- $A_p$  = area of perimeter, exposed foundation wall plus sill box, m<sup>2</sup>
- $A_g$  = area of ground below ( $A_f = A_g$ ), m<sup>2</sup>
- $U_f$  = average heat transfer coefficient through floor, W/(m<sup>2</sup>·K)
- $U_g$  = average heat transfer coefficient through ground (horizontal air film and 3 m of soil), W/(m<sup>2</sup>·K)
- $U_p$  = combined heat transfer coefficient of sill box and foundation wall (both above and below grade), W/(m<sup>2</sup>·K)
- $V_c$  = volume of crawl space, m<sup>3</sup>
- $\rho c_p$  = volumetric heat capacity of air = 1.2 kJ/(m<sup>3</sup>·K)
- 0.67 = assumed air exchange rate, volumes/hour

**Example 4.** A crawl space of 120 m<sup>2</sup> with a 44 m perimeter is considered. The construction of the perimeter wall is shown in Figure 3. The indoor, outdoor, and the deep-down ground temperatures are 20, -12, and 10°C, respectively. Estimate the heat loss and crawl space temperature with and without insulation. The heat transmission coefficient (U-factor) for each component is indicated in Table 13.

**Solution:** Three cases are examined.

*Case A.* This base case is a vented and uninsulated crawl space. The crawl space temperature approaches that of the outdoors, -12°C, and the heat loss is  $1.42 \times 120[20 - (-12)] = 5450$  W.

*Case B.* The crawl space is vented. The floor above is insulated with an  $R = 1.94$  K·m<sup>2</sup>/W blanket; no insulation on the perimeter. The temperature of the crawl space approaches that of the outdoors, -12°C. The heat loss is calculated as

$$q_f = 120 \times 0.432[20 - (-12)] = 1660$$

*Case C.* The crawl space is not vented during the heating season. The floor above is not insulated, but the perimeter wall is insulated with  $R = 0.95$  K·m<sup>2</sup>/W down to 900 mm below grade.

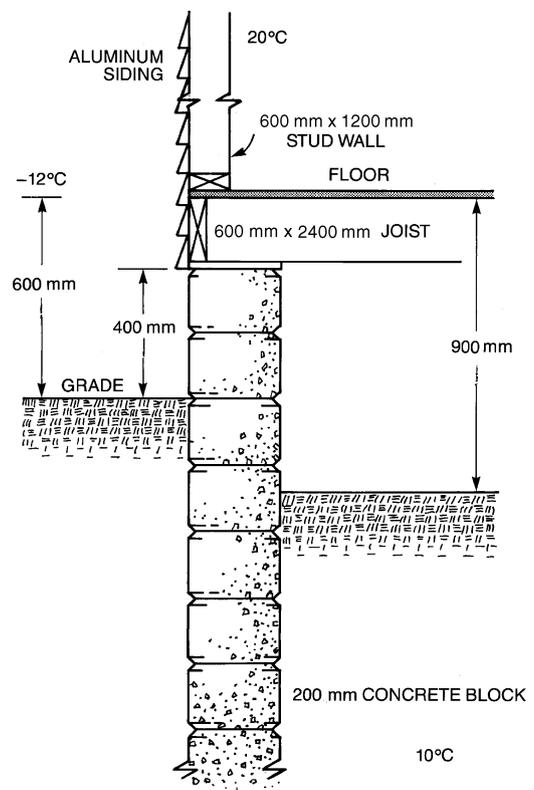

Fig. 3 Uninsulated Crawl Space

**Table 13 Estimated U-Factors for Insulated and Uninsulated Crawl Spaces**

Component	Uninsulated	Insulated <sup>a</sup>
	W/K per metre of Perimeter	W/K per metre of Perimeter
400 mm exposed concrete blocks	1.22	0.316
190 mm sill box	0.324	0.123
1st 300 mm block wall below grade	0.614	0.22
2nd 300 mm block wall below grade	0.381	0.242
3rd 300 mm block wall below grade	0.23	0.173
Total for perimeter wall	2.77	1.07
	W/(m <sup>2</sup> ·K)	W/(m <sup>2</sup> ·K)
Ground	0.437	0.437
Floor above crawl space	1.42	0.432 <sup>a</sup>

<sup>a</sup>Perimeter walls are insulated with R = 0.95 K·m<sup>2</sup>/W; the floor is insulated with R = 1.94 K·m<sup>2</sup>/W blanket or batts.

$$q_f = 120 \times 1.42(20 - t_c)$$

$$q_p = 44 \times 1.07[t_c - (-12)]$$

$$q_g = 120 \times 0.437(t_c - 10)$$

$$q_a = 120 \times 0.9 \times 1.2 \times 0.67[t_c - (-12)]/3.6$$

The crawl space temperature is solved using Equation (4):  $t_c = 10.5^\circ\text{C}$ . The heat loss is 1620 W.

The results show that base case A can potentially lose the most heat. However, when the floor above is insulated, the crawl space must be vented to eliminate any condensation potential, and the heating ductwork and utility pipeline in the crawl space must be adequately insulated. When the perimeter is insulated, the vents must be closed during the heating season and opened for the rest of the year; the heating ductwork and utility pipeline do not need insulation.

Case	Venting	Insulation	Heat Loss Through Floor Above, W	Temperature of Crawl Space, °C
A	Yes	None	5450	-12
B	Yes	R = 1.94 K·m <sup>2</sup> /W on floor above	1660	-12
C	No	R = 0.95 K·m <sup>2</sup> /W on perimeter wall	1620	10.5

**CALCULATING TRANSMISSION HEAT LOSS**

Steady-state heat loss by conduction and convection heat transfer through any surface is

$$q = UA(t_i - t_o) \tag{5}$$

where

- $q$  = heat transfer through wall, glass, roof, ceiling, floor, or other exposed surface, W
- $A$  = area of surface, m<sup>2</sup>
- $U$  = air-to-air heat transfer coefficient, W/(m<sup>2</sup>·K)
- $t_i$  = indoor air temperature near surface involved, °C
- $t_o$  = outdoor air temperature or temperature of adjacent unheated space, °C

**Example 5.** Calculate the transmission loss through a 200 mm brick wall having an area of 14 m<sup>2</sup>, if the indoor temperature  $t_i$  is 21 °C, and the outdoor temperature  $t_o$  is -23 °C.

**Solution:** The overall heat transfer coefficient  $U$  of a plain 200 mm brick wall is 2.33 W/(m<sup>2</sup>·K). Substituting into Equation (5),

$$q = 14 \times 2.33[21 - (-23)] = 1435 \text{ W}$$

**Through Ceiling and Roof**

Transmission heat loss through top floor ceilings, attics, and roofs may be estimated by either of two methods:

1. Substitute in Equation (5) the ceiling area  $A$ , the indoor/outdoor temperature difference ( $t_i - t_o$ ), and the proper U-factor:

*Flat roofs.* Use appropriate coefficients in Equation (3) if side walls extend appreciably above the ceiling or the floor below.

*Pitched roofs.* Calculate the combined roof and ceiling coefficient as outlined in Chapter 25.

2. For *pitched roofs*, estimate the attic temperature (based on the indoor and outdoor design temperatures) using Equation (3), and substitute for  $t_o$  in Equation (5), obtaining the value of  $t_a$ , together with the ceiling area  $A$  and the ceiling U-factor. Attic temperatures do not need to be calculated for *flat roofs*, as the ceiling-roof heat loss can be determined as suggested in Method 1 above.

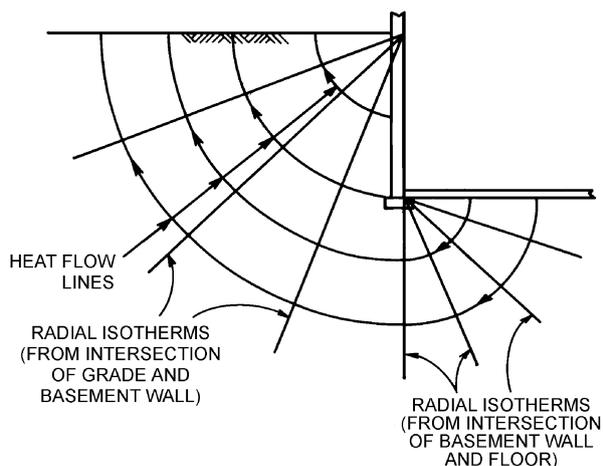

**From the Basement**

The basement interior is considered conditioned space if a minimum temperature of 5.5 K below indoor design air temperature is maintained over the heating season. In many instances, the house heating plant, water heater, and heating ducts are in the basement, so it remains at or above 10 °C.

Heat transmission from the below-grade portion of the basement wall to the ambient air cannot be estimated by simple, one-dimensional heat conduction. In fact, field measurement of an uninsulated basement by Latta and Boileau (1969) showed that the isotherms near the wall are not parallel lines but closer to radial lines centered at the intersection of the grade line and the wall. Therefore, heat flow paths approximately follow a concentric circular pattern (Figure 4).

Such heat flow paths are altered when insulation is added to the wall or floor. An extreme case would be no heat loss from the basement wall and floor (i.e., infinite insulation applied to the wall and floor). In this case, the isotherms would be horizontal lines parallel to the grade line, and the heat flow would be vertical. When finite insulation or partial insulation is applied to the wall and floor, the heat flow paths take shapes somewhere between the circular and vertical lines (Figure 5).

**Ground Temperature.** Ground temperatures assumed for estimating basement heat losses will differ for basement floors and walls. The temperatures under floors are generally higher than those adjacent to walls. This is discussed further in the section on Basement Design Temperatures.

**Fig. 4 Heat Flow from Basement**

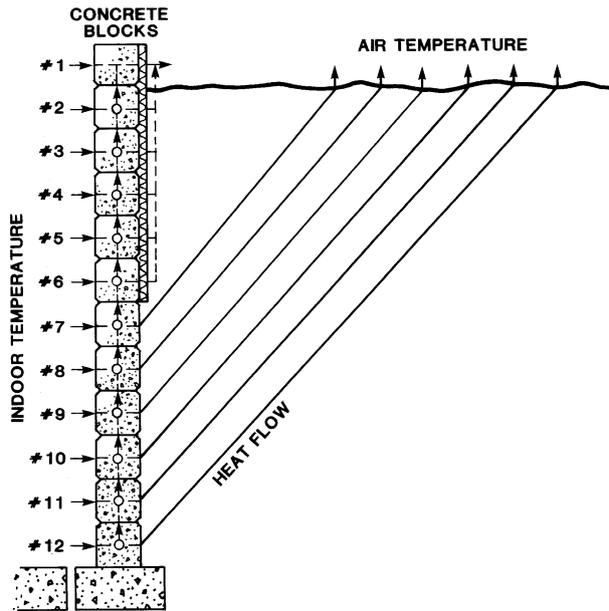

Fig. 5 Heat Flow Path for Partially Insulated Basement Wall

Through Basement Walls

Houghten et al. (1942) observed nonuniform heat flux across the basement wall with respect to the depth of the wall because each heat flow path contains a different thermal resistance. For a basement wall that has its top portion exposed to ambient air, heat may be conducted vertically through the concrete wall and dissipated to the ambient from the top portion of the wall (Wang 1979, Bligh et al. 1978). Under certain conditions, this vertical heat flux becomes significant and should not be ignored.

Once the heat paths are known or assumed, a steady-state analysis can calculate the overall heat transmission coefficient for each segment of the basement wall. Referring to Figures 4 and 5, the total

Table 14 Heat Loss Below Grade in Basement Walls

Depth, m	Path Length Through Soil, m	Heat Loss Coefficient, W/(m <sup>2</sup> ·K) <sup>a</sup>							
		Un-insulated		R = 0.73 m <sup>2</sup> ·K/W		R = 1.47 m <sup>2</sup> ·K/W		R = 2.20 m <sup>2</sup> ·K/W	
0 to 0.3	0.2	2.33	Σ <sup>b</sup>	0.86	3.53	0.53	Σ <sup>b</sup>	0.38	Σ <sup>b</sup>
0.3 to 0.6	0.69	1.26	3.59	0.66	1.52	0.45	0.98	0.36	0.74
0.6 to 0.9	1.18	0.88	4.47	0.53	2.05	0.38	1.36	0.30	1.04
0.9 to 1.2	1.68	0.67	5.14	0.45	2.50	0.34	1.70	0.27	1.31
1.2 to 1.5	2.15	0.54	5.68	0.39	2.89	0.30	2.00	0.25	1.56
1.5 to 1.8	2.64	0.45	6.13	0.34	3.23	0.27	2.27	0.23	1.79
1.8 to 2.1	3.13	0.39	6.52	0.30	3.53	0.25	2.52	0.21	2.00

Source: Latta and Boileau (1969).

<sup>a</sup>Soil conductivity was assumed to be 1.38 W/(m·K).

<sup>b</sup>Σ = heat loss to current depth.

Table 15 Heat Loss Through Basement Floors

Depth of Foundation Wall below Grade, m	Heat Loss Coefficient, W/(m <sup>2</sup> ·K)			
	Shortest Width of House, m			
	6	7.3	8.5	9.7
1.5	0.18	0.16	0.15	0.13
1.8	0.17	0.15	0.14	0.12
2.1	0.16	0.15	0.13	0.12

Note: Δt = (t<sub>a</sub> - A)

thermal resistance for each depth increment of the basement wall can be found by summing the thermal resistances along each heat flow path. Based on these resistances, the heat loss at each depth increment can be estimated for a unit temperature difference between the basement and the average mean winter temperature. Table 14 lists such heat loss values at different depths for an uninsulated and an insulated concrete wall (Latta and Boileau 1969). Also listed are the lengths of the heat flow path through the soil (circular path).

Through Basement Floors

The same steady-state design used for the basement wall can be applied to the basement floor, except that the length of the heat flow path is longer (see Figure 4). Thus, the heat loss through the basement floor is much smaller than that through the wall. An average value for the heat loss through the basement floor can be multiplied by the floor area to give total heat loss from the floor. Table 15 lists typical values.

Basement Design Temperatures

Although internal design temperature is given by basement air temperature, none of the usual external design air temperatures apply because of the heat capacity of the soil. However, ground surface temperature fluctuates about a mean value by an amplitude A, which varies with geographic location and surface cover. Therefore, suitable external design temperatures can be obtained by subtracting A for the location from the mean winter air temperature t<sub>a</sub>. Values for t<sub>a</sub> can be obtained from meteorological records, and A can be estimated from the map in Figure 6. This map is part of one prepared by Chang (1958) giving annual ranges in ground temperature at a depth of 100 mm.

**Example 6.** Consider a basement 8.5 m wide by 9.1 m long sunk 1.8 m below grade, with R = 1.47 K·m<sup>2</sup>/W insulation applied to the top 0.6 m of the wall below grade. Assume an internal air temperature of 21°C and an external design temperature (t<sub>a</sub> - A) of 7°C.

Solution:

Wall (using Table 14)

- 0.3 m below grade ..... 0.53 × 0.3 = 0.159 W/(m·K)
- 0.6 m below grade ..... 0.45 × 0.3 = 0.135 W/(m·K)
- 0.9 m below grade ..... 0.88 × 0.3 = 0.264 W/(m·K)
- 1.2 m below grade ..... 0.67 × 0.3 = 0.201 W/(m·K)
- 1.5 m below grade ..... 0.54 × 0.3 = 0.162 W/(m·K)
- 1.8 m below grade ..... 0.45 × 0.3 = 0.135 W/(m·K)
- Total per metre length of wall ..... 1.056 W/(m·K)

- Basement perimeter ..... 2(8.5 + 9.1) = 35.2 m
- Total wall heat loss ..... 1.056 × 35.2 = 37.2 W/K

Floor (using Table 15)

- Average heat loss per m<sup>2</sup> ..... 0.14 W/(m<sup>2</sup>·K)
- Floor area 8.5 × 9.1 ..... 77.35 m<sup>2</sup>
- Total floor heat loss ..... 0.14 × 77.35 = 10.8 W/K

Total

- Total basement heat loss below grade .... 37.2 + 10.8 = 48 W/K
- Design temperature difference ..... 21 - (-7) = 28 K
- Maximum rate of heat loss from below-grade basement ..... 48 × 28 = 1344 W

If a basement is completely below grade and unheated, its temperature ranges between that in the rooms above and that of the ground. Basement windows lower the basement temperature when it is cold outdoors, and heat given off by the heating plant increases the basement temperature. The exact basement temperature is indeterminate if the basement is not heated. In general, heat from the heating plant sufficiently warms the air near the basement ceiling to make unnecessary an allowance for floor heat loss from rooms located over the basement.

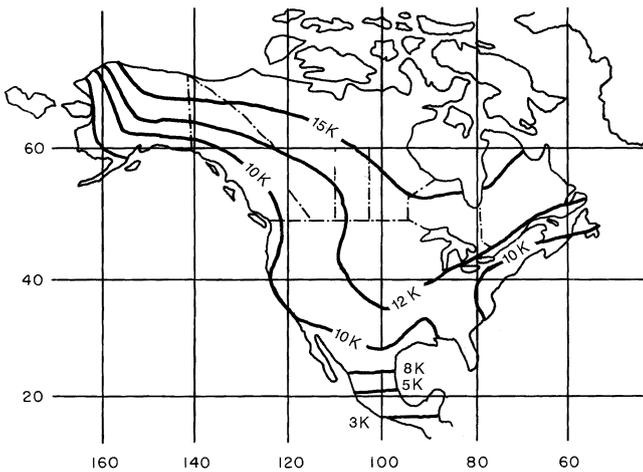

Fig. 6 Lines of Constant Amplitude

### Transient Calculations for Basement Walls

The heat loss from basement walls can be estimated more accurately with a finite element or finite difference computer program by transient simulations (Wang 1979, Bligh et al. 1978). The solution is in the form of heat loss over time, which can be converted to an average U-factor. This approach also offers the possibility for estimating the depth below grade to which insulation is economical. Direct and indirect evidence of hollow concrete block walls shows that a convective path exists within the blocks vertically along the wall (Harrje et al. 1979). Therefore, insulation should be arranged to reduce this convective heat transfer.

Peony et al. (1979) showed that the dynamic thermal performance of a masonry wall is better when insulation is placed on the exterior. Moreover, transient simulation showed that insulation is more effective when it is placed on the exterior side of the basement wall. Depending on the exposed portion of the block wall and the temperature difference between indoor and outdoor air, exterior application can be 10 to 20% more efficient than a corresponding interior application. However, such exterior insulation must be installed properly to maintain its integrity.

### Calculating Transmission Heat Loss from Floor Slabs

Concrete slab floors may be (1) unheated, relying for warmth on heat delivered above floor level by the heating system, or (2) heated, containing heated pipes or ducts that constitute a radiant slab or portion of it for complete or partial heating of the house.

The perimeter insulation of a slab-on-grade floor is quite important for comfort and energy conservation. In unheated slab floors, the floor edge must be insulated in order to keep the floor warm. Drafts from windows or exposed walls can create pools of chilly air over considerable areas of the floor. In heated slab floors, the floor edge must be insulated to prevent excessive heat loss from the heating pipe or duct embedded in the floor or from the baseboard heater.

Wang (1979) and Bligh et al. (1978) found that heat loss from an unheated concrete slab floor is mostly through the perimeter rather than through the floor and into the ground. Total heat loss is more nearly proportional to the length of the perimeter than to the area of the floor, and it can be estimated by the following equation for both unheated and heated slab floors:

$$q = F_2 P (t_i - t_o) \quad (6)$$

where

$q$  = heat loss through perimeter, W

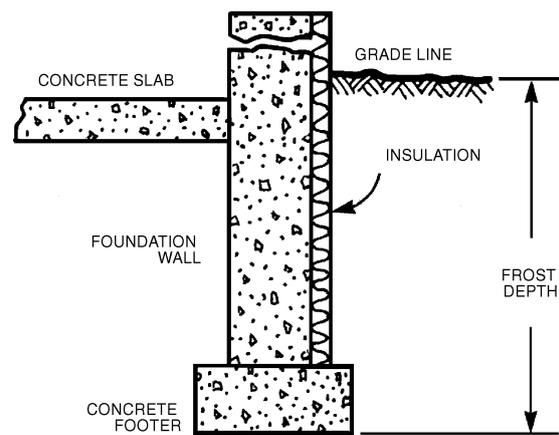

Fig. 7 "I"-Shaped or Vertical Insulation System

$F_2$  = heat loss coefficient per foot of perimeter (see Table 16), W/(m·K)

$P$  = perimeter or exposed edge of floor, m

$t_i$  = indoor temperature, °C (For the heated slab,  $t_i$  is the weighted average heating duct or pipe temperature.)

$t_o$  = outdoor temperature, °C

Vertical "I"-shaped systems are used to insulate slab floor perimeters. In the "I" system, the insulation is placed vertically next to the exposed slab edge, extending downward below grade, as shown in Figure 7.

Breaks or joints must be avoided when the insulation is installed; otherwise, local thermal bridges can be formed, and the overall efficiency of the insulation is reduced.

### Transient Calculations for Floor Slabs

Figure 8 shows four basic slab-on-grade constructions analyzed with a finite element computer program by Wang (1979). Figures 8A-C represent unheated slabs; Figure 8D can be considered a heated slab. Each was investigated with and without insulation of  $R=0.95 \text{ K}\cdot\text{m}^2/\text{W}$  under three climatic conditions (4130, 2970, and 1640 kelvin days). Table 16 lists the results in terms of heat loss coefficient  $F_2$ , based on kelvin days.

Table 16 shows that the heat loss coefficient  $F_2$  is sensitive to both construction and insulation. The reverse loss, or heat loss into the ground and outward through the edges of the slab and foundation wall, is significant when heating pipes, heating ducts, or baseboard heaters are placed near the slab perimeters. To prevent reverse loss, the designer may find it advantageous to use perimeter insulation even in warmer climates. For severe winter regions (above 3300 kelvin days), the insulation value should be increased to  $R > 1.8 \text{ K}\cdot\text{m}^2/\text{W}$ .

Figure 8A shows that this construction benefits from the wall insulation between block and brick; the insulation is extended roughly 400 mm below the slab floor. Without this wall insulation, the heat loss coefficient  $F_2$  would be close to that of the 100 mm block wall construction (Figure 8B). Table 16 can be used to estimate  $F_2$  under different kelvin days of heating season weather.

### CALCULATING INFILTRATION HEAT LOSS

Infiltration of outside air causes both **sensible** and **latent** heat loss. The energy required to raise the temperature of outdoor infiltrating air to indoor air temperature is the sensible component. The energy associated with net loss of moisture from the space is the latent component. Infiltration is discussed in detail in Chapter 26.

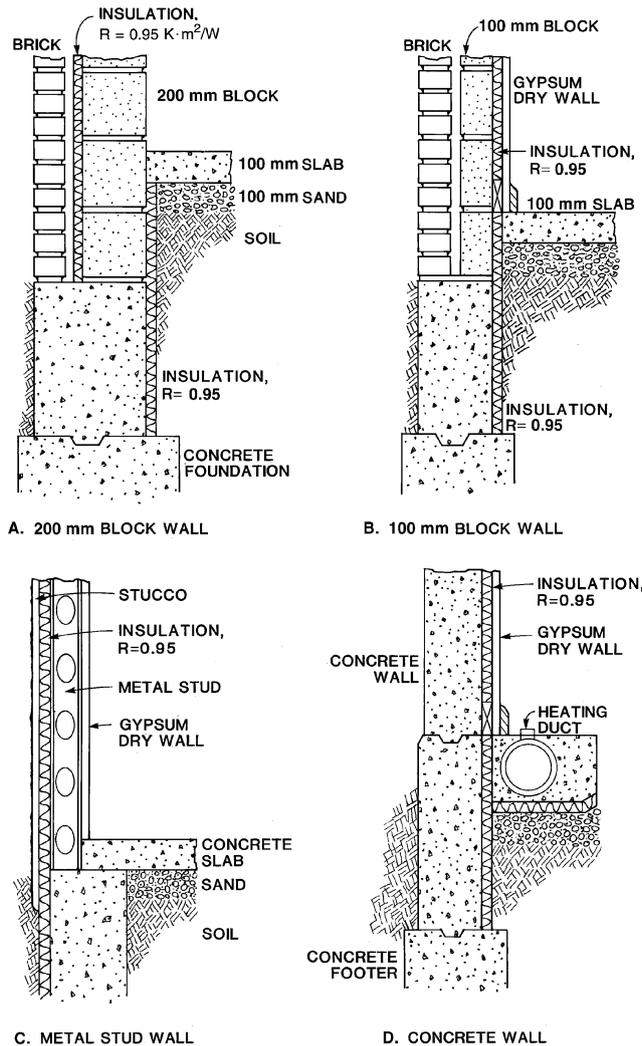

Fig. 8 Slab-on-Grade Foundation Insulation

**Sensible Heat Loss**

The energy required to warm outdoor air entering by infiltration to the temperature of the room is given by

$$q_s = c_p Q \rho (t_i - t_o) \tag{7}$$

where

- $q_s$  = heat flow required to raise temperature of air leaking into building from  $t_o$  to  $t_i$ , W
- $c_p$  = specific heat of air, kJ/(kg·K)
- $Q$  = volumetric flow of outdoor air entering building, L/s
- $\rho$  = density of air at temperature  $t_o$ , kg/m<sup>3</sup>

Using standard air [ $\rho = 1.20$  kg/m<sup>3</sup> and  $c_p = 1.0$  kJ/(kg·K)], Equation (7) reduces to

$$q_s = 1.2Q(t_i - t_o) \tag{8}$$

The volumetric flow  $Q$  of outdoor air entering depends on wind speed and direction, width of cracks or size of openings, type of openings, and other factors explained in Chapter 26. Two methods used to obtain the quantity of infiltration air are the **crack length** and the **air change**. Louvers and doors and the direction they face,

**Table 16 Heat Loss Coefficient  $F_2$  of Slab Floor Construction, W/K per metre of Perimeter**

Construction	Insulation	Kelvin Days (18°C Base)		
		1640 K·d/yr	2970 K·d/yr	4130 K·d/yr
200 mm block wall, brick facing	Uninsulated	1.07	1.17	1.24
	R = 0.95 K·m <sup>2</sup> /W from edge to footer	0.83	0.86	0.97
100 mm block wall, brick facing	Uninsulated	1.38	1.45	1.61
	R = 0.95 from edge to footer	0.81	0.85	0.93
Metal stud wall, stucco	Uninsulated	1.99	2.07	2.32
	R = 0.95 from edge to footer	0.88	0.92	1.00
Poured concrete wall with duct near perimeter <sup>a</sup>	Uninsulated	3.18	3.67	4.72
	R = 0.95 from edge to footer, 910 mm under floor	1.11	1.24	1.56

<sup>a</sup>Weighted average temperature of the heating duct was assumed at 43°C during the heating season (outdoor air temperature less than 18°C).

as well as any other factors affecting infiltration, may need to be considered.

**Latent Heat Loss**

When moisture must be added to the indoor air to maintain winter comfort conditions, the energy needed to evaporate an amount of water equivalent to what is lost by infiltration (latent component of infiltration heat loss) must be determined. This energy may be calculated by

$$q_l = \frac{Q\rho(W_i - W_o)h_{fg}}{1000} \tag{9}$$

where

- $q_l$  = heat flow required to increase moisture content of air leakage into building from  $W_o$  to  $W_i$ , W
- $Q$  = volumetric flow of outdoor air entering building, L/s
- $\rho$  = density of air at temperature  $t_i$ , kg/m<sup>3</sup>
- $W_i$  = humidity ratio of indoor air, g/kg (dry air)
- $W_o$  = humidity ratio of outdoor air, g/kg (dry air)
- $h_{fg}$  = latent heat of vapor at  $t_i$ , kJ/kg

If the latent heat of vapor  $h_{fg}$  is 2500 kJ/kg, and the air density is 1.2 kg/m<sup>3</sup>, Equation (7) reduces to

$$q_l = 3.0Q(W_i - W_o) \tag{10}$$

**Crack Length Method**

The basis of calculation for the crack method is that the amount of crack used for computing the infiltration heat loss should not be less than one-half the total length of crack in the outside walls of the room. In a building without partitions, air entering through cracks on the windward side must leave through cracks on the leeward side. Therefore, one-half the total crack for each side and end of the building is used for calculation. In a room with one exposed wall, all the crack is used. With two, three, or four exposed walls, either the wall with the crack that will result in the greatest air leakage or at least one-half the total crack is used, whichever is greater.

In residences, total infiltration loss of the house is generally considered equal to the sum of infiltration losses of the various rooms. But, at any given time, infiltration takes place only on the windward side or sides and not on the leeward. Therefore, for determining total heat requirements of larger buildings, it is more accurate to base total infiltration loss on the wall with the most total crack or on at

least half the total crack in the building, whichever is greater. When the crack method rather than Equations (8) and (10) is used for estimating leakage, the heat loss in terms of the crack length may be expressed as

$$q_s = 1.2BL(t_i - t_o) \quad (11)$$

and

$$q_l = 3.0BL(W_i - W_o) \quad (12)$$

where

$B$  = air leakage for wind velocity and type of window or door crack involved, L/s per metre of crack

$L$  = length of window or door crack to be considered, m

### Air Change Method

Some designers base infiltration on an estimated number of air changes rather than the length of window cracks. The number of air changes given in Chapter 26 should be considered only as a guide. When calculating infiltration losses by the air change method, Equations (8) and (10) can be used by substituting for  $Q$  the volume of the room multiplied by the number of air changes.

### Exposure Factors

Some designers use empirical exposure factors to increase calculated heat loss of rooms or spaces on the side(s) of the building exposed to prevailing winds. However, exposure factors are not needed with the method of calculating heat loss described in this chapter. Instead, they may be (1) regarded as safety factors to allow for additional capacity for rooms or spaces exposed to prevailing winds or (2) used to account for the effects of radiation loss, particularly in the case of multistory buildings. Tall buildings may have severe infiltration heat losses induced by stack effect that require special analysis. Although a 15% exposure allowance is often assumed, the actual allowance, if any, is largely a matter of experience and judgment; no test data are available from which to develop rules for the many conditions encountered.

## PICKUP LOAD

For intermittently heated buildings and night thermostat setback, additional heat is required to raise the temperature of air, building materials, and material contents of a building to the specified temperature. The pickup load, which is the rate at which this additional heat must be supplied, depends on the heat capacity of the structure, its material contents, and the time in which these are to be heated.

Relatively little information on pickup load exists; however, Smith (1941, 1942) addressed pickup loads for buildings heated only occasionally, such as auditoriums and churches. Nelson and MacArthur (1978) studied the relationship between thermostat setback, furnace capacity, and recovery time. Based on this limited information, the following design guidelines are offered.

Because design outdoor temperatures generally provide a substantial margin for outdoor temperatures typically experienced during operating hours, many engineers make no allowance for this additional heat in most buildings. However, the additional heat should be computed and allowed for, as conditions require. In the case of intermittently heated buildings, an additional 10% capacity should be provided.

In buildings with setback-type thermostats, the furnace must be oversized to reestablish the space temperature in an acceptable time. The amount of oversizing depends on such factors as the amount of setback, inside-to-outside temperature difference, building construction, and acceptable pickup time. Figure 9 shows this relationship for a particular residence. As a rule for residences, a 5.6 K night setback requires 40% oversizing for acceptable pickup time and minimum energy requirements (Nel-

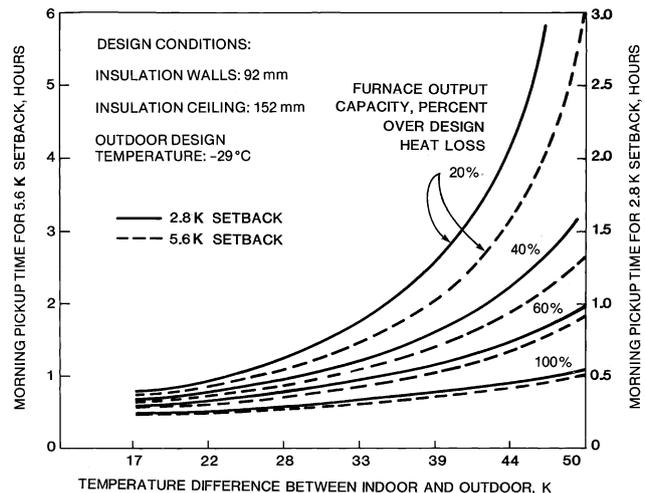

Fig. 9 Furnace Operating Times Required to Pick Up Space Temperature Following 2.8 and 5.6 K Night Setback

son and MacArthur 1978). For smaller setback, the oversizing can be proportionally less. If daytime as well as night setback is practiced, oversizing of up to 60% is warranted.

**T**HIS CHAPTER presents two load calculation methods that represent a significant departure from those in common use. The technology involved, however—the principle of calculating a heat balance for a given space—is not new. The first of the two methods is the **heat balance (HB) method**. The calculation procedures and scientific principles are explained in equation format. These equations are coded in a generic computer program named Hbfort, released with *Cooling and Heating Load Calculation Principles* (Pedersen et al. 1998), and linked to a user interface program to allow input and output in either inch-pound or SI units. The source code for these programs has been refined and enhanced under ASHRAE Research Project 987 and can be found in the *ASHRAE Load Calculation Toolkit*.

The second method is called the **radiant time series (RTS) method**, which is a simplified method directly related to and derived from the HB calculation procedure. This chapter presents the principles of both procedures rather than a working tool for the cooling load practitioner. The load prediction of an actual, multiple-room building requires a complex computer program.

While the procedures described in this chapter are the most reliable means for estimating cooling load for a defined building space, the methods described in earlier editions of the Handbook series are valid for many applications. Each of these earlier procedures is, however, a simplification of the heat balance principles, and their use requires experience to deal with atypical situations or unusual circumstances. In fact, any cooling or heating load estimate is no better than the assumptions used to define conditions and parameters such as physical makeup of the various envelope surfaces, conditions of occupancy and use, and ambient weather conditions outside the building. The experience of the practitioner can never be ignored.

The procedures described in this chapter are concerned with a given space or zone in a building. When estimating the loads for a group of spaces such as might be handled by a single air-handling system, the assembled zones must be analyzed to consider (1) the

simultaneous effects taking place; (2) any diversification of heat gains for occupants, lighting, or other internal load sources; (3) ventilation; and/or (4) any other unique circumstances. With large buildings that involve more than a single HVAC system, simultaneous loads and any additional diversities also must be considered. The methods presented in this chapter are expressed as hourly load summaries, reflecting 24 h input schedules and profiles of the individual load variables. Specific systems and applications may require different profiles.

In comparing the HB and RTS methods against the methods described in earlier versions of this chapter, the primary difference is the directness of approach as opposed to the simplifying techniques necessitated by the limited computer capability available in earlier days. The **transfer function method (TFM)**, for example, required many calculation steps. Also, this method was originally designed for energy analysis with emphasis on daily, monthly, and annual energy use and, thus, was more oriented to average hourly cooling loads than peak design loads.

The **total equivalent temperature differential method with time averaging (TETD/TA)** has been a highly reliable—if subjective—method of load estimating since its initial presentation in the 1967 *ASHRAE Handbook—Fundamentals*. Originally conceived as a manual method of calculation, it proved suitable only as a computer application because of the need to calculate an extended profile of hourly heat gain values from which the radiant components had to be averaged over a time perceived to represent the general mass of the building involved. Because this perception of thermal storage characteristics of a given building was almost entirely subjective, with little specific information for the user to judge variations, the TETD/TA method's primary usefulness has always been to the experienced engineer.

The **cooling load temperature differential method with solar cooling load factors (CLTD/CLF)** was an attempt to simplify the two-step TFM and TETD/TA methods into a single-step technique that allowed proceeding directly from raw data to cooling load without the intermediate conversion of radiant heat gain to cooling load. A series of factors were taken from cooling load calculation results (produced by more sophisticated methods) as “equivalent temperature differences” for use in traditional conduction ( $q = UA\Delta t$ ) equa-

The preparation of this chapter is assigned to TC 4.1, Load Calculation Data and Procedures.

tions. The results, however, are approximate cooling load values rather than simple heat gain values. The simplifications required for this process limit the applicability of this method. In fact, past versions of this chapter listed several areas of potential use that should be avoided as beyond the range of applicability.

### COOLING LOAD PRINCIPLES

The variables affecting cooling load calculations are numerous, often difficult to define precisely, and always intricately interrelated. Many cooling load components vary in magnitude over a wide range during a 24 h period. Because these cyclic changes in load components often are not in phase with each other, each must be analyzed to establish the maximum cooling load for a building or zone. A zoned system (a system of conditioning equipment serving several independent areas, each with its own temperature control) need provide no greater total cooling load capacity than the largest hourly summary of simultaneous zone loads throughout a design day; however, it must handle the peak cooling load for each zone at its individual peak hour. At certain times of the day during the heating or intermediate seasons, some zones may require heating while others require cooling.

#### Calculation Accuracy

A realistic cooling load calculation gives values adequate for acceptable system performance. Variation in the heat transmission coefficients of typical building materials and composite assemblies, the differing motivations and skills of those who construct the building, and the manner in which the building is actually operated are some of the variables that make a precise calculation impossible. Even if the designer uses reasonable procedures to account for these factors, the calculation can never be more than a good estimate of the actual cooling load.

#### Heat Flow Rates

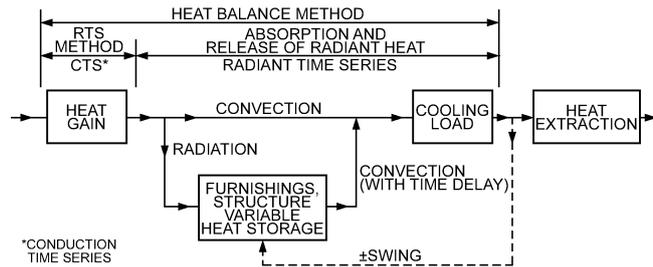

In air-conditioning design, four related heat flow rates, each of which varies with time, must be differentiated: (1) space heat gain, (2) space cooling load, (3) space heat extraction rate, and (4) cooling coil load.

**Space Heat Gain.** This instantaneous rate of heat gain is the rate at which heat enters into and/or is generated within a space. Heat gain is classified by (1) the mode in which it enters the space and (2) whether it is a sensible or latent gain.

*Mode of entry.* The mode of entry includes (1) solar radiation through transparent surfaces; (2) heat conduction through exterior walls and roofs; (3) heat conduction through ceilings, floors, and interior partitions; (4) heat generated in the space by occupants, lights, and appliances; (5) energy transfer as a result of ventilation and infiltration of outdoor air; and (6) miscellaneous heat gains.

*Sensible or latent heat.* Sensible heat is added directly to the conditioned space by conduction, convection, and/or radiation. Latent heat gain occurs when moisture is added to the space (e.g., from vapor emitted by occupants and equipment). To maintain a constant humidity ratio, water vapor must condense on the cooling apparatus and be removed at a rate equal to the rate it is added to the space. The amount of energy required to offset the latent heat gain essentially equals the product of the rate of condensation and the latent heat of condensation. In selecting cooling apparatus, it is necessary to distinguish between sensible and latent heat gain. Every cooling apparatus has a maximum sensible heat removal capacity and a maximum latent heat removal capacity for particular operating conditions.

**Space Cooling Load.** This is the rate at which heat must be removed from the space to maintain a constant space air temperature. The sum of all space instantaneous heat gains at any given time does not necessarily (or even frequently) equal the cooling load for the space at that same time.

**Fig. 1 Origin of Difference Between Magnitude of Instantaneous Heat Gain and Instantaneous Cooling Load**

**Radiant heat gain.** Radiant energy must first be absorbed by the surfaces that enclose the space (walls, floor, and ceiling) and the objects in the space (furniture, etc.). When these surfaces and objects become warmer than the surrounding air, some of their heat is transferred to the air by convection. The composite heat storage capacity of these surfaces and objects determines the rate at which their respective surface temperatures increase for a given radiant input and thus governs the relationship between the radiant portion of heat gain and its corresponding part of the space cooling load (Figure 1). The thermal storage effect is critically important in differentiating between instantaneous heat gain for a given space and its cooling load at that moment. Predicting the nature and magnitude of this phenomenon in order to estimate a realistic cooling load for a particular combination of circumstances has long been a subject of interest to design engineers. The section on Bibliography lists some of the early work on the subject.

**Space Heat Extraction Rate.** The rate at which heat is removed from the conditioned space equals the space cooling load only if the room air temperature is held constant. Along with the intermittent operation of the cooling equipment, the control system characteristics usually permit a minor cyclic variation or swing in room temperature. Therefore, a proper simulation of the control system gives a more realistic value of energy removal over a fixed period than using the values of the space cooling load. However, this concept is primarily important for estimating energy use over time; it is not needed to calculate design peak cooling load for equipment selection.

**Cooling Coil Load.** The rate at which energy is removed at the cooling coil that serves one or more conditioned spaces equals the sum of the instantaneous space cooling loads (or space heat extraction rate if it is assumed that the space temperature does not vary) for all the spaces served by the coil, plus any external loads. Such external loads include fan heat gain, duct heat gain, and outdoor air heat and moisture brought into the cooling equipment to satisfy the ventilation requirement.

#### Cooling Load Estimation in Practice

Frequently, a cooling load must be calculated before every parameter in the conditioned space can be properly or completely defined. An example is a cooling load estimate for a new building with many floors of unleased spaces where detailed partition requirements, furnishings, lighting selection, and layout cannot be predefined. Potential tenant modifications once the building is occupied also must be considered. The load estimating process requires proper engineering judgment that includes a thorough understanding of heat balance fundamentals.

### INITIAL DESIGN CONSIDERATIONS

To calculate a space cooling load, detailed building design information and weather data at selected design conditions are required. Generally, the following steps should be followed.

## Data Assembly

**Building Characteristics.** Obtain characteristics of the building. Building materials, component size, external surface colors, and shape are usually determined from building plans and specifications.

**Configuration.** Determine building location, orientation, and external shading from building plans and specifications. Shading from adjacent buildings can be determined by a site plan or by visiting the proposed site but should be carefully evaluated as to its probable permanence before it is included in the calculation. The possibility of abnormally high ground-reflected solar radiation (i.e., from adjacent water, sand, or parking lots) or solar load from adjacent reflective buildings should not be overlooked.

**Outdoor Design Conditions.** Obtain appropriate weather data, and select outdoor design conditions. For outdoor design conditions for a large number of weather stations, see Chapter 27. Note, however, that these values for the design dry-bulb and mean coincident wet-bulb temperatures may vary considerably from data traditionally used in various areas. Use judgment to ensure that results are consistent with expectations. Also, consider prevailing wind velocity and the relationship of a project site to the selected weather station.

In recent years, several research projects have greatly expanded the amount of available weather data (Colliver et al. 1995, 1998, 2000). In addition to the conventional dry-bulb with mean coincident wet-bulb, data are now available for wet-bulb and dew-point with mean coincident dry-bulb. The peak load for a space that requires both large quantities of outside air and close control of moisture may occur at peak wet-bulb or peak dew-point conditions when the corresponding dry-bulb temperature is significantly lower than normal design conditions.

**Indoor Design Conditions.** Select indoor design conditions, such as indoor dry-bulb temperature, indoor wet-bulb temperature, and ventilation rate. Include permissible variations and control limits.

**Operating Schedules.** Obtain a proposed schedule of lighting, occupancy, internal equipment, appliances, and processes that contribute to the internal thermal load. Determine the probability that the cooling equipment will be operated continuously or shut off during unoccupied periods (e.g., nights and/or weekends).

**Date and Time.** Select the time of day and month to do the cooling load calculation. Frequently, several different times of day and several different months must be analyzed to determine the peak load time. The particular day and month are often dictated by peak solar conditions. For southern exposures in north latitudes above 32° having large fenestration areas, the peak space cooling load usually occurs in December or January. To calculate a space cooling load under these conditions, the warmest temperature for the winter months must be known. These data can be found for the United States in Chapter 27, Table 4B.

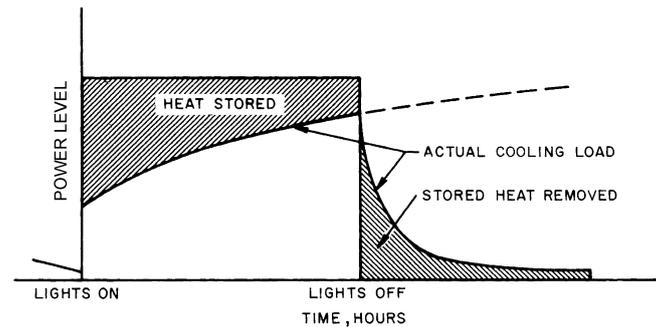

## Additional Considerations

The proper design and sizing of all-air or air-and-water central air-conditioning systems require more than calculation of the cooling load in the space to be conditioned. The type of air-conditioning system, fan energy, fan location, duct heat loss and gain, duct leakage, heat extraction lighting systems, and type of return air system all affect system load and component sizing. Adequate system design and component sizing require that system performance be analyzed as a series of psychrometric processes.

# HEAT SOURCES AND HEAT GAIN CALCULATION CONCEPTS

## TIME DELAY EFFECT

The energy absorbed by walls, floor, furniture, etc., contributes to space cooling load only after a time lag, with some part of this

**Fig. 2 Thermal Storage Effect in Cooling Load from Lights**

energy still present and reradiating after the heat sources have been switched off or are no longer present (Figure 2).

There is always significant delay between the time of switching on or otherwise activating a heat source and the point when reradiated energy equals that being instantaneously stored. This time lag must be considered when calculating cooling load because the load felt by the space can be much lower than the instantaneous heat gain being generated, and the peak load for the space may be affected significantly.

## PEOPLE

Table 1 gives representative rates at which heat and moisture are given off by human beings in different states of activity. Often these sensible and latent heat gains constitute a large fraction of the total load. Even for short-term occupancy, the extra heat and moisture brought in by people may be significant. Chapter 8 should be consulted for detailed information; however, Table 1 summarizes design data representing conditions commonly encountered.

The conversion of sensible heat gain from people to space cooling load is affected by the thermal storage characteristics of that space, since some percentage of the sensible load is radiant energy. Latent heat gains are considered instantaneous.

## LIGHTING

Because lighting is often the major space load cooling component, an accurate estimate of the space heat gain it imposes is needed. Calculation of this load component is not straightforward; the rate of cooling load due to lighting at any given moment can be quite different from the heat equivalent of power supplied instantaneously to those lights.

## Instantaneous Heat Gain from Lighting

The primary source of heat from lighting comes from light-emitting elements, or lamps, although significant additional heat may be generated from associated appurtenances in the light fixtures that house such lamps. Generally, the instantaneous rate of heat gain from electric lighting may be calculated from

$$q_{el} = WF_{ul}F_{sa} \quad (1)$$

where

- $q_{el}$  = heat gain, W
- $W$  = total light wattage
- $F_{ul}$  = lighting use factor
- $F_{sa}$  = lighting special allowance factor

The **total light wattage** is obtained from the ratings of all lamps installed, both for general illumination and for display use.

The **lighting use factor** is the ratio of the wattage in use, for the conditions under which the load estimate is being made, to the total

**Table 1 Representative Rates at Which Heat and Moisture Are Given Off by Human Beings in Different States of Activity**

Degree of Activity		Total Heat, W		Sensible Heat, W	Latent Heat, W	% Sensible Heat that is Radiant <sup>b</sup>	
		Adult Male	Adjusted, M/F <sup>a</sup>			Low V	High V
		Seated at theater	Theater, matinee	115	95	65	30
Seated at theater, night	Theater, night	115	105	70	35	60	27
Seated, very light work	Offices, hotels, apartments	130	115	70	45

Heavy machine work; lifting	Factory	470	470	185	285		
Athletics	Gymnasium	585	525	210	315		

**Notes:**

1. Tabulated values are based on 24°C room dry-bulb temperature. For 27°C room dry bulb, the total heat remains the same, but the sensible heat values should be decreased by approximately 20%, and the latent heat values increased accordingly.

2. Also refer to Table 4, Chapter 8, for additional rates of metabolic heat generation.

3. All values are rounded to nearest 5 W.

<sup>a</sup>Adjusted heat gain is based on normal percentage of men, women, and children for the application listed, with the postulate that the gain from an adult female is

85% of that for an adult male, and that the gain from a child is 75% of that for an adult male.

<sup>b</sup>Values approximated from data in Table 6, Chapter 8, where  $v$  is air velocity with limits shown in that table.

<sup>c</sup>Adjusted heat gain includes 18 W for food per individual (9 W sensible and 9 W latent).

<sup>d</sup>Figure one person per alley actually bowling, and all others as sitting (117 W) or standing or walking slowly (231 W).

installed wattage. For commercial applications such as stores, the use factor would generally be unity.

The **special allowance factor** is for fluorescent fixtures and/or fixtures that are either ventilated or installed so that only part of their heat goes to the conditioned space. For fluorescent or high-intensity discharge fixtures, the special allowance factor accounts primarily for ballast losses. Table 2 shows that the special allowance factor for a two-lamp fluorescent fixture ranges from 0.94 for T8 lamps with an electronic ballast to 1.21 for energy-saver T12 lamps with a standard electromagnetic ballast. High-intensity discharge fixtures, such as metal halide, may have special allowance factors varying from 1.07 to 1.44, depending on the lamp wattage and quantity of lamps per fixture, and should be dealt with individually. A wide variety of lamp and ballast combinations is available, and ballast catalog data provide the overall fixture wattage.

For ventilated or recessed fixtures, manufacturers' or other data must be sought to establish the fraction of the total wattage that may be expected to enter the conditioned space directly (and subject to time lag effect) versus that which must be picked up by return air or in some other appropriate manner.

### Light Heat Components

Cooling load caused by lights recessed into ceiling cavities is made up of two components: one part (known as the **heat-to-space** load) comes from the light heat directly contributing to the space heat gain, and the other is the light heat released into the above-ceiling cavity, which (if used as a return air plenum) is mostly picked up by the return air that passes over or through the light fixtures. In such a ceiling return air plenum, this second part of the load (sometimes referred to as **heat-to-return**) never enters the conditioned space. It does, however, add to the overall load and significantly influences the load calculation.

Even though the total cooling load imposed on the cooling coil from these two components remains the same, the larger the fraction of heat output picked up by the return air, the more the space cooling

load is reduced. The minimum required airflow rate for the conditioned space is decreased as the space cooling load decreases. Supply fan power decreases accordingly, which ultimately results in reduced energy consumption for the system and possibly reduced equipment size as well.

For ordinary design load estimation, the heat gain for each component may be calculated simply as a fraction of the total lighting load by using judgment to estimate heat-to-space and heat-to-return percentages (Mitalas and Kimura 1971).

### Return Air Light Fixtures

Two generic types of return air light fixture are available—those that allow and those that do not allow return air to flow through the lamp chamber. The first type is sometimes called a heat-of-light fixture. The percentage of light heat released through the plenum side of various ventilated fixtures can be obtained from lighting fixture manufacturers. For representative data, see Nevins et al. (1971). Even unventilated fixtures lose some heat to plenum spaces; however, most of the heat ultimately enters the conditioned space from a dead-air plenum or is picked up by return air via ceiling return air openings. The percentage of heat to return air ranges from 40 to 60% for heat-to-return ventilated fixtures or 15 to 25% for unventilated fixtures.

### Plenum Temperatures

As heat from lighting is picked up by the return air, the temperature differential between the ceiling cavity and the conditioned space causes part of that heat to flow from the ceiling back to the conditioned space. Return air from the conditioned space can be ducted to capture light heat without passing through a ceiling plenum as such, or the ceiling space can be used as a return air plenum, causing the distribution of light heat to be handled in distinctly different ways. Most plenum temperatures do not rise more than 0.5 to 1.5 K above space temperature, thus generating only a relatively small thermal gradient for heat transfer through plenum surfaces but

Abbreviations: Mag = electromagnetic; ES = energy saver; Std = standard; HID = high-intensity discharge; HO = high output; VHO = very high output; PH = preheat; RS = rapid start

a relatively large percentage reduction in space cooling load. (Many engineers believe that a major reason for plenum temperatures not becoming more elevated is due to leakage into the plenum from supply air ducts normally concealed there.)

**Energy Balance**

Where the ceiling space is used as a return air plenum, an energy balance requires that the heat picked up from the lights into the return air (1) become a part of the cooling load to the return air (represented by a temperature rise of the return air as it passes through the ceiling space), (2) be partially transferred back into the conditioned space through the ceiling material below, and/or (3) may be partially “lost” (from the space) through the floor surfaces above the plenum. In a multistory building, the conditioned space frequently gains heat through its floor from a similar plenum below, offsetting the loss just mentioned. The radiant component of heat leaving the ceiling or floor surface of a plenum is normally so small that all such heat transfer is considered convective for calculation purposes.

Figure 3 shows a schematic diagram of a typical return air plenum. The following equations, using the heat flow directions shown

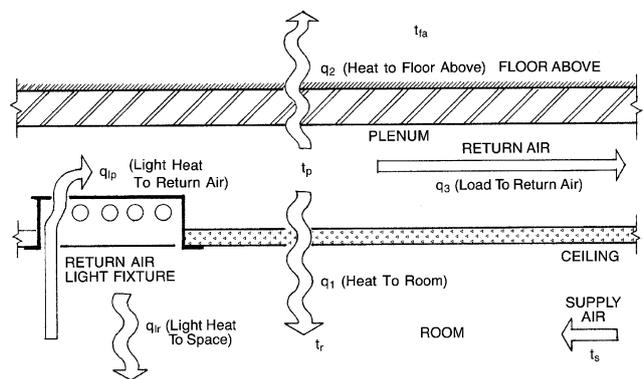

Fig. 3 Schematic Diagram of Typical Return Air Plenum

in Figure 3, represent the heat balance of a return air plenum design for a typical interior room in a multifloor building:

$$q_1 = U_c A_c (t_p - t_r) \tag{2}$$

$$q_2 = U_f A_f (t_p - t_{fa}) \tag{3}$$

$$q_3 = 1.23 Q (t_p - t_r) \tag{4}$$

$$q_{lp} - q_2 - q_1 - q_3 = 0 \tag{5}$$

$$Q = \frac{q_r + q_1}{1.23(t_r - t_s)} \tag{6}$$

where

- $q_1$  = heat gain to space from plenum through ceiling, W
- $q_2$  = heat loss from plenum through floor above, W
- $q_3$  = heat gain “pickup” by return air, W
- $Q$  = return airflow, L/s
- $q_{lp}$  = light heat gain to plenum via return air, W
- $q_{lr}$  = light heat gain to space, W
- $q_f$  = heat gain from plenum below, through floor, W
- $q_w$  = heat gain from exterior wall, W
- $q_r$  = space cooling load, including appropriate treatment of  $q_{lr}$ ,  $q_f$  and/or  $q_w$ , W
- $t_p$  = plenum temperature, °C
- $t_r$  = space temperature, °C
- $t_{fa}$  = space temperature of floor above, °C
- $t_s$  = supply air temperature, °C

From heat balance Equation (5),  $t_p$  can be found as the resultant return air temperature or plenum temperature. The results, although rigorous and best solved by computer, are important in determining the cooling load, which affects equipment size selection, future energy consumption, and other factors.

Equations (2) through (6) are simplified to illustrate the heat balance relationship. Heat gain into a return air plenum is not limited to the heat of lights alone. Exterior walls directly exposed to the ceiling space will transfer heat directly to or from the return air. For single-story buildings or the top floor of a multistory building, the roof heat gain or loss enters or leaves the ceiling plenum rather than entering or leaving the conditioned space directly. The supply air quantity calculated by Equation (6) is only for the conditioned space under consideration and is assumed equal to the return air quantity.

The amount of airflow through a return plenum above a conditioned space may not be limited to that supplied into the space under consideration; it will, however, have no noticeable effect on plenum temperature if the surplus comes from an adjacent plenum operating under similar conditions. Where special conditions exist, heat balance Equations (2) through (6) must be modified appropriately. Finally, even though the building’s thermal storage has some effect, the amount of heat entering the return air is small and may be considered as convective for calculation purposes.

### ELECTRIC MOTORS

Instantaneous heat gain from equipment operated by electric motors within a conditioned space is calculated as

$$q_{em} = (P/E_M) F_{UM} F_{LM} \tag{7}$$

where

- $q_{em}$  = heat equivalent of equipment operation, W
- $P$  = motor power rating, W
- $E_M$  = motor efficiency, decimal fraction < 1.0
- $F_{UM}$  = motor use factor, 1.0 or decimal fraction < 1.0
- $F_{LM}$  = motor load factor, 1.0 or decimal fraction < 1.0

The motor use factor may be applied when motor use is known to be intermittent with significant nonuse during all hours of operation (e.g., overhead door operator). For conventional applications, its value would be 1.0.

The motor load factor is the fraction of the rated load being delivered under the conditions of the cooling load estimate. In Equation (7), it is assumed that both the motor and the driven

equipment are in the conditioned space. If the motor is outside the space or airstream,

$$q_{em} = P F_{UM} F_{LM} \tag{8}$$

When the motor is inside the conditioned space or airstream but the driven machine is outside,

$$q_{em} = P \left( \frac{1.0 - E_M}{E_M} \right) F_{UM} F_{LM} \tag{9}$$

Equation (9) also applies to a fan or pump in the conditioned space that exhausts air or pumps fluid outside that space.

Tables 3A and 3B give average efficiencies and related data representative of typical electric motors, generally derived from the lower efficiencies reported by several manufacturers of open, drip-proof motors. These reports indicate that totally enclosed

**Table 3B Typical Overload Limits with Standard Motors**

Motor Type	Watts			
	40 to 190	120 to 250	500 to 560	750 and up
AC open	1.4	1.35	1.25	1.15
AC TEFC <sup>a</sup> and DC	—	1.0	1.0	1.0

Note: Some shaded pole, capacitor start, and special purpose motors have a service factor varying from 1.0 up to 1.75.

<sup>a</sup>Some totally enclosed fan-cooled (TEFC) motors have a service factor above 1.0.

fan-cooled (TEFC) motors are slightly more efficient. For speeds lower or higher than those listed, efficiencies may be 1 to 3% lower or higher, depending on the manufacturer. Should actual voltages at motors be appreciably higher or lower than rated nameplate voltage, efficiencies in either case will be lower. If electric motor load is an appreciable portion of cooling load, the motor efficiency should be obtained from the manufacturer. Also, depending on design, the maximum efficiency might occur anywhere between 75 to 110% of full load; if underloaded or overloaded, the efficiency could vary from the manufacturer's listing.

**Overloading or Underloading**

Heat output of a motor is generally proportional to the motor load, within the overload limits. Because of typically high no-load motor current, fixed losses, and other reasons,  $F_{LM}$  is generally assumed to be unity, and no adjustment should be made for underloading or overloading unless the situation is fixed, can be accurately established, and the reduced load efficiency data can be obtained from the motor manufacturer.

**Radiation and Convection**

Unless the manufacturer's technical literature indicates otherwise, the heat gain normally should be equally divided between radiant and convective components for the subsequent cooling load calculations.

**APPLIANCES**

In a cooling load estimate, heat gain from all appliances—electrical, gas, or steam—should be taken into account. Because of the variety of appliances, applications, schedules, use, and installations, estimates can be very subjective. Often, the only information available about heat gain from equipment is that on its nameplate.

**Cooking Appliances**

These appliances include common heat-producing cooking equipment found in conditioned commercial kitchens. Marn (1962) concluded that appliance surfaces contributed most of the heat to commercial kitchens and that when appliances were installed under an effective hood, the cooling load was independent of the fuel or energy used for similar equipment performing the same operations.

Gordon et al. (1994) and Smith et al. (1995) found that gas appliances may exhibit slightly higher heat gains than their electric counterparts under wall-canopy hoods operated at typical ventilation rates. This is due to the fact that the heat contained in the combustion products exhausted from a gas appliance may increase the temperatures of the appliance and surrounding surfaces, as well as the hood above the appliance, more than the heat produced by its electric counterpart. These higher temperature surfaces radiate heat to the kitchen, adding moderately to the radiant gain directly associated with the appliance cooking surface.

Marn (1962) confirmed that where the appliances are installed under an effective hood, only radiant gain adds to the cooling load; convected and latent heat from the cooking process and combustion products are exhausted and do not enter the kitchen. Gordon et al. (1994) and Smith et al. (1995) substantiated these findings.

**Sensible Heat Gain for Hooded Cooking Appliances.** To establish a heat gain value, nameplate energy input ratings may be used with appropriate usage and radiation factors. Where specific rating data are not available (nameplate missing, equipment not yet purchased, etc.) or as an alternative approach, recommended heat gains listed in Table 5 for a wide variety of commonly encountered equipment items may be used. In estimating the appliance load, probabilities of simultaneous use and operation for different appliances located in the same space must be considered.

The radiant heat gain from hooded cooking equipment can range from 15 to 45% of the actual appliance energy consumption (Talbert et al. 1973, Gordon et al. 1994, Smith et al. 1995). This ratio of heat gain to appliance energy consumption may be expressed as a radiation factor. It is a function of both appliance type and fuel source. The radiation factor  $F_R$  is applied to the average rate of appliance energy consumption, determined by applying usage factor  $F_U$  to the nameplate or rated energy input. Marn (1962) found that radiant heat temperature rise can be substantially reduced by shielding the fronts of cooking appliances. Although this approach may not always be practical in a commercial kitchen, radiant gains can also be reduced by adding side panels or partial enclosures that are integrated with the exhaust hood.

**Heat Gain from Meals.** For each meal served, the heat transferred to the dining space is approximately 15 W, of which 75% is sensible and 25% is latent.

**Heat Gain for Electric and Steam Appliances.** The average rate of appliance energy consumption can be estimated from the nameplate or rated energy input  $q_{input}$  by applying a duty cycle or usage factor  $F_U$ . Thus, the sensible heat gain  $q_{sensible}$  for generic types of electric, steam, and gas appliances installed under a hood can be estimated using one of the following equations:

$$q_{sensible} = q_{input} F_U F_R \tag{10}$$

or

$$q_{sensible} = q_{input} F_L \tag{11}$$

where  $F_L$  is defined as the ratio of sensible heat gain to the manufacturer's rated energy input.

Table 4 lists usage factors, radiation factors, and load factors based on appliance energy consumption rate for typical electrical, steam, and gas appliances under standby or idle conditions.

**Unhooded Equipment.** For all cooking appliances not installed under an exhaust hood or directly vent-connected and located in the conditioned area, the heat gain may be estimated as 50% ( $F_U = 0.50$ )

**Table 4A Hooded Electric Appliance Usage Factors, Radiation Factors, and Load Factors**

Appliance	Usage Factor $F_U$	Radiation Factor $F_R$	Load Factor $F_L = F_U F_R$ Elec/Steam
Griddle	0.16	0.45	0.07
Fryer	0.06	0.43	0.03

or the rated hourly input, regardless of the type of energy or fuel used. On average, 34% of the heat may be assumed to be latent and the remaining 66% sensible. Note that cooking appliances ventilated by “ductless” hoods should be treated as unhooded appliances from the perspective of estimating heat gain. In other words, all energy consumed by the appliance and all moisture produced by the cooking process is introduced to the kitchen as a sensible or latent cooling load.

**Recommended Heat Gain Values.** As an alternative procedure, Table 5 lists recommended rates of heat gain from typical commercial cooking appliances. The data in the “with hood” columns assume installation under a properly designed exhaust hood connected to a mechanical fan exhaust system.

### Hospital and Laboratory Equipment

Hospital and laboratory equipment items are major sources of heat gain in conditioned spaces. Care must be taken in evaluating the probability and duration of simultaneous usage when many components are concentrated in one area, such as a laboratory, an operating room, etc. Commonly, heat gain from equipment in a laboratory ranges from 50 to 220 W/m<sup>2</sup> or, in laboratories with outdoor exposure, as much as four times the heat gain from all other sources combined.

**Medical Equipment.** It is more difficult to provide generalized heat gain recommendations for medical equipment than for general office equipment because medical equipment is much more varied in type and in application. Some heat gain testing has been done and can be presented, but the equipment included represents only a small sample of the type of equipment that may be encountered.

The data presented for medical equipment in Table 6 are relevant for portable and bench-top equipment. Medical equipment is very specific and can vary greatly from application to application. The data are presented to provide guidance in only the most general sense. For large equipment, such as MRI, engineers must obtain heat gain from the manufacturer.

**Laboratory Equipment.** Equipment in laboratories is similar to medical equipment in that it will vary significantly from space to space. Chapter 13 of the 1999 *ASHRAE Handbook—Applications* discusses heat gain from equipment, stating that it may range from 50 to 270 W/m<sup>2</sup> in highly automated laboratories. Table 7 lists some values for laboratory equipment, but, as is the case for medical equipment, it is for general guidance only. Wilkins and Cook (1999) also examined laboratory equipment heat gains.

### Office Equipment

Computers, printers, copiers, calculators, checkwriters, posting machines, etc., can generate 9 to 13 W/m<sup>2</sup> for general offices or 18 to 22 W/m<sup>2</sup> for purchasing and accounting departments. ASHRAE *Research Project 822* developed a method to measure the actual heat gain from equipment in buildings and the radiant/convective percentages (Hosni et al. 1998; Jones et al. 1998). This methodology was then incorporated into ASHRAE *Research Project 1055* and applied to a wide range of equipment (Hosni et al. 1999) as a follow-up to independent research by Wilkins et al. (1991) and Wilkins and McGaffin (1994). Komor (1997) found similar results. Analysis of measured data showed that results for office equipment could be generalized, but results from laboratory and hospital equipment proved too diverse. The following general guidelines for office equipment are a result of these studies.

**Nameplate Versus Measured Energy Use.** Nameplate data rarely reflect the actual power consumption of office equipment. Actual power consumption of such equipment is assumed equal to the total (radiant plus convective) heat gain, but the ratio of such energy to the nameplate value varies widely. ASHRAE *Research Project 1055* (Hosni et al. 1999) found that for general office equipment with nameplate power consumption of less than 1000 W, the

actual ratio of total heat gain to nameplate ranged from 25% to 50%, but when all tested equipment is considered, the range is broader. Generally, if the nameplate value is the only information known and no actual heat gain data are available for similar equipment, it would be conservative to use 50% of nameplate as heat gain and more nearly correct if 25% of nameplate were used. Much better results can be obtained, however, by considering the heat gain as being predictable based on the type of equipment.

Office equipment is grouped into categories such as computers, monitors, printers, facsimile machines, and copiers, with heat gain results within each group analyzed to establish patterns.

**Computers.** Based on tests by Hosni et al. (1999) and Wilkins and McGaffin (1994), nameplate values on computers should be ignored when performing cooling load calculations. Table 8 presents typical heat gain values for computers with varying degrees of safety factor.

**Monitors.** Based on monitors tested by Hosni et al. (1999), heat gain correlates approximately with screen size as

$$q_{mon} = 0.2S - 20 \quad (12)$$

where

$$q_{mon} = \text{heat gain from monitor, W}$$

$$S = \text{nominal screen size, mm}$$

Wilkins and McGaffin tested ten monitors (330 to 480 mm), finding the average heat gain value to be 60 W. This testing was done in 1992 when DOS was prevalent and the Windows™ operating system was just being introduced. Monitors displaying Windows consumed more power than those displaying DOS. Table 8 tabulates typical values.

**Laser Printers.** Hosni et al. (1999) found that the power consumed by laser printers, and therefore the heat gain, depended largely on the level of throughput for which the printer was designed. It was observed that smaller printers are used more intermittently and that larger printers may run continuously for longer periods. Table 9 presents data on laser printers.

These data can be applied by taking the value for continuous operation and then applying an appropriate diversity factor. This would likely be most appropriate for larger open office areas. Another approach could be to take the value that most closely matches the expected operation of the printer with no diversity. This may be appropriate when considering a single room or small area.

**Copiers.** Hosni et al. (1999) also tested five copy machines considered to be of two types, desktop and office (freestanding high-volume copiers). Larger machines used in production environments were not addressed. Table 9 summarizes of the results. It was observed that desktop copiers rarely operated continuously but that office copiers frequently operated continuously for periods of an hour or more.

**Miscellaneous Office Equipment.** Table 10 presents data on miscellaneous office equipment such as vending machines and mailing equipment.

**Diversity.** The ratio of the measured peak electrical load at the equipment panels to the sum of the maximum electrical load of each individual item of equipment is the usage diversity. A small, one- or two-person office containing equipment listed in Tables 8 through 10 can be expected to contribute heat gain to the space at the sum of the appropriate listed values. Progressively larger areas with many equipment items will always experience some degree of usage diversity resulting from whatever percentage of such equipment is not in operation at any given time.

Wilkins and McGaffin (1994) measured diversity in 23 areas within five different buildings totaling over 25 600 m<sup>2</sup>. Diversity was found to range between 37 and 78%, with the average (normalized based on area) being 46%. Figure 4 illustrates the relationship between nameplate, the sum of the peaks, and the actual electrical load with diversity accounted for, based on the average of the total

Table 5 Recommended Rates of Heat Gain From Typical Commercial Cooking Appliances

Appliance	Size	Energy Rate, W		Recommended Rate of Heat Gain, <sup>a</sup> W

area tested. Data on actual diversity can be used as a guide, but diversity varies significantly with occupancy. The proper diversity factor for an office of mail order catalog telephone operators is different from that for an office of sales representatives who travel regularly.

**Heat Gain per Unit Area.** Wilkins (1998) and Wilkins and Hosni (2000) summarized recent research on a heat gain per unit area basis. The diversity testing showed that the actual heat gain per unit area, or load factor, ranged from 4.7 to 11.6 W/m<sup>2</sup>, with an average (normalized based on area) of 8.7 W/m<sup>2</sup>. Spaces tested

**Fig. 4 Office Equipment Load Factor Comparison** (Wilkins and McGaffin 1994)

were fully occupied and highly automated, comprising 21 unique areas in five buildings, with a computer and monitor at every workstation. Table 11 presents a range of load factors with a subjective description of the type of space to which they would apply. Table 12 presents more specific data that can be used to better quantify the amount of equipment in a space and the expected load factor. The medium load density is likely to be appropriate for most standard office spaces. Medium/heavy or heavy load densities may be encountered but can be considered extremely conservative estimates even for densely populated and highly automated spaces.

**Radiant Convective Split.** Hosni et al. (1999) found that the radiant-convective split for equipment was fairly uniform, the most important differentiating feature being whether or not the equipment had a cooling fan. Table 13 is a summary of those results.

**HEAT GAIN THROUGH FENESTRATION AREAS**

The primary weather-related variable influencing the cooling load for a building is solar radiation. The effect of solar radiation is more pronounced and immediate in its impact on exposed non-opaque surfaces. The calculation of solar heat gain and conductive heat transfer through various glazing materials and associated mounting frames, with or without interior and/or exterior shading devices, is discussed in Chapter 30. This chapter covers the

application of such data to the overall heat gain evaluation and the conversion of the calculated heat gain into a composite cooling load for the conditioned space. Table 14 includes some useful solar equations.

**Fenestration Direct Solar, Diffuse Solar, and Conductive Heat Gains**

For fenestration heat gain, use the following equations:

Direct beam solar heat gain  $q_b$ :

$$q_b = AE_D \text{SHGC}(\theta) \text{IAC} \quad (13)$$

Diffuse solar heat gain  $q_d$ :

$$q_d = A(E_d + E_r) \langle \text{SHGC} \rangle_D \text{IAC} \quad (14)$$

Conductive heat gain  $q_c$ :

$$q_c = UA(T_{out} - T_{in}) \quad (15)$$

Total fenestration heat gain  $Q$ :

$$Q = q_b + q_d + q_c \quad (16)$$

where

$A$  = window area,  $\text{m}^2$

$E_D$ ,  $E_d$ , and  $E_r$  = direct, diffuse, and ground-reflected irradiance, calculated using the equations in Table 14

$\text{SHGC}(\theta)$  = direct solar heat gain coefficient as a function of incident angle  $\theta$ ; may be interpolated between values in Table 13 of Chapter 30

$\langle \text{SHGC} \rangle_D$  = diffuse solar heat gain coefficient (also referred to as hemispherical SHGC); from Table 13 of Chapter 30

$T_{in}$  = inside temperature,  $^{\circ}\text{C}$

$T_{out}$  = outside temperature,  $^{\circ}\text{C}$

$U$  = overall U-factor, including frame and mounting orientation from Table 4 of Chapter 30,  $\text{W}/(\text{m}^2 \cdot \text{K})$

IAC = inside shading attenuation coefficient, = 1.0 if no inside shading device

If specific window manufacturer's SHGC and U-factor data are available, those should be used. For fenestration equipped with inside shading (blinds, drapes or shades), IAC is listed in Tables 19,

20, and 22 of Chapter 30. The inside shading attenuation coefficients given are used to calculate both direct and diffuse solar heat gains.

### Exterior Shading

Nonuniform exterior shading, caused by roof overhangs, side fins, or building projections, requires separate hourly calculations for the externally shaded and unshaded areas of the window in question, with the inside shading SHGC still used to account for any internal shading devices. The areas, shaded and unshaded, depend on the location of the shadow line on a surface in the plane of the glass. Sun (1968) developed fundamental algorithms for analysis of shade patterns. McQuiston and Spitler (1992) provide graphical data to facilitate shadow line calculation.

An alternative, more accurate method described by Todorovic et al. (1993) first calculates cooling loads as if the external shading were absent, then adjusts (reduces) the result to account for the shading effect. This correction applies a "negative cooling load factor," calculated in much the same way as a conventional cooling load but using the time-varying area of the shaded portion of the glass as the heat gain element. Todorovic (1987) describes the solution of the moving shade line problem in the context of consequent cooling load.

The equations for calculating shade angles [Chapter 30, Equations (107) to (110)] can be used to determine the shape and area of moving shadow falling across a given window from external shading elements during the course of a design day. Thus, a subprofile of heat gain for that window can be created by separating its sunlit and shaded areas for each hour.

**Table 14 Solar Equations**

#### Solar Angles

All angles are in degrees. The solar azimuth  $\phi$  and the surface azimuth  $\psi$  are measured in degrees from south; angles to the east of south are negative, and angles to the west of south are positive. Calculate solar altitude, azimuth, and surface incident angles as follows:

Apparent solar time AST, in decimal hours:

$$\text{AST} = \text{LST} + \text{ET}/60 + (\text{LSM} - \text{LON})/15$$

Hour angle  $H$ , degrees:

$$H = 15(\text{hours of time from local solar noon}) = 15(\text{AST} - 12)$$

Solar altitude  $\beta$ :

$$\sin\beta = \cos L \cos\delta \cos H + \sin L \sin\delta$$

Solar azimuth  $\phi$ :

$$\cos\phi = (\sin\beta \sin L - \sin\delta) / (\cos\beta \cos L)$$

Surface-solar azimuth  $\gamma$ :

$$\gamma = \phi - \psi$$

Incident angle  $\theta$ :

$$\cos\theta = \cos\beta \cos\gamma \sin\Sigma + \sin\beta \cos\Sigma$$

where

ET = equation of time, decimal minutes

$L$  = latitude

LON = local longitude, decimal degrees of arc

LSM = local standard time meridian, decimal degrees of arc

=  $60^{\circ}$  for Atlantic Standard Time

=  $75^{\circ}$  for Eastern Standard Time

=  $90^{\circ}$  for Central Standard Time

=  $105^{\circ}$  for Mountain Standard Time

=  $120^{\circ}$  for Pacific Standard Time

=  $135^{\circ}$  for Alaska Standard Time

=  $150^{\circ}$  for Hawaii-Aleutian Standard Time

LST = local standard time, decimal hours

$\delta$  = solar declination,  $^{\circ}$

$\psi$  = surface azimuth,  $^{\circ}$

$\Sigma$  = surface tilt from horizontal, horizontal =  $0^{\circ}$

Values of ET and  $\delta$  are given in Table 7 of Chapter 30 for the 21st day of each month.

#### Direct, Diffuse, and Total Solar Irradiance

Direct normal irradiance  $E_{DN}$

$$\text{If } \beta > 0 \quad E_{DN} = \left[ \frac{A}{\exp(B/\sin\beta)} \right] \text{CN}$$

Otherwise,  $E_{DN} = 0$

Surface direct irradiance  $E_D$

If  $\cos\theta > 0$   $E_D = E_{DN} \cos\theta$

Otherwise,  $E_D = 0$

Ratio  $Y$  of sky diffuse on vertical surface to sky diffuse on horizontal surface

If  $\cos\theta > -0.2$   $Y = 0.55 + 0.437 \cos\theta + 0.313 \cos^2\theta$

Otherwise,  $Y = 0.45$

Diffuse irradiance  $E_d$

Vertical surfaces  $E_d = CYE_{DN}$

Surfaces other than vertical  $E_d = CE_{DN}(1 + \cos\Sigma)/2$

Ground-reflected irradiance  $E_r = E_{DN}(C + \sin\beta)\rho_g(1 - \cos\Sigma)/2$

Total surface irradiance  $E_t = E_D + E_d + E_r$

where

$A$  = apparent solar constant

$B$  = atmospheric extinction coefficient

$C$  = sky diffuse factor

CN = clearness number multiplier for clear/dry or hazy/humid locations. See Figure 5 in Chapter 32 of the 1999 ASHRAE Handbook—Applications for CN values.

$E_d$  = diffuse sky irradiance

$E_r$  = diffuse ground-reflected irradiance

$\rho_g$  = ground reflectivity

Values of  $A$ ,  $B$ , and  $C$  are given in Table 7 of Chapter 30 for the 21st day of each month. Values of ground reflectivity  $\rho_g$  are given in Table 10 of Chapter 30.

**Temperature Considerations**

To estimate the conductive heat gain through fenestration at any time, applicable values of the outdoor and indoor dry-bulb temperatures must be used. Chapter 27 gives monthly cooling load design values of outdoor dry-bulb temperatures for many locations. These are generally midafternoon temperatures; for other times, the method described below in the section on Outdoor Air Temperatures can be used to estimate temperatures. Where local microclimatic conditions prevail or data are not included in Chapter 27, local weather stations or the National Oceanic and Atmospheric Administration can supply temperature data. Winter design temperatures should not be used because such data are for heating design rather than coincident conductive heat gain with sunlit glass during the winter months.

**HEAT GAIN THROUGH EXTERIOR SURFACES**

Heat gain through exterior opaque surfaces is derived from the same elements of solar radiation and thermal gradient as that for fenestration areas. It differs primarily as a function of the mass and nature of the wall or roof construction, since those elements affect the rate of conductive heat transfer through the composite assembly to the interior surface.

**SOL-AIR TEMPERATURE**

Sol-air temperature is the temperature of the outdoor air that in the absence of all radiation changes gives the same rate of heat entry into the surface as would the combination of incident solar radiation, radiant energy exchange with the sky and other outdoor surroundings, and convective heat exchange with the outdoor air.

**Heat Flux into Exterior Sunlit Surfaces**

The heat balance at a sunlit surface gives the heat flux into the surface  $q/A$  as

$$\frac{q}{A} = \alpha E_t + h_o(t_o - t_s) - \epsilon \Delta R \tag{17}$$

where

- $\alpha$  = absorptance of surface for solar radiation
- $E_t$  = total solar radiation incident on surface,  $W/(m^2 \cdot K)$
- $h_o$  = coefficient of heat transfer by long-wave radiation and convection at outer surface,  $W/(m^2 \cdot K)$
- $t_o$  = outdoor air temperature, °C
- $t_s$  = surface temperature, °C
- $\epsilon$  = hemispherical emittance of surface
- $\Delta R$  = difference between long-wave radiation incident on surface from sky and surroundings and radiation emitted by blackbody at outdoor air temperature,  $W/m^2$

Assuming the rate of heat transfer can be expressed in terms of the sol-air temperature  $t_e$ ,

$$\frac{q}{A} = h_o(t_e - t_s) \tag{18}$$

and from Equations (17) and (18),

$$t_e = t_o + \frac{\alpha E_t}{h_o} - \frac{\epsilon \Delta R}{h_o} \tag{19}$$

**Horizontal Surfaces.** For horizontal surfaces that receive long-wave radiation from the sky only, an appropriate value of  $\Delta R$  is about  $63 W/m^2$ , so that if  $\epsilon = 1$  and  $h_o = 17 W/(m^2 \cdot K)$ , the long-wave correction term is about 4 K (Bliss 1961) and the correction itself thus -4 K.

**Vertical Surfaces.** Because vertical surfaces receive long-wave radiation from the ground and surrounding buildings as well as from

the sky, accurate  $\Delta R$  values are difficult to determine. When solar radiation intensity is high, surfaces of terrestrial objects usually have a higher temperature than the outdoor air; thus, their long-wave radiation compensates to some extent for the sky's low emittance. Therefore, it is common practice to assume  $\epsilon \Delta R = 0$  for vertical surfaces.

**Tabulated Temperature Values**

The sol-air temperatures in Table 15 have been calculated based on  $\epsilon \Delta R/h_o$  values of 4 K for horizontal surfaces and 0 K for vertical surfaces; total solar intensity values used for the calculations were calculated using the equations included in Table 14.

**Surface Colors**

Sol-air temperature values are given for two values of the parameter  $\alpha/h_o$  (Table 15); the value of 0.026 is appropriate for a light-colored surface, while 0.052 represents the usual maximum value for this parameter (i.e., for a dark-colored surface or any surface for which the permanent lightness can not reliably be anticipated).

**Example 1. Calculating sol-air temperature using solar equations.** Calculate the sol-air temperature at 3 P.M., Central Daylight Time on July 21 for a vertical light-colored wall surface, facing southwest, located at 40° North latitude and 90° West longitude, with an outdoor temperature of 34.4°C. The clearness number CN is assumed to be 1.0 and ground reflectivity  $\rho_g = 0.2$ .

**Solution:** Sol-air temperature is calculated using Equation (19). For a light-colored wall,  $\alpha/h_o = 0.026$ , and for vertical surfaces,  $\epsilon \Delta R/h_o = 0$ . The solar irradiance  $E_t$  must be determined using the equations in Table 14.

**Solar Angles:**

$\psi$  = southwest orientation = +45°.  $\Sigma$  = surface tilt from horizontal (where horizontal = 0°) = 90° for vertical wall surface. Local solar time (LST) is one hour earlier than Daylight Time, so 3 P.M. DST = 2 P.M. LST = hour 14. Calculate solar altitude, solar azimuth, surface solar azimuth, and incident angle as follows.

From Table 7 in Chapter 30, solar position data and constants for July 21 are

- ET = -6.2 min
- $\delta = 20.6^\circ$
- A = 1085 W/m<sup>2</sup>
- B = 0.207
- C = 0.136

Local standard meridian (LSM) for Central Time Zone = 90°. Apparent solar time AST

$$\begin{aligned} \text{AST} &= \text{LST} + \text{ET}/60 + (\text{LSM} - \text{LON})/15 \\ &= 14 + (-6.2/60) + [(90 - 90)/15] \\ &= 13.897 \end{aligned}$$

Hour angle  $H$ , degrees:

$$\begin{aligned} H &= 15(\text{AST} - 12) \\ &= 15(13.897 - 12) \\ &= 28.45^\circ \end{aligned}$$

Solar altitude  $\beta$ :

$$\begin{aligned} \sin \beta &= \cos L \cos \delta \cos H + \sin L \sin \delta \\ &= \cos(40) \cos(20.6) \cos(28.45) + \sin(40) \sin(20.6) \\ &= 0.8566 \\ \beta &= \sin^{-1}(0.8566) = 58.9^\circ \end{aligned}$$

Solar azimuth  $\phi$ :

$$\begin{aligned} \cos \phi &= (\sin \beta \sin L - \sin \delta) / (\cos \beta \cos L) \\ &= [(\sin(58.9) \sin(40) - \sin(20.6))] / [\cos(58.9) \cos(40)] \\ &= 0.502 \\ \phi &= \cos^{-1}(0.502) = 59.9^\circ \end{aligned}$$

Surface-solar azimuth  $\gamma$ :

$$\begin{aligned} \gamma &= \phi - \psi \\ &= 59.9 - 45 \\ &= 14.9^\circ \end{aligned}$$

Table 15 Sol-Air Temperatures for July 21, 40° North Latitude

Incident angle  $\theta$ :

$$\begin{aligned} \cos\theta &= \cos\beta\cos\gamma\sin\Sigma + \sin\beta\cos\Sigma \\ &= \cos(58.9)\cos(14.9)\sin(90) + \sin(58.9)\cos(90) \\ &= 0.499 \\ \theta &= \cos^{-1}(0.499) = 60.1^\circ \end{aligned}$$

**Direct, Diffuse, and Total Solar Irradiance:**

Direct normal irradiance  $E_{DN}$

$$\begin{aligned} E_{DN} &= \left[ \frac{A}{\exp(B/\sin\beta)} \right] \text{CN} \\ &= \frac{1085}{\exp[0.207/\sin(58.9)]} (1.0) \\ &= 852 \text{ W/m}^2 \end{aligned}$$

Surface direct irradiance  $E_D$

$$\begin{aligned} E_D &= E_{DN}\cos\theta \\ &= (852)\cos(60.1) \\ &= 425 \text{ W/m}^2 \end{aligned}$$

Ratio  $Y$  of sky diffuse on vertical surface to sky diffuse on horizontal surface

$$\begin{aligned} Y &= 0.55 + 0.437 \cos\theta + 0.313 \cos^2\theta \\ &= 0.55 + 0.437 \cos(60.1) + 0.313 \cos^2(60.1) \\ &= 0.846 \end{aligned}$$

Diffuse irradiance  $E_d$

Vertical surfaces

$$\begin{aligned} E_d &= CYE_{DN} \\ &= (0.136)(0.846)(852) \\ &= 98 \text{ W/m}^2 \end{aligned}$$

Ground-reflected irradiance  $E_r$

$$\begin{aligned} E_r &= E_{DN}(C + \sin\beta)\rho_g(1 - \cos\Sigma)/2 \\ &= (852)[0.136 + \sin(58.9)](0.2)[1 - \cos(90)]/2 \\ &= 85 \text{ W/m}^2 \end{aligned}$$

Total surface irradiance  $E_t$

$$\begin{aligned} E_t &= E_D + E_d + E_r \\ &= 425 + 98 + 85 \\ &= 608 \text{ W/m}^2 \end{aligned}$$

**Sol-air temperature** [from Equation (19)]:

$$\begin{aligned} t_e &= t_o + \alpha E_t/h_o - \varepsilon\Delta R/h_o \\ &= 34.4 + (0.026)(608) - 0 \\ &= 50.2^\circ\text{C} \end{aligned}$$

This procedure was used to calculate the sol-air temperatures included in Table 15. Due to the tedious solar angle and intensity calculations, use of a simple computer spreadsheet or other computer software implementing these calculations can reduce the effort involved. A spreadsheet is illustrated in Table 16, calculating a 24 h sol-air temperature profile for the data of this example.

**OUTDOOR AIR TEMPERATURES**

The hourly air temperatures in Column 2, Table 16, are for a location with a design temperature of 35°C and a range of 11.7 K. To compute corresponding temperatures for other locations, select a suitable design temperature from Table 4B of Chapter 27 for the month being calculated and note the outdoor daily range from Table 1B of Chapter 27. For each hour, take the percentage of the daily range indicated in Table 17 of this chapter and subtract it from the design temperature.

**Example 2. Air temperature calculation.** Calculate the July dry-bulb temperature at 1200 h for Reno, Nevada.

**Solution:** From Table 1B, Chapter 27, the daily range is 20.7 K, and from Table 4B, Chapter 27, the 1% design dry-bulb temperature for July is 36°C. From Table 17, the percentage of the daily range at 1200 h is 23%. Thus, the dry-bulb temperature at 1200 is  $36 - (0.23 \times 20.7) = 31.2^\circ\text{C}$ .

**Data Limitations**

The outdoor daily range is the difference between the average daily maximum and average daily minimum temperatures during the warmest month. More reliable results could be obtained by determining or estimating the shape of the temperature curve for typical hot days at the building site and considering each month separately. Peak cooling load is often determined by solar heat gain through fenestration; this peak may occur in winter months and/or at a time of day when outside air temperature is not at its peak.

## HEAT GAIN THROUGH INTERIOR SURFACES

Whenever a conditioned space is adjacent to a space with a different temperature, transfer of heat through the separating physical section must be considered. The heat transfer rate is given by

$$q = UA(t_b - t_i) \quad (20)$$

where

- $q$  = heat transfer rate, W
- $U$  = coefficient of overall heat transfer between adjacent and conditioned space, W/(m<sup>2</sup>·K)
- $A$  = area of separating section concerned, m<sup>2</sup>
- $t_b$  = average air temperature in adjacent space, °C
- $t_i$  = air temperature in conditioned space, °C

Values of  $U$  can be obtained from Chapter 25. Temperature  $t_b$  may differ greatly from  $t_i$ . The temperature in a kitchen or boiler room, for example, may be as much as 8 to 28 K above the outdoor air temperature. Actual temperatures in adjoining spaces should be measured when possible. Where nothing is known except that the adjacent space is of conventional construction, contains no heat sources, and itself receives no significant solar heat gain,  $t_b - t_i$  may be considered to be the difference between the outdoor air and conditioned space design dry-bulb temperatures minus 3 K. In some cases, the air temperature in the adjacent space will correspond to the outdoor air temperature or higher.

### Floors

For floors directly in contact with the ground or over an underground basement that is neither ventilated nor conditioned, heat transfer may be neglected for cooling load estimates.

## INFILTRATION AND VENTILATION HEAT GAIN

### Ventilation

Outdoor air must be introduced to ventilate conditioned spaces. Chapter 26 suggests minimum outdoor air requirements for representative applications, but the minimum levels are not necessarily adequate for all psychological attitudes and physiological responses. Where maximum economy in space and load is essential, as in submarines or other restricted spaces, as little as 0.5 L/s of outdoor air per person can be sufficient, provided that recirculated air is adequately decontaminated (Consolazio and Pecora 1947).

Local codes and ordinances frequently specify ventilation requirements for public places and for industrial installations. For example, minimum requirements for safe practice in hospital operating rooms are given in NFPA *Standard* 99. Although 100% outdoor air is sometimes used in operating rooms, this standard does not require it, and limiting the outdoor air to 6 to 8 changes per hour is finding increasing acceptance.

ASHRAE *Standard* 62 recommends minimum ventilation rates for most common applications. For general applications, such as offices, 10 L/s per person is suggested.

Ventilation air is normally introduced at the air-conditioning apparatus rather than directly into the conditioned space and thus becomes a cooling coil load component instead of a space load component. Calculations for estimating this heat gain are discussed later in the section on Heat Gain Calculations Using Standard Air Values.

Reducing heat gain from outdoor air by using filtered recirculated air in combination with outdoor air should be considered. Recirculated air can also be treated to control odor (see Chapter 13 of this volume and Chapter 44 of the 1999 *ASHRAE Handbook—Applications*).

### Infiltration

The principles of estimating infiltration in buildings, with emphasis on the heating season, are discussed in Chapter 26. For

the cooling season, infiltration calculations are usually limited to doors and windows. Air leakage through doors can be estimated using the information in Chapter 26. Table 3 in Chapter 26, adjusted for the average wind velocity in the locality, may be used to compute infiltration for windows. In calculating window infiltration for an entire structure, the total window area on all sides of the building is not involved since wind does not act on all sides simultaneously. In any case, infiltration from all windows in any two adjacent wall exposures should be included. A knowledge of the prevailing wind direction and velocity is helpful in selecting exposures.

When economically feasible, sufficient outdoor air should be introduced as ventilation air through the air-conditioning equipment to maintain a constant outward escape of air and thus eliminate the infiltration portion of the gain. The pressure maintained must overcome wind pressure through cracks and door openings. When the quantity of outside air introduced through the cooling equipment is not sufficient to maintain the required pressure to eliminate infiltration, the entire infiltration load should be included in the space heat gain calculations.

### Standard Air Volumes

Because the specific volume of air varies appreciably, calculations are more accurate when made on the basis of air mass instead of volume. However, volume values are often required for selection of coils, fans, ducts, etc., in which cases volume values based on measurement at standard conditions may be used for accurate results. One standard value is 1.2 kg (dry air)/m<sup>3</sup> (0.833 m<sup>3</sup>/kg). This density corresponds to about 16°C at saturation and 21°C dry air (at 101.325 kPa). Because air usually passes through the coils, fans, ducts, etc., at a density close to standard, the accuracy desired normally requires no correction. When airflow is to be measured at a particular condition or point, such as at a coil entrance or exit, the corresponding specific volume can be read from the psychrometric chart.

**Example 3. Standard air calculation.** Assume outdoor air at standard conditions is flowing at 10 m<sup>3</sup>/s. What is the flow rate when the outdoor air is at 35°C dry-bulb and 24°C wet-bulb (0.893 m<sup>3</sup>/kg)?

**Solution:** The measured rate at that condition should be 10 (0.893/0.833) = 10.7 m<sup>3</sup>/s.

### Heat Gain Calculations Using Standard Air Values

Air-conditioning design often requires calculation of the following.

#### 1. Total heat

Total heat gain  $q_t$  corresponding to the change of a given standard flow rate  $Q_s$  through an enthalpy difference  $\Delta h$  is

$$q_t = 1.2Q_s\Delta h \quad (21)$$

where air density = 1.2 kg/m<sup>3</sup>.

#### 2. Sensible heat

Sensible heat gain  $q_s$  corresponding to the change of dry-bulb temperature  $\Delta t$  for given airflow (standard conditions)  $Q_s$  is

$$q_s = 1.2(1.006 + 1.84W)Q_s\Delta t \quad (22)$$

where

- 1.006 = specific heat of dry air, kJ/(kg·K)
- $W$  = humidity ratio, kg (water)/kg (air)
- 1.84 = specific heat of water vapor, kJ/(kg·K)

The specific heats are for a range from about -75 to 90°C. When  $W = 0$ , the value of  $1.20(1.006 + 1.84W) = 1.21$ ; when  $W = 0.01$ , the value is 1.23; when  $W = 0.02$ , the value is 1.25; and when  $W = 0.03$ ,

the value is 1.27. Because a value of  $W = 0.01$  approximates conditions found in many air-conditioning problems, the sensible heat change (in  $W$ ) can normally be found as

$$q_s = 1.23Q_s\Delta t \quad (23)$$

### 3. Latent heat

Latent heat gain  $q_l$  corresponding to the change of humidity ratio  $\Delta W$  for given airflow (standard conditions)  $Q_s$  is

$$q_l = 1.20 \times 2500Q_s\Delta W = 3010Q_s\Delta W \quad (24)$$

where 2500 is the approximate heat content of 50% rh vapor at 24°C less the heat content of water at 10°C. 50% rh at 24°C is a common design condition for the space, and 10°C is normal condensate temperature from cooling and dehumidifying coils.

The constants 1.20, 1.23, and 3010 are useful in air-conditioning calculations at sea level (101.325 kPa) and for normal temperatures and moisture ratios. For other conditions, more precise values should be used. For an altitude of 1500 m (84.556 kPa), appropriate values are 1.00, 1.03, and 2500.

### LATENT HEAT GAIN FROM MOISTURE THROUGH PERMEABLE BUILDING MATERIALS

The diffusion of moisture through all common building materials is a natural phenomenon that is always present. Chapters 23 and 24 cover the principles and specific methods used to control moisture. Moisture transfer through walls is often neglected in the usual comfort air-conditioning application because the actual rate is quite small and the corresponding latent heat gain is insignificant. The permeability and permeance values for various building materials are given in Table 9, Chapter 25. Vapor retarders are frequently installed to keep moisture transfer to a minimum.

Certain industrial applications call for a low moisture content to be maintained in a conditioned space. In such cases, the latent heat gain accompanying moisture transfer through walls may be greater than any other latent heat gain. This gain is computed by

$$q_m = MA\Delta p_v(h_g - h_f) \quad (25)$$

where

- $q_m$  = latent heat gain, W
- $M$  = permeance of wall assembly,  $\text{ng}/(\text{s}\cdot\text{m}^2\cdot\text{Pa})$
- $A$  = area of wall surface,  $\text{m}^2$
- $\Delta p_v$  = vapor pressure difference, Pa
- $h_g$  = enthalpy at room conditions,  $\text{kJ}/\text{kg}$
- $h_f$  = enthalpy of water condensed at cooling coil,  $\text{kJ}/\text{kg}$   
= 2500  $\text{kJ}/\text{kg}$  when room temperature is 24°C and condensate off coil is 10°C

### HEAT GAIN FROM MISCELLANEOUS SOURCES

The calculation of the cooling load is affected by such factors as (1) type of HVAC system, (2) effectiveness of heat exchange surfaces, (3) fan location, (4) duct heat gain or loss, (5) duct leakage, (6) heat-extraction lighting systems, (7) type of return air system, and (8) sequence of controls. System performance needs to be analyzed as a sequence of individual psychrometric processes. The most straightforward method first defines all known (or desired) state points on a psychrometric chart. Next, the actual entering and leaving dry- and wet-bulb conditions are calculated for such components as the cooling and/or heating coils (based on zone or space load), the amount of outside air introduced into the system through the equipment, and the amount of heat gain or loss at various points.

This overall process must verify that the space conditions originally sought can actually be met by the designed system by considering all sensible and latent heat changes to the air as it travels from

the space conditions through the return air system and equipment back to the conditioned space. If the design is successful (i.e., within the degree of correctness of the various design assumptions), appropriate equipment components can safely be selected. If not, the designer must judge if the results will be “close enough” to satisfy the needs of the project, or if one or more assumptions and/or design criteria must first be modified and the calculations rerun.

### Heat Gain from Fans

Fans that circulate air through HVAC systems add energy to the system by one or all of the following processes:

- Temperature rise in the airstream from fan inefficiency. Depending on the equipment, fan efficiencies generally range between 50 and 70%, with an average value of 65%. Thus, some 35% of the energy required by the fan appears as instantaneous heat gain to the air being transported.
- Temperature rise in the airstream as a consequence of air static and velocity pressure. The “useful” 65% of the total fan energy that creates pressure to move air spreads out throughout the entire air transport system in the process of conversion to sensible heat. Designers commonly assume that the temperature change equivalent of this heat occurs at a single point in the system, depending on fan location as noted below.
- Temperature rise from heat generated by motor and drive inefficiencies. The relatively small gains from fan motors and drives are normally disregarded unless the motor and/or drive are physically located within the conditioned airstream. Equations (7), (8), and (9) may be used to estimate heat gains from typical motors. Belt drive losses are often estimated as 3% of the motor power rating. Conversion to temperature rise is calculated by Equation (26).

The location of each fan relative to other elements (primarily the cooling coil) and the type of system (e.g., single zone, multizone, double-duct, terminal reheat, VAV), along with the concept of equipment control (space temperature alone, space temperature and relative humidity, etc.), must be known before the analysis can be completed. A fan located upstream of the cooling coil (blowthrough supply fan, return air fan, outside air fan) adds the heat equivalent of its inefficiency to the airstream at that point; thus, a slightly elevated entering dry-bulb temperature to the cooling coil results. A fan located downstream of the cooling coil raises the dry-bulb temperature of air leaving the cooling coil. This rise can be offset by reducing the cooling coil temperature or, alternatively, by increasing airflow across the cooling coil as long as its impact on space conditions is considered.

### Duct Heat Gain and Leakage

Unless return air duct systems are extensive or subjected to rigorous conditions, only the heat gained or lost by supply duct systems is significant; it is normally estimated as a percentage of space sensible cooling load (usually about 1%) and applied to the dry-bulb temperature of the air leaving the coil in the form of an equivalent temperature reduction.

Air leakage out of (or into) ductwork can have much greater impact than conventional duct heat gain or loss, but it is normally about the same or less. Outward leakage from supply ducts is a direct loss of cooling and/or dehumidifying capacity and must be offset by increased airflow (sometimes reduced supply air temperatures) unless it enters the conditioned space directly. Inward leakage to return ducts causes temperature and/or humidity variations, but these are often ignored under ordinary circumstances due to the low temperature and pressure differentials involved. Chapter 34 has further details on duct sealing and leakage.

A well-designed and installed duct system should not leak more than 1 to 3% of the total system airflow. All HVAC equipment and

volume control units connected into a duct system are usually delivered from manufacturers with allowable leakage not exceeding 1 or 2% of maximum airflow rating. Where duct systems are specified to be sealed and leak tested, both low- and medium-pressure types can be constructed and required to fall within this range. Designers normally assume this loss to approximate 1% of the space load, handled in a similar manner to that for duct heat gain. Latent heat considerations are frequently ignored.

Poorly designed or installed duct systems can have leakage rates of 10 to 30%. Leakage from low-pressure lighting troffer connections lacking proper taping and sealing can be 35% or more of the terminal air supply. Improperly sealed high-pressure systems can leak as much as 10% or more from the high-pressure side alone. Such extremes destroy the validity of any load calculation. Although leaks do not always affect overall system loads enough to cause problems, they will always adversely impact required supply air quantities. Also, uninsulated supply ductwork running through return air plenums results in high thermal leakage, which reduces the space-cooling capability of the supply air and may cause condensation during a warm startup.

## HEAT BALANCE METHOD OF COOLING LOAD CALCULATION

The estimation of cooling load for a space involves calculating a surface-by-surface conductive, convective, and radiative heat balance for each room surface and a convective heat balance for the room air. Sometimes called the **exact solution**, these principles form the foundation for all methods described in this chapter.

Some of the computations required by this rigorous approach to calculating space cooling load make the use of modern digital computers essential. The heat balance procedure is not new. Many energy calculation programs have used it in some form for many years. The first implementation that incorporated all the elements to form a complete method was NBSLD (Kusuda 1967). The heat balance procedure is also implemented in both the BLAST and TARP energy analysis programs (Walton 1983). Prior to the implementation of ASHRAE *Research Project 875*, the method had never been described completely or in a form applicable to cooling load calculations. The papers resulting from RP-875 describe the heat balance procedure in detail (Pedersen et al. 1997, Liesen and Pedersen 1997, McClellan and Pedersen 1997).

The HB method is codified in the software called Hbfort that accompanies *Cooling and Heating Load Calculation Principles* (Pedersen et al. 1998).

### HEAT BALANCE MODEL ASSUMPTIONS

All calculation procedures involve some kind of model. All models require simplifying assumptions and therefore are approximate. The most fundamental assumption is that the air in the thermal zone can be modeled as **well mixed**, meaning it has a uniform temperature throughout the zone. ASHRAE *Research Project 664* (Fisher et al. 1997) established that this assumption is valid over a wide range of conditions.

The next major assumption is that the surfaces of the room (walls, windows, floor, etc.) can be treated as having

- Uniform surface temperatures
- Uniform long-wave (LW) and short-wave (SW) irradiation
- Diffuse radiating surfaces
- One-dimensional heat conduction within

The resulting formulation is called the **heat balance model**. It is important to note that the foregoing assumptions, although common, are quite restrictive and set certain limits on the information that can be obtained from the model.

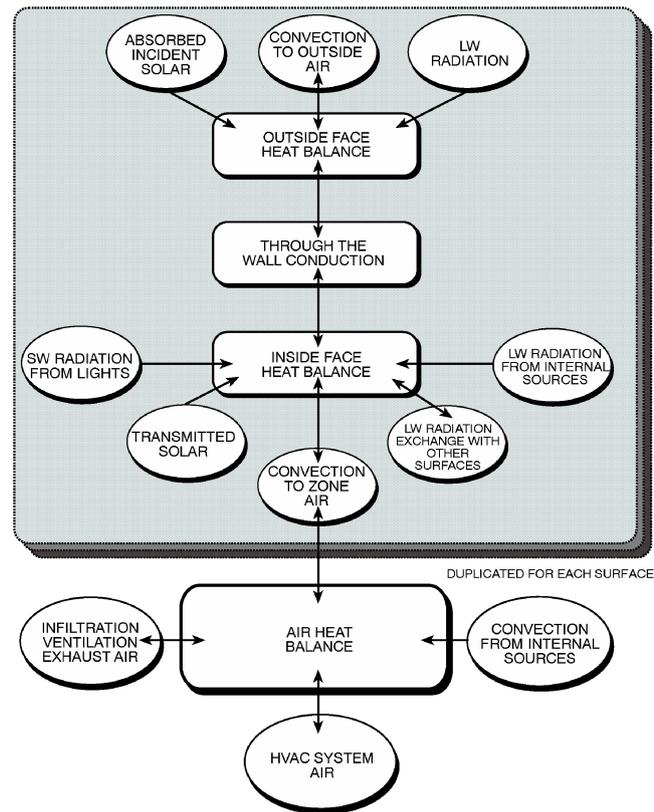

Fig. 5 Schematic of Heat Balance Processes in a Zone

### ELEMENTS OF HEAT BALANCE MODEL

Within the framework of the foregoing assumptions, the heat balance model can be viewed as four distinct processes:

1. Outside face heat balance
2. Wall conduction process
3. Inside face heat balance
4. Air heat balance

Figure 5 shows the relationship between these processes for a single opaque surface. The top part of the figure, inside the shaded box, is repeated for each of the surfaces enclosing the zone. The process for transparent surfaces would be similar but would have the absorbed solar component appear in the conduction process block instead of at the outside face. Also, the absorbed component would split into an inward-flowing fraction and an outward-flowing fraction. These components would participate in the surface heat balances.

#### Outside Face Heat Balance

The heat balance on the outside face of each surface is

$$q''_{\alpha sol} + q''_{LWR} + q''_{conv} - q''_{ko} = 0 \quad (26)$$

where

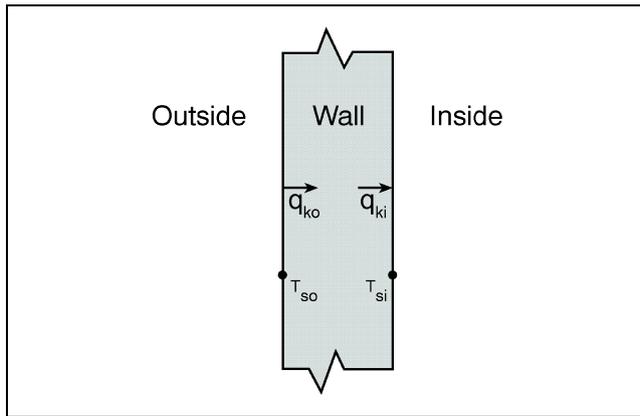

$q''_{\alpha sol}$  = absorbed direct and diffuse solar radiation flux ( $q/A$ ),  $W/m^2$

$q''_{LWR}$  = net long-wave radiation flux exchange with air and surroundings,  $W/m^2$

$q''_{conv}$  = convective exchange flux with outside air,  $W/m^2$

$q''_{ko}$  = conductive flux ( $q/A$ ) into wall,  $W/m^2$

All terms are positive for net flux to the face except the conduction term, which is traditionally taken to be positive in the direction from outside to inside the wall.

**Fig. 6 Schematic of Wall Conduction Process**

Each of the heat flux terms in Equation (26) has been modeled in several ways, and in some formulations the first three terms are combined by using the sol-air temperature.

### Wall Conduction Process

The wall conduction process has been formulated in more ways than any of the other processes. Among the possible ways to model this process are

1. Numerical finite difference
2. Numerical finite element
3. Transform methods
4. Time series methods

This process introduces part of the time dependence inherent in the load calculation process. Figure 6 shows schematically the surface temperatures on the inside and outside faces of the wall element and corresponding conductive heat fluxes away from the outside face and toward the inside face. All four quantities are functions of time. The direct formulation of the process has the two temperature functions as input or known quantities and the two heat fluxes as outputs or resultant quantities.

In some models, the surface heat transfer coefficients are included as part of the wall element. Then the temperatures in question are the inside and outside air temperatures. This is not an acceptable formulation because it hides the heat transfer coefficients and prohibits changing them as airflow conditions change. Also, it prohibits treating the internal long-wave radiation exchange appropriately.

Since the heat balances on both sides of the element induce both the temperature and heat flux, the solution technique must deal with this simultaneous condition. From a computational standpoint, two methods that have been used widely are a finite difference procedure and a method using conduction transfer functions. Because of the computational time advantage, the conduction transfer function formulation has been selected for the heat balance procedure presented here.

### Inside Face Heat Balance

The heart of the heat balance method is the internal heat balance involving the inside faces of the zone surfaces. This heat balance has many heat transfer components, and they are all coupled. Both long-wave (LW) and short-wave (SW) radiation are important, as well as wall conduction and convection to the air. The inside face heat balance for each surface can be written as follows:

$$q''_{LWX} + q''_{SW} + q''_{LWS} + q''_{ki} + q''_{sol} + q''_{conv} = 0 \quad (27)$$

where

$$q''_{LWX} = \text{net long-wave radiant flux exchange between zone surfaces, W/m}^2$$

$$q''_{SW} = \text{net short-wave radiation flux to surface from lights, W/m}^2$$

$$q''_{LWS} = \text{long-wave radiation flux from equipment in zone, W/m}^2$$

$$q''_{ki} = \text{conductive flux through the wall, W/m}^2$$

$$q''_{sol} = \text{transmitted solar radiative flux absorbed at surface, W/m}^2$$

$$q''_{conv} = \text{convective heat flux to zone air, W/m}^2$$

These terms are explained in the following paragraphs.

**LW Radiation Exchange among Zone Surfaces.** The two limiting cases for modeling internal LW radiation exchange are

1. Zone air is completely transparent to LW radiation
2. Zone air completely absorbs LW radiation from surfaces in the zone

Most heat balance models treat air as completely transparent, and then it does not participate in the LW radiation exchange among the surfaces in the zone. The second model is attractive because it can be formulated simply using a combined radiative and convective heat transfer coefficient from each surface to the zone air and in that way decouples the radiant exchange among surfaces in the zone. However, because the transparent air model allows the radiant exchange and is more realistic, the second model is inferior.

Furniture in a zone increases the amount of surface area that can participate in the radiative and convective heat exchanges. It also adds thermal mass to the zone. These two changes can affect the time response of the zone cooling load.

**SW Radiation from Lights.** The short-wavelength radiation from lights is usually assumed to be distributed over the surfaces in the zone in some manner. The HB procedure retains this approach but allows the distribution function to be changed.

**LW Radiation from Internal Sources.** The traditional model for this source defines a radiative/convective split for the heat introduced into a zone from equipment. The radiative part is then distributed over the surfaces in the zone in some manner. This is not a completely realistic model, and it departs from the heat balance principles. If it were handled in a true heat balance model, the equipment surfaces would be treated just as other LW radiant sources within the zone. However, since information about the surface temperature of equipment is rarely known, it is reasonable to keep the radiative/convective split concept even though it ignores the true nature of the radiant exchange. ASHRAE Research Project 1055 (Hosni et al. 1999) determined radiative/convective splits for many additional equipment types, as listed in Table 13.

**Transmitted Solar Heat Gain.** The calculation procedure for determining transmitted solar energy through fenestration as described in Chapter 30 uses the solar heat gain coefficient (SHGC) directly rather than relating it to double-strength glass as is done when using a shading coefficient (SC). The difficulty with this plan is that the SHGC includes both the transmitted solar and the inward-flowing fraction of the solar radiation absorbed in the window. With the heat balance method, this latter part should be added to the conduction component so that it can be included in the inside face heat balance.

Transmitted solar radiation is also distributed over surfaces in the zone in a prescribed manner. It is possible to calculate the actual position of beam solar radiation, but this involves partial surface irradiation, which is inconsistent with the rest of the zone model that assumes uniform conditions over an entire surface.

### Using SHGC to Calculate Solar Heat Gain

The total solar heat gain through fenestration consists of the directly transmitted solar radiation plus the inward-flowing fraction of the solar radiation that is absorbed in the glazing system.

Both parts contain beam and diffuse contributions. The transmitted radiation goes directly onto surfaces within the zone and is accounted for in the surface inside heat balance. The zone heat balance model accommodates the resulting heat fluxes without difficulty. The second part, the inward-flowing fraction of the absorbed solar radiation, gets involved in an interaction with the other surfaces of the enclosure through long-wave radiant exchange and with the zone air through convective heat transfer. As such, it is dependent both on the geometric and radiative properties of the zone enclosure and the convection characteristics inside and outside the zone. The solar heat gain coefficient (SHGC) combines the transmitted solar radiation and the inward-flowing fraction of the absorbed radiation. The SHGC is defined as

$$\text{SHGC} = \tau + \sum_{k=1}^n N_k \alpha_k \quad (28)$$

where

- $\tau$  = solar transmittance of glazing
- $\alpha_k$  = solar absorptance of the  $k$ th layer of the glazing system
- $n$  = number of layers
- $N_k$  = inward-flowing fraction of absorbed radiation in the  $k$ th layer

Note that Equation (28) is written in a generic way. It can be written for a specific incidence angle and/or radiation wavelength and integrated over the wavelength and/or angle, but the principle is the same in each case. Refer to Chapter 30 for the specific expressions.

Unfortunately, the inward-flowing fraction  $N$  interacts with the zone in many ways. This interaction can be expressed as

$$N = f(\text{inside convection coefficient, outside convection coefficient, glazing system overall heat transfer coefficient, zone geometry, zone radiation properties})$$

The only way to model these interactions correctly is to combine the window model with the zone heat balance model and solve the two simultaneously. This combination has been done recently in some energy analysis programs but is not generally available in load calculation procedures. In addition, the SHGC used for rating glazing systems is based on specific values of the inside, outside, and overall heat transfer coefficients and does not include any zonal long-wavelength radiation considerations. So, the challenge is to devise a way to use SHGC values within the framework of a heat balance calculation in the most accurate way possible. This will be done in the following paragraphs.

**Using SHGC Data.** The normal incidence SHGC used to rate and characterize glazing systems is not sufficient for determining solar heat gain for load calculations. These calculations require

solar heat gain as a function of the incident solar angle in order to determine the hour-by-hour gain profile. Thus, it is necessary to use angular SHGC values and also diffuse SHGC values. These can be obtained from the Window 4.1 program (LBL 1994). This program does a detailed optical and thermal simulation of a glazing system and, when applied to a single clear layer, produces the information shown in Table 18.

Table 18 shows the parameters as a function of incident solar angle and also the diffuse values. The specific parameters shown are

$V_{tc}$  = transmittance in the visible spectrum

$R_f$  and  $R_b$  = front and back surface visible reflectances

$T_{sol}$  = solar transmittance [symbol  $\tau$  in Equations (28), (29), and (30)]

$R_f$  and  $R_b$  = front and back surface solar reflectances

$A_{bs1}$  = solar absorptance for layer 1, which is the only layer in this case [symbol  $\alpha$  in Equations (28), (29), and (30)]

SHGC = solar heat gain coefficient at the center of the glazing

The parameters used for heat gain calculations are  $T_{sol}$ ,  $A_{bs}$ , and SHGC. For the specific convective conditions assumed in the Window 4.1 program, the inward-flowing fraction of the absorbed solar can be obtained by rearranging Equation (28) to give:

$$N_k \alpha_k = \text{SHGC} - \tau \quad (29)$$

This quantity, when multiplied by the appropriate incident solar intensity, will provide the amount of absorbed solar radiation that flows inward. In the heat balance formulation for zone loads, this heat flux is combined with that caused by conduction through the glazing and included in the surface heat balance.

The outward-flowing fraction of the absorbed solar radiation is used in the heat balance on the outside face of the glazing and is determined from

$$(1 - N_k) \alpha_k = \alpha_k - N_k \alpha_k = \alpha_k - (\text{SHGC} - \tau) \quad (30)$$

If there is more than one layer, the appropriate summation of absorptances must be done.

There is some potential inaccuracy in using the Window 4.1 SHGC values because the inward-flowing fraction part was determined under specific conditions for the inside and outside heat transfer coefficients. However, it is possible to rerun the program with inside and outside coefficients of one's own choosing. Normally, however, this is not a large effect, and only in highly absorptive glazing systems might it cause significant error.

**Table 18 Single Layer Glazing Data Produced by Window 4.1**

Parameter	Incident Angle										Diffuse (Hemis.)
	0	10	20	30	40	50	60	70	80	90	
$V_{tc}$	0.901	0.901	0.9	0.897	0.89	0.871	0.824	0.706	0.441	0	0.823
$R_f$	0.081	0.081	0.082	0.083	0.09	0.108	0.155	0.271	0.536	1	0.146
$R_b$	0.081	0.081	0.082	0.083	0.09	0.108	0.155	0.271	0.536	1	0.146
$T_{sol}$	0.85	0.85	0.848	0.844	0.835	0.814	0.766	0.652	0.399	0	0.77
$R_f$	0.075	0.074	0.075	0.076	0.082	0.099	0.144	0.255	0.509	1	0.136

<b>SHGC</b>	0.87	0.87	0.868	0.865	0.857	0.837	0.79	0.677	0.423	0	0.792

Source: LBL (1994).

For solar heat gain calculations, then, it seems reasonable to use the generic window property data that comes from Window 4.1. Considering Table 18, the procedure is as follows:

1. Determine the angle of incidence for the glazing.
2. Determine the corresponding SHGC.
3. Evaluate  $N_k \alpha_k$  using Equation (28).
4. Multiply  $T_{sol}$  by the incident beam radiation intensity to get the transmitted beam solar radiation.
5. Multiply  $N_k \alpha_k$  by the incident beam radiation intensity to get inward-flowing absorbed heat.
6. Repeat steps 2 through 5 with the diffuse parameters and diffuse radiation.
7. Add the beam and diffuse components of transmitted and inward-flowing absorbed heat.

Table 13 in Chapter 30 contains SHGC information for many additional glazing systems. That table is similar to Table 18 but is slightly abbreviated. Again, the information needed for heat gain calculations is  $T_{sol}$ , SHGC, and  $A_{bs}$ .

The same caution regarding the inside and outside heat transfer coefficients applies to the information in Table 13 in Chapter 30. Those values were also obtained with specific inside and outside heat transfer coefficients, and the inward-flowing fraction  $N$  is dependent upon those values.

**Convection to Zone Air.** The inside convection coefficients presented in past editions of this chapter and used in most load calculation procedures and energy programs are based on very old, natural convection experiments and do not accurately describe the heat transfer coefficients in a mechanically ventilated zone. In previous load calculation procedures, these coefficients were buried in the procedures and could not be changed. A heat balance formulation keeps them as working parameters. In this way, research results such as those from ASHRAE *Research Project 664* (Fisher 1998) can be incorporated into the procedures. It also permits determining the sensitivity of the load calculation to these parameters.

### Air Heat Balance

In heat balance formulations aimed at determining cooling loads, the capacitance of the air in the zone is neglected and the air heat balance is done as a quasi-steady balance in each time period. Four factors contribute to the air heat balance:

$$q_{conv} + q_{CE} + q_{IV} + q_{sys} = 0 \quad (31)$$

where

- $q_{conv}$  = convective heat transfer from surfaces, W
- $q_{CE}$  = convective parts of the internal loads, W
- $q_{IV}$  = sensible load due to infiltration and ventilation air, W
- $q_{sys}$  = heat transfer to/from the HVAC system, W

The **convection from zone surfaces**  $q_{conv}$  is the sum of all the convective heat transfer quantities from the inside surface heat balance. This comes to the air via the convective heat transfer coefficient on the surfaces.

The **convective parts of the internal loads**  $q_{CE}$  is the companion to  $q''_{LWS}$ , the radiant contribution from internal loads described previously [Equation (27)]. It is added directly to the air heat balance. Such a treatment also violates the tenets of the heat balance approach because surfaces producing the internal loads exchange heat with the zone air through normal convective processes. However, once again, this level of detail is generally not included in the heat balance, so it is included directly into the air heat balance instead.

In keeping with the well-mixed model for the zone air, any air that enters by way of **infiltration or ventilation** ( $q_{IV}$ ) is immediately mixed with the zone air. The amount of infiltration air is uncertain. Sometimes it is related to the indoor-outdoor temperature

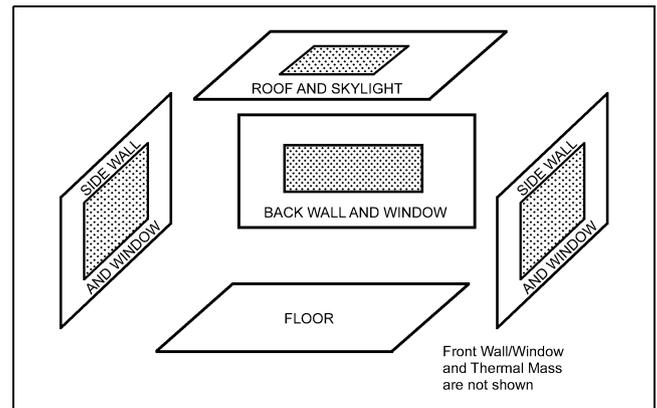

Fig. 7 Schematic View of General Heat Balance Zone

difference and wind speed; however it is determined, it is added directly to the air heat balance.

The conditioned air that enters the zone from the **HVAC system** and provides  $q_{sys}$  is also mixed directly with the zone air.

### GENERAL ZONE FOR LOAD CALCULATION

The heat balance procedure is tailored to a single thermal zone, shown in Figure 7. The definition of a thermal zone depends on how the fixed temperature is going to be controlled. If air is circulated through an entire building or an entire floor in such a way that it is uniformly well stirred, the entire building or floor could be considered a thermal zone. On the other hand, if each room has a different control scheme, each room may need to be considered as a separate thermal zone. The framework needs to be flexible enough to accommodate any zone arrangement, but the heat balance aspect of the procedure also requires that a complete zone be described. This zone consists of four walls, a roof or ceiling, a floor, and a “thermal mass surface” (described in the section on Input Required for Heat Balance Procedure). Each wall and the roof can include a window (or skylight in the case of the roof). This makes a total of 12 surfaces, any of which may have zero area if it is not present in the zone to be modeled.

The heat balance processes for this general zone are formulated for a 24 h steady-periodic condition. The variables of the problem are the inside and outside temperatures of the 12 surfaces plus either the HVAC system energy required to maintain a specified air temperature or the air temperature, if the system capacity is specified. This makes a total of  $25 \times 24$  or 600 variables. While it is possible to set up the problem for a simultaneous solution of these variables, the relatively weak coupling of the problem from one hour to the next permits a double iterative approach. One iteration is through all the surfaces in each hour, and the other iteration is through the 24 h of a day. This procedure automatically reconciles the nonlinear aspects of the surface radiative exchange and the other heat flux terms.

### MATHEMATICAL DESCRIPTION OF HEAT BALANCE PROCEDURE

#### Conduction Process

Because it links the outside and inside heat balances, the wall conduction process regulates the time dependence of the cooling load. For the heat balance procedure presented here, the wall conduction process is formulated using **conduction transfer functions** (CTFs), which relate conductive heat fluxes to the current and past surface temperatures and the past heat fluxes. The general form for the inside heat flux is

$$q''_{ki}(t) = -Z_o T_{si, \theta} - \sum_{j=1}^{nz} Z_j T_{si, \theta-j\delta} + Y_o T_{so, \theta} + \sum_{j=1}^{nz} Y_j T_{so, \theta-j\delta} + \sum_{j=1}^{nq} \Phi_j q''_{ki, \theta-j\delta} \quad (32)$$

For the outside heat flux, the form is

$$q''_{ko}(t) = -Y_o T_{si, \theta} - \sum_{j=1}^{nz} Y_j T_{si, \theta-j\delta} + X_o T_{so, \theta} + \sum_{j=1}^{nz} X_j T_{so, \theta-j\delta} + \sum_{j=1}^{nq} \Phi_j q''_{ko, \theta-j\delta} \quad (33)$$

where

- $X_j$  = outside CTF,  $j = 0, 1, \dots, nz$
- $Y_j$  = cross CTF,  $j = 0, 1, \dots, nz$
- $Z_j$  = inside CTF,  $j = 0, 1, \dots, nz$
- $\Phi_j$  = flux CTF,  $j = 1, 2, \dots, nq$
- $\theta$  = time
- $\delta$  = time step
- $T_{si}$  = inside face temperature, °C
- $T_{so}$  = outside face temperature, °C
- $q''_{ki}$  = conductive heat flux on inside face, W/m<sup>2</sup>
- $q''_{ko}$  = conductive heat flux on outside face, W/m<sup>2</sup>

The subscript following the comma indicates the time period for the quantity in terms of the time step  $\delta$ . Also, the first terms in the series have been separated from the rest in order to facilitate solving for the current temperature in the solution scheme.

The two summation limits  $nz$  and  $nq$  depend on wall construction and depend somewhat on the scheme used for calculating the CTFs. If  $nq = 0$ , the CTFs are generally referred to as **response factors**, but then theoretically  $nz$  is infinite. The values for  $nz$  and  $nq$  are generally set to minimize the amount of computation. A development of CTFs can be found in Hittle (1981).

### Heat Balance Equations

The primary variables in the heat balance for the general zone are the 12 inside face temperatures and the 12 outside face temperatures at each of the 24 h, assigning  $i$  as the surface index and  $j$  as the hour index, or, in the case of CTFs, the sequence index. Then, the primary variables are:

$$T_{so,i,j} = \text{outside face temperature, } i = 1, 2, \dots, 12; j = 1, 2, \dots, 24$$

$$T_{si,i,j} = \text{inside face temperature, } i = 1, 2, \dots, 12; j = 1, 2, \dots, 24$$

In addition,  $q_{sys,j}$  = cooling load,  $j = 1, 2, \dots, 24$

Equations (26) and (33) are combined and solved for  $T_{so}$  to produce 12 equations applicable in each time step:

$$T_{so,i,j} = \left( \sum_{k=1}^{nz} T_{si,i,j-k} Y_{i,k} - \sum_{k=1}^{nz} T_{so,i,j-k} Z_{i,k} - \sum_{k=1}^{nq} \Phi_{i,k} q''_{ko,i,j-k} + q''_{asol,i,j} + q''_{LWR,i,j} + T_{si,i,j} Y_{i,0} + T_{o,j} h_{co,i,j} \right) / (Z_{i,0} + h_{co,i,j}) \quad (34)$$

where

$$T_o = \text{outside air temperature}$$

$$h_{co} = \text{outside convection coefficient, introduced by using } q''_{conv} = h_{co}(T_o - T_{so})$$

Equation (34) shows the need for separating  $Z_{i,0}$  because the contribution of the current surface temperature to the conductive flux can be collected with the other terms involving that temperature.

Equations (27) and (32) are combined and solved for  $T_{si}$  to produce the next 12 equations:

$$T_{si,i,j} = \left( T_{si,i,j} Y_{i,0} + \sum_{k=1}^{nz} T_{so,i,j-k} Y_{i,k} - \sum_{k=1}^{nz} T_{si,i,j-k} Z_{i,k} + \sum_{k=1}^{nq} \Phi_{i,k} q''_{ki,i,j-k} + T_{a,j} h_{ci,j} + q''_{LWS} + q''_{LWX} + q''_{SW} + q''_{sol} \right) / (Z_{i,0} + h_{ci,i,j}) \quad (35)$$

where

$$T_a = \text{zone air temperature}$$

$$h_{ci} = \text{convective heat transfer coefficient on the inside, obtained from } q''_{conv} = h_{ci}(T_a - T_{si})$$

Note that in Equations (34) and (35), the opposite surface temperature at the current time appears on the right-hand side. The two equations could be solved simultaneously to eliminate those variables. Depending on the order of updating the other terms in the equations, this can have a beneficial effect on solution stability.

The remaining equation comes from the air heat balance, Equation (31). This provides the cooling load  $q_{sys}$  at each time step:

$$q_{sys,j} = \sum_{i=1}^{12} A_i h_{ci} (T_{si,i,j} - T_a) + q_{CE} + q_{IV} \quad (36)$$

In Equation (36), the convective heat transfer term is expanded to show the interconnection between the surface temperatures and the cooling load.

### Overall HB Iterative Solution Procedure

The iterative HB procedure consists of a series of initial calculations that proceed sequentially, followed by a double iteration loop as shown in the following steps:

1. Initialize areas, properties, and face temperatures for all surfaces, 24 h.
2. Calculate incident and transmitted solar flux for all surfaces and hours.
3. Distribute transmitted solar energy to all inside faces, 24 h.
4. Calculate internal load quantities for all 24 h.
5. Distribute LW, SW, and convective energy from internal loads to all surfaces for all hours.
6. Calculate infiltration and ventilation loads for all hours.
7. Iterate the heat balance according to the following scheme:

```

For Day = 1 to Maxdays
  For j = 1 to 24           {hours in the day}
    For Surfacer = 1 to Maxlter
      For i = 1 to 12       {The twelve zone surfaces}
        Evaluate Equations (34) and (35)
      Next i
    Next Surfacer
    Evaluate Equation (36)
  Next j
  If not converged, Next Day
  
```

8. Display results.

Generally, four or six surface iterations are sufficient to provide convergence. The convergence check on the day iteration should be based on the difference between the inside and the outside conductive heat flux terms  $q_k$ . A limit such as requiring the difference between all inside and outside flux terms to be less than 1% of either flux works well.

### INPUT REQUIRED FOR HEAT BALANCE PROCEDURE

Previous methods for calculating cooling loads attempted to simplify the procedure by precalculating representative cases and grouping the results with various correlating parameters. This generally tended to reduce the amount of information required to apply the procedure. In the case of the heat balance procedure, no precalculations are made, so the procedure requires a fairly complete description of the zone.

**Global Information.** Because the procedure incorporates a solar calculation, some global information is required, including latitude, longitude, time zone, month, day of month, north axis of the zone, and the zone height (floor to floor). Additionally, to take full advantage of the flexibility of the method to incorporate, for example, variable outside heat transfer coefficients, such things as wind speed, wind direction, and terrain roughness may be specified. Normally, these variables and others default to some reasonable set of values, but the flexibility remains.

**Wall Information (Each Wall).** Because the walls are involved in three of the fundamental processes (external and internal heat balance and wall conduction), each wall of the zone requires a fairly large set of variables. They include

- Facing angle with respect to building north
- Tilt (degrees from horizontal)
- Area
- Solar absorptivity outside
- Long-wave emissivity outside
- Short-wave absorptivity inside
- Long-wave emissivity inside
- Exterior boundary temperature condition (solar vs. nonsolar)
- External roughness
- Layer-by-layer construction information

Again, some of these parameters can be defaulted, but they are changeable, and they indicate the more fundamental character of the heat balance method since they are related to true heat transfer processes.

**Window Information (Each Window).** The situation for windows is similar to that for walls, but the windows require some additional information because of their role in the solar load. The necessary parameters include:

- Area
- Normal solar transmissivity
- Normal SHGC
- Normal total absorptivity
- Long-wave emissivity outside
- Long-wave emissivity inside
- Surface-to-surface thermal conductance
- Reveal (for solar shading)
- Overhang width (for solar shading)
- Distance from overhang to window (for solar shading)

**Roof and Floor Details.** The roof and floor surfaces are specified similarly to walls. The main difference is that the ground outside boundary condition will probably be specified more often for a floor.

**Thermal Mass Surface Details.** An “extra” surface, called a thermal mass surface, can serve several functions. It is included in the radiant heat exchange with the other surfaces in the space but is

only exposed to the inside air convective boundary condition. As an example, this surface would be used to account for the movable partitions in a space. The construction of the partitions is specified layer by layer, similar to specification for walls, and those layers store and release heat via the same conduction mechanism as walls. As a general definition, the extra thermal mass surface should be sized to represent all of the surfaces in the space that are exposed to the air mass, except the walls, roof, floor, and windows. In the formulation, both sides of the thermal mass participate in the exchange.

**Internal Heat Gain Details.** The space can be subjected to several internal heat sources: people, lights, electrical equipment, and infiltration. In the case of infiltration, the energy is assumed to go immediately into the air heat balance, so it is the least complicated of the heat gains. For the others, several parameters must be specified. These include the following fractions:

- Fraction of heat gain that is sensible energy
- Fraction of heat gain that is latent energy
- Fraction of energy that enters as short-wave radiation
- Fraction of energy that enters as long-wave radiation
- Fraction of energy that enters the air immediately as convection
- Activity level of people
- Fraction of energy of lighting heat gain that goes directly to the return air

**Radiant Distribution Functions.** As mentioned previously, the generally accepted assumptions for the heat balance method include specifying the distribution of radiant energy from several sources to the surfaces that enclose the space. This requires a distribution function that specifies the fraction of the total radiant input that is absorbed by each surface. The types of radiation that require distribution functions are

- Long-wave radiation from equipment and lights
- Short-wave radiation from lights
- Transmitted solar radiation

**Other Required Information.** Additional flexibility is included in the model so that results of research can be incorporated easily. This includes the capability to specify such things as

- Heat transfer coefficients/convection models
- Solar coefficients
- Sky models

The amount of input information required may seem extensive, but many of the parameters can be set to default values in most routine applications. However, all of the parameters listed can be changed when necessary to fit unusual circumstances or when additional information is obtained.

## RADIANT TIME SERIES (RTS) METHOD

The radiant time series (RTS) method is a new simplified method for performing design cooling load calculations that is derived from the heat balance (HB) method described above. It effectively replaces all other simplified (non-heat-balance) methods, such as the transfer function method (TFM), the cooling load temperature difference/cooling load factor (CLTD/CLF) method, and the total equivalent temperature difference/time averaging (TETD/TA) method.

The casual observer might well ask why yet another load calculation method is necessary. This method was developed in response to the desire to offer a method that is rigorous, yet does not require iterative calculations, and that quantifies each component contribution to the total cooling load. In addition, it is desirable for the user to be able to inspect and compare the coefficients for different construction and zone types in a form illustrating their relative impact

on the result. These characteristics of the RTS method make it easier to apply engineering judgment during the cooling load calculation process.

The RTS method is suitable for peak design load calculations, but it should not be used for annual energy simulations due to its inherent limiting assumptions. The RTS method, while simple in concept, involves too many calculations to be used practically as a manual method, although it can easily be implemented in a simple computerized spreadsheet, as illustrated in the examples. For a manual cooling load calculation method, refer to the CLTD/CLF method included in the 1997 ASHRAE Handbook—Fundamentals.

### RTS COOLING LOAD ASSUMPTIONS AND PRINCIPLES

Design cooling loads are based on the assumption of **steady-periodic conditions** (i.e., the design day’s weather, occupancy, and heat gain conditions are identical to those for preceding days such that the loads repeat on an identical 24 h cyclical basis). Thus, the heat gain for a particular component at a particular hour is the same as 24 h prior, which is the same as 48 h prior, etc. This assumption is the basis for the RTS derivation from the HB method.

Cooling load calculations must address two time-delay effects inherent in building heat transfer processes: (1) delay of conductive heat gain through opaque massive exterior surfaces (walls, roofs, or floors) and (2) delay of radiative heat gain conversion to cooling loads.

Exterior walls and roofs conduct heat due to temperature differences between outdoor and indoor air. In addition, solar energy on exterior surfaces is absorbed, then transferred by conduction to the building interior. Due to the mass and thermal capacity of the wall or roof construction materials, there is a substantial time delay in heat input at the exterior surface becoming heat gain at the interior surface.

As described earlier in the section on Cooling Load Principles, most heat sources transfer energy to a room by a combination of convection and radiation. The convection part of heat gain immediately becomes cooling load. The radiation part must first be absorbed by the finishes and mass of the interior room surfaces and becomes cooling load only when it is later transferred by convection from those surfaces to the room air. Thus, radiant heat gains become cooling loads over a delayed period of time.

### OVERVIEW OF THE RADIANT TIME SERIES METHOD

Figure 8 gives an overview of the radiant time series method. In the calculation of solar radiation, transmitted solar heat gain through windows, sol-air temperature, and infiltration, the RTS method is exactly the same as previous simplified methods (TFM and TETD/TA). Important areas that are different include the computation of conductive heat gain, the splitting of all heat gains into radiant and convective portions, and the conversion of radiant heat gains into cooling loads.

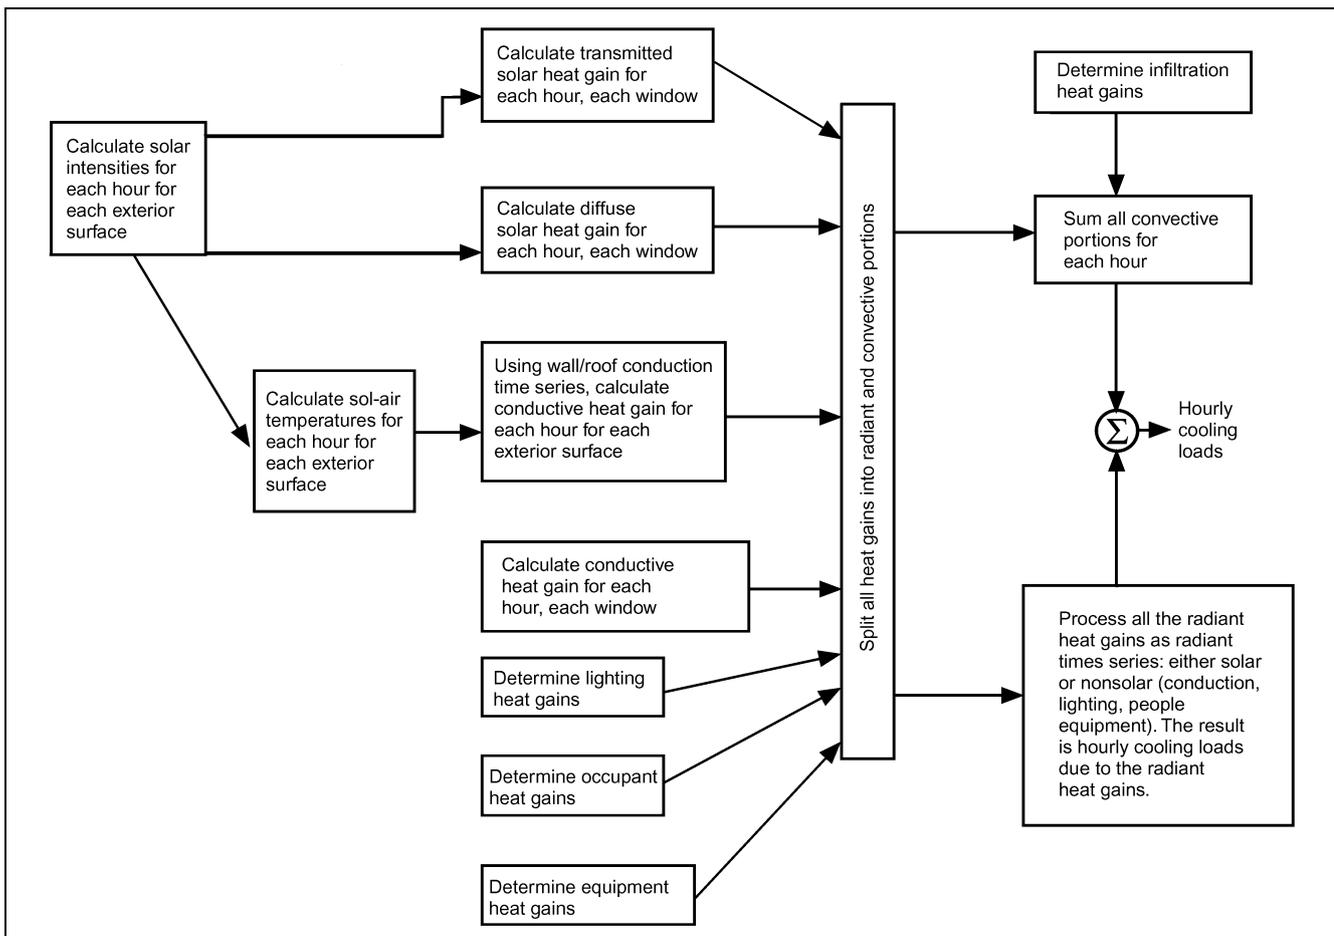

Fig. 8 Overview of Radiant Time Series Method

The RTS method accounts for both conduction time delay and radiant time delay effects by multiplying hourly heat gains by 24 h time series. The time series multiplication, in effect, distributes heat gains over time. Series coefficients, which are called **radiant time factors** and **conduction time factors**, are derived using the heat balance method. Radiant time factors reflect the percentage of an earlier radiant heat gain that becomes cooling load during the current hour. Likewise, conduction time factors reflect the percentage of an earlier heat gain at the exterior of a wall or roof that becomes

heat gain at the inside during the current hour. By definition, each radiant or conduction time series must total 100%.

These series can be used to easily compare the time-delay impact of one construction versus another. This ability to compare choices is of particular benefit in the design process, when all construction details may not have been decided. Comparison can illustrate the magnitude of difference between the choices, allowing the engineer to apply judgment and make more informed assumptions in estimating the load.

Figure 9 illustrates CTS values for three walls with similar U-factors but with light to heavy construction. Figure 10 illustrates CTS for three walls with similar construction but with different amounts of insulation, thus with significantly different U-factors. Figure 11 illustrates RTS values for zones varying from light to heavy construction.

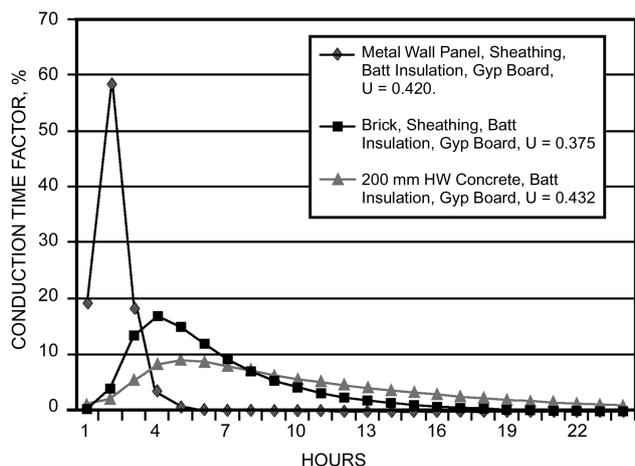

Fig. 9 CTS for Light to Heavy Walls

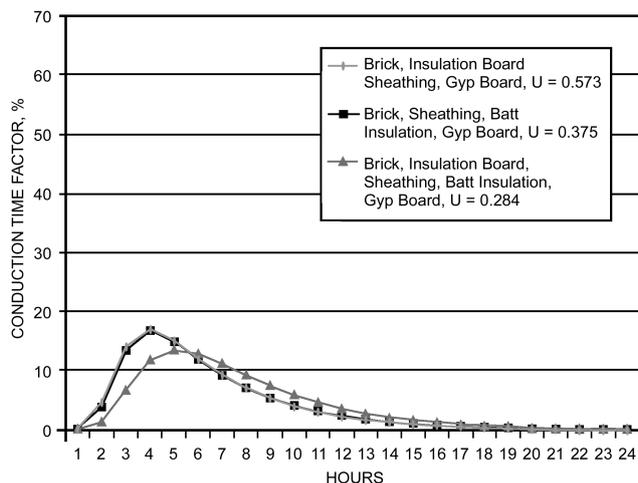

Fig. 10 CTS for Walls with Similar Mass and Increasing Insulation

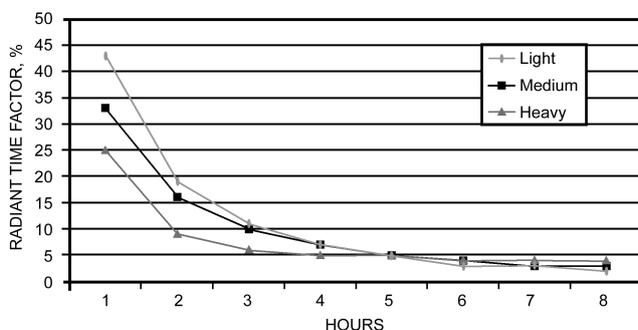

Fig. 11 RTS for Light to Heavy Construction

### RADIANT TIME SERIES PROCEDURE

The general procedure for calculating cooling load for each load component (lights, people, walls, roofs, windows, appliances, etc.) with RTS is as follows:

1. Calculate 24 h profile of component heat gain for design day (for conduction, first account for conduction time delay by applying conduction time series).
2. Split heat gains into radiant and convective parts (see Table 19 for radiant and convective fractions).
3. Apply appropriate radiant time series to radiant part of heat gains to account for time delay in conversion to cooling load.
4. Sum convective part of heat gain and delayed radiant part of heat gain to determine cooling load for each hour for each cooling load component.

After calculating cooling loads for each component for each hour, sum those to determine the total cooling load for each hour and select the hour with the peak load for design of the air-conditioning system. This process should be repeated for multiple design months to determine the month when the peak load occurs, especially with windows on southern exposures (northern exposure in southern latitudes), which can result in higher peak room cooling loads in winter months than in summer.

### Conductive Heat Gain Using Conduction Time Series

In the RTS method, conduction through exterior walls and roofs is calculated using conduction time series (CTS). Wall and roof conductive heat input at the exterior is defined by the familiar conduction equation as

Table 19 Convective and Radiant Percentages of Total Sensible Heat Gain

Heat Gain Source	Radiant Heat, %	Convective Heat, %
Transmitted solar, no inside shade	100	0
Window solar, with inside shade	63	37
Absorbed (by fenestration) solar	63	37
Fluorescent lights, suspended, unvented	67	33
Fluorescent lights, recessed, vented to return air	59	41
Fluorescent lights, recessed, vented to return air and supply air	19	81
Incandescent lights	80	20
People	See Table I	
Conduction, exterior walls	63	37
Conduction, exterior roofs	84	16
Infiltration and ventilation	0	100
Machinery and appliances (see Table 13)	20 to 80	80 to 20

$$q_{i,\theta-n} = UA(t_{e,\theta-n} - t_{rc}) \tag{37}$$

$$q_{\theta} = c_0 q_{i,\theta} + c_1 q_{i,\theta-1} + c_2 q_{i,\theta-2} + c_3 q_{i,\theta-3} + \dots + c_{23} q_{i,\theta-23} \tag{38}$$

where

- $q_{i,\theta-n}$  = conductive heat input for the surface  $n$  hours ago, W
- $U$  = overall heat transfer coefficient for the surface, W/(m<sup>2</sup>·K)
- $A$  = surface area, m<sup>2</sup>
- $t_{e,\theta-n}$  = sol-air temperature  $n$  hours ago, °C
- $t_{rc}$  = presumed constant room air temperature, °C

where

- $q_{\theta}$  = hourly conductive heat gain for the surface, W
- $q_{i,\theta}$  = heat input for the current hour, W
- $q_{i,\theta-n}$  = heat input  $n$  hours ago, W
- $c_0, c_1, \dots$  = conduction time factors

Conductive heat gain through walls or roofs can be calculated using conductive heat inputs for the current hours and past 23 h and conduction time series:

Conduction time factors for representative wall and roof types are included in Tables 20 and 21. Those values were derived by first calculating conduction transfer functions for each example wall and roof construction. The assumption of steady-periodic heat input conditions for design load calculations allowed the conduction transfer functions to be reformulated into periodic response factors

as demonstrated by Spitler and Fisher (1999a). The periodic response factors were further simplified by dividing the 24 periodic response factors by the respective overall wall or roof U-factor to form the conduction time series (CTS). The conduction time factors can then be used in Equation (38) and provide a means for comparison of time delay characteristics between different wall and roof constructions. Construction material data used in the calculations for walls and roofs included in Tables 20 and 21 are listed in Table 22.

Heat gains calculated for walls or roofs using periodic response factors (and thus CTS) are identical to those calculated using conduction transfer functions for the steady periodic conditions assumed in design cooling load calculations. The methodology for calculating periodic response factors from conduction transfer functions was originally developed as part of ASHRAE Research Project 875 (Spitler et al. 1997, Spitler and Fisher 1999b).

**Example 4. Wall heat gain using conduction time series.** Using the data from Example 1 and Table 15, calculate the heat gain at 3 P.M. Central Daylight Time on July 21 through 9.3 m<sup>2</sup> of a wall composed of light-colored 100 mm brick, 50 mm of insulation ( $R = 1.76 \text{ m}^2 \cdot \text{K}/\text{W}$ ) and 200 mm lightweight concrete block. An air space is included between the brick and insulation. Overall U-factor of the wall is 0.386 W/(m<sup>2</sup>·K). Inside room temperature is 23.9°C.

**Solution:** Conductive heat gain is calculated using Equations (37) and (38). First, calculate the 24 h heat input profile using Equation (37) and the sol-air temperatures from Table 15 for a southwest-facing wall with light exterior color:

$$\begin{aligned}
 q_{i,1} &= (0.386)(9.3)(24.4 - 23.9) = 2.0 \text{ W} \\
 q_{i,2} &= (0.386)(9.3)(24.4 - 23.9) = 2.0 \\
 q_{i,3} &= (0.386)(9.3)(23.9 - 23.9) = 0 \\
 q_{i,4} &= (0.386)(9.3)(23.3 - 23.9) = -2.0 \\
 q_{i,5} &= (0.386)(9.3)(23.3 - 23.9) = -2.0 \\
 q_{i,6} &= (0.386)(9.3)(24.3 - 23.9) = 1.6
 \end{aligned}$$

 \text{Total 24 h heat input} &= 779.1 \text{ W}
 \end{aligned}$$

These data are used with conduction time series to calculate the wall heat gain. From Table 20, the most similar wall construction is wall number 14. This is a brick and block wall that has similar mass and thermal capacity. Using Equation (38), the conduction time factors for wall 14 can be used in conjunction with the 24 h heat input profile calculated above to determine the wall heat gain at 3 P.M. Central Day-light Time (which is actually 2 P.M. or hour 14 local standard time):

Due to the tedious calculations involved, use of a simple computer spreadsheet or other computer software implementing these calculations can reduce the effort involved. A spreadsheet is illustrated in Table 23, calculating a 24 h heat gain profile for the data of this example.

### Calculating Cooling Load Using RTS

The instantaneous cooling load is defined as the rate at which heat energy is convected to the zone air at a given point in time. The computation of cooling load is complicated by the radiant exchange between surfaces, furniture, partitions, and other mass in the zone. Most heat gain sources transfer energy by both convection and radiation. Radiative heat transfer introduces to the process a time dependency that is not easily quantified. Radiation is absorbed by the thermal masses in the zone and then later transferred by convection into the space. This process creates a time lag and dampening effect. The convection portion of heat gains, on the other hand, is assumed to immediately become cooling load in the hour in which that heat gain occurs.

Heat balance procedures calculate the radiant exchange between surfaces based on their surface temperatures and emissivities, but they typically rely on estimated “radiative-convective splits” to determine the contribution of internal loads, including people, light-

ing, appliances, and equipment, to the radiant exchange. The radiant time series procedure further simplifies the heat balance procedure by also relying on an estimated radiative-convective split of wall and roof conductive heat gain instead of simultaneously solving for the instantaneous convective and radiative heat transfer from each surface, as is done in the heat balance procedure.

Thus, the cooling load for each load component (lights, people, walls, roofs, windows, appliances, etc.) for a particular hour is the sum of the convective portion of the heat gain for that hour plus the time-delayed portion of radiant heat gains for that hour and the previous 23 h. Table 19 contains recommendations for splitting each of the heat gain components into convective and radiant portions.

The radiant time series method converts the radiant portion of hourly heat gains to hourly cooling loads using radiant time factors, the coefficients of the radiant time series. Radiant time factors are used to calculate the cooling load for the current hour on the basis of current and past heat gains. The radiant time series for a particular zone gives the time-dependent response of the zone to a single pulse of radiant energy. The series shows the portion of the radiant pulse that is convected to the zone air for each hour. Thus,  $r_0$  represents the fraction of the radiant pulse convected to the zone air in the current hour  $r_1$  in the previous hour, and so on. The radiant time series thus generated is used to convert the radiant portion of hourly heat gains to hourly cooling loads according to the following equation:

$$Q_{r,\theta} = r_0q_{r,\theta} + r_1q_{r,\theta-1} + r_2q_{r,\theta-2} + r_3q_{r,\theta-3} + \dots + r_{23}q_{r,\theta-23} \quad (39)$$

where

$$\begin{aligned}
 Q_{r,\theta} &= \text{radiant cooling load } (Q_r) \text{ for the current hour } (\theta), \text{ W} \\
 q_{r,\theta} &= \text{radiant heat gain for the current hour, W} \\
 q_{r,\theta-n} &= \text{radiant heat gain } n \text{ hours ago, W} \\
 r_0, r_1, \text{ etc.} &= \text{radiant time factors}
 \end{aligned}$$

The radiant cooling load for the current hour, which is calculated using RTS and Equation (39), is added to the convective portion to determine the total cooling load for that component for that hour.

Radiant time factors are generated by a heat balance based procedure. A separate series of radiant time factors is theoretically required for each unique zone and for each unique radiant energy distribution function assumption. For most common design applications, RTS variation depends primarily on the overall massiveness of the construction and the thermal responsiveness of the surfaces the radiant heat gains strike.

One of the goals in developing RTS was to provide a simplified method that was based directly on the heat balance method; thus, it was deemed desirable to generate the RTS coefficients directly from a heat balance. To this end, a heat balance computer program was developed. This program, called Hbfort, which may be used to generate RTS coefficients, is included as part of *Cooling and Heating Load Calculation Principles* (Pedersen et al. 1998). The RTS procedure is described by Spitler et al. (1997). The procedure for generating RTS coefficients may be thought of as analogous to the custom weighting factor generation procedure used by DOE 2.1 (Kerrisk et al. 1981; Sowell 1988a, 1988b). In both cases, a zone model is pulsed with a heat gain. In the case of DOE 2.1, the resulting loads are used to estimate the best values of the transfer function method weighting factors to most closely match the load profile. In the case of the procedure described here, a unit periodic heat gain pulse is used to generate loads for a 24 h period. As long as the heat gain pulse is a unit pulse, the resulting loads are equivalent to the RTS coefficients.

Two different series of radiant time factors are utilized—one for direct transmitted solar heat gain (radiant energy assumed to be distributed to the floor and furnishings only) and one for all other types of heat gains (radiant energy assumed to be uniformly distributed on all internal surfaces). Nonsolar RTS apply to radiant heat gains from people, lights, appliances, walls, roofs, and floors. Also, for diffuse

solar heat gain and direct solar heat gain from fenestration with inside shading (blinds, drapes, etc.), the nonsolar RTS should be used. Radiation from those sources is assumed to be more uniformly distributed onto all room surfaces. Effect of beam solar radiation distribution assumptions is addressed by Hittle (1999).

Representative RTS data for light, medium, and heavyweight constructions are provided in Tables 24 and 25. Those were calculated using the Hbfort computer program (Pedersen et al. 1998) with zone characteristics listed in Table 26. Customized RTS values may be calculated using the HB method where the zone is not reasonably similar to these typical zones or where more precision is desired.

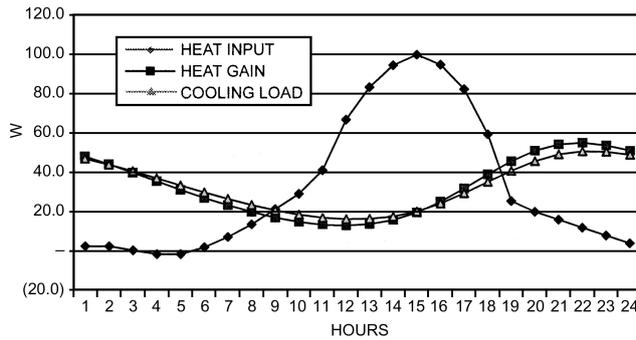

ASHRAE Research Project 942 compared HB and RTS results over a wide range of zone types and input variables (Spitler et al. 1998, Rees et al. 2000). In general, total cooling loads calculated using the RTS method closely agreed with or were slightly higher than those of the HB method with the same inputs. The project examined more than 5000 test cases of varying zone parameters. The dominating variable was overall thermal mass, and results were grouped into lightweight, U.S. medium-weight, U.K. medium-weight, and heavyweight construction. Best agreement between RTS and HB results was obtained for light- and medium-weight

construction. Greater differences occurred in heavyweight cases, with RTS generally predicting slightly higher peak cooling loads than HB. Greater differences also were observed in zones with extremely high internal radiant loads and large glazing areas or with a very lightweight exterior envelope. In this case, heat balance calculations predict that some of the internal radiant load will be transmitted to the outdoor environment and never becomes cooling load within the space. The RTS methodology does not account for energy being transferred out of the space to the environment and thus predicted higher cooling loads.

**Example 5. Wall cooling load using radiant time series.** Using the data from Example 4, calculate the cooling load at 3 P.M. Central Daylight Time on July 21 through 9.3 m<sup>2</sup> of a wall composed of 100 mm brick, 50 mm of insulation ( $R = 1.76 \text{ m}^2 \cdot \text{K/W}$ ), and 200 mm lightweight concrete block in an office building of average commercial construction.

**Solution:** Total cooling load for the wall is calculated by summing the convective and radiant portions. The convective portion is simply the wall heat gain for the hour being calculated, from Example 4, times the convective fraction for walls from Table 19:

$$Q_c = (15.8)(37\%) = 5.85 \text{ W}$$

**Fig. 12 Wall Heat Input, Heat Gain for Example 5 and Cooling Load Using CTS and RTS**

The radiant portion of the cooling load is calculated using conductive heat gains for the current and past 23 h, the radiant fraction for walls from Table 19 (63%), and radiant time series from Table 24, in accordance with Equation (39). From Table 24, select the RTS for medium-weight construction, assuming 50% glass and carpeted floors as is often found in modern office construction. Take the wall heat gains from Table 23. Thus, the radiant cooling load for the wall is

$$\begin{aligned}
 Q_{r,14} &= r_0(0.63)q_{i,14} + r_1(0.63)q_{i,13} + r_2(0.63)q_{i,12} + r_3(0.63)q_{i,11} + \dots \\

 &\quad + (0.01)(0.63)(54.0) + (0.01)(0.63)(55.3) + (0.01)(0.63)(54.4) \\
 &\quad + (0.01)(0.63)(51.0) + (0.01)(0.63)(45.6) + (0.00)(0.63)(38.9) \\
 &\quad + (0.00)(0.63)(31.7) + (0.00)(0.63)(25.0) + (0.00)(0.63)(19.4) \\
 &= 11.6 \text{ W}
 \end{aligned}$$

The total wall cooling load at the designated hour is thus

$$Q_{wall} = Q_c + Q_{r14} = 5.8 + 11.6 = 17.4 \text{ W}$$

Again, due to the tedious calculations involved, use of a simple computer spreadsheet or other computer software implementing these calculations can reduce the effort involved. The spreadsheet illustrated in Table 23 is expanded in Table 27 to include splitting the heat gain into convective and radiant portions, applying RTS to the radiant portion, and totaling the convective and radiant loads to determine a 24 hour cooling load profile for the data of this example. Figure 12 shows wall heat input, heat gain, and total cooling load versus time for the 24 h calculated.

**Example 6. Window cooling load using radiant time series.** Calculate the cooling load for a 1.858 m<sup>2</sup> double-glazed bronze low-e window at 3 P.M. Central Daylight Time on July 21, at the location and for the conditions defined in Example 1, in an office building of average commercial construction. Use SHGC data for glass type 17f from Table 13 in Chapter 30. Use window U-factor = 3.18.

**Solution:** To determine the window cooling load, first calculate the 24 h heat gain profile for the window, then split those heat gains into radiant and convective portions, apply the appropriate RTS to the radiant portion, then sum the convective and radiant cooling load components to determine total window cooling load at the designated time. The window heat gain components are calculated using Equations (13) through (15).

From Example 1, at hour 14 standard time (3 P.M. Central Daylight Time):

$$\begin{aligned}
 E_D &= 425 \text{ W/m}^2 \\
 E_d &= 98 \text{ W/m}^2 \\
 E_r &= 85 \text{ W/m}^2 \\
 \theta &= 60.1^\circ
 \end{aligned}$$

From Chapter 30, Table 13, for glass type 17f,

$$\begin{aligned}
 \text{SHGC}(\theta) &= \text{SHGC}(60.1) = 0.349 \text{ (interpolated)} \\
 \langle \text{SHGC} \rangle_D &= 0.38
 \end{aligned}$$

Therefore, window heat gain components for hour 14 are

$$\begin{aligned}
 q_{b14} &= AE_D \text{SHGC}(\theta) = (1.858)(425)(0.349) = 276 \text{ W} \\
 q_{d14} &= A(E_d + E_r) \langle \text{SHGC} \rangle_D = (1.858)(98 + 85)(0.38) = 129 \text{ W} \\
 q_{c14} &= UA(t_{out} - t_{in}) = (3.18)(1.858)(34.4 - 23.9) = 62.4
 \end{aligned}$$

This procedure is repeated to determine these values for a 24 h heat gain profile, as illustrated in Table 28.

Total cooling load for the window is calculated by summing the convective and radiant portions. For windows with inside shading (blinds, drapes, etc.), the direct beam, diffuse, and conductive heat gains may be summed and treated together in calculating cooling loads. However, in this example, the window does not have inside shading, and the direct beam solar heat gain should be treated separately from the diffuse and conductive heat gains. The direct beam heat gain, without inside shading, is treated as 100% radiant, and solar RTS factors from Table 25 are used to convert the beam heat gains to cooling loads. The diffuse and conductive heat gains can be totaled and split into radiant and convection portions according to Table 19 percentages, and nonsolar RTS factors from Table 24 are used to convert the radiant portion to cooling load.

The solar beam cooling load is calculated using heat gains for the current hour and past 23 h and radiant time series from Table 25, in accordance with Equation (39). From Table 25, select the solar RTS for medium-weight construction, assuming 50% glass and carpeted floors as is often found in modern office construction. Using Table 28 values for direct solar heat gain, the radiant cooling load for the window direct beam solar component is

$$\begin{aligned}
 Q_{b,14} &= r_0q_{b,14} + r_1q_{b,13} + r_2q_{b,12} + r_3q_{b,11} + \dots + r_{23}q_{b,1} \\
 &= (0.54)(276) + (0.16)(175) + (0.08)(82) + (0.04)(1) \\
 &\quad + (0.03)(0) + (0.02)(0) + (0.01)(0) + (0.01)(0) + (0.01)(0) \\
 &\quad + (0.01)(0) + (0.01)(0) + (0.01)(0) + (0.01)(0) + (0.01)(0) \\
 &\quad + (0.01)(0) + (0.01)(0) + (0.01)(0) + (0.01)(0) + (0.01)(0) \\
 &\quad + (0.00)(6) + (0.00)(143) + (0.00)(262) + (0.00)(326) \\
 &\quad + (0.00)(329) \\
 &= 184 \text{ W}
 \end{aligned}$$

This process is repeated for other hours; results are listed in Table 29.

For diffuse and conductive heat gains, the radiant fraction according to Table 19 is 63%. The radiant portion is processed using nonsolar RTS coefficients from Table 24. The results are listed in Table 29.

The total window cooling load at the designated hour is thus

$$Q_{window} = Q_b + Q_{diff + cond} = 184 + 170 = 354 \text{ W}$$

Again, due to the tedious calculations involved, use of a simple computer spreadsheet or other computer software implementing these calculations can reduce the effort involved. The spreadsheet illustrated in Table 28 is expanded in Table 29 to include splitting the heat gain into convective and radiant portions, applying RTS to the radiant portion, and totaling the convective and radiant loads to determine a 24 h cooling load profile for the data of this example.

**Example 7. Internal cooling load using radiant time series.** Calculate the cooling load at 10 A.M. for a 100 m<sup>2</sup> office space due to suspended fluorescent lights with a total load of 2000 W, in an office building of average commercial construction. The lights are 50% on at 7 A.M., 100% on from 8 A.M. to 6 P.M., then off the remainder of the time.

**Solution:** To determine the lighting cooling load, first calculate the 24 h heat gain profile for the lighting load, then split those heat gains into radiant and convective portions, apply the appropriate RTS to the radiant portion, and sum the convective and radiant cooling load components to determine total cooling load at the designated time. The lighting heat gain profile, based on the schedule indicated, is

$$\begin{aligned}
 q_1 &= (2000 \text{ W})(0\%) &= 0 \\
 q_2 &= (2000 \text{ W})(0\%) &= 0 \\
 q_3 &= (2000 \text{ W})(0\%) &= 0 \\
 q_4 &= (2000 \text{ W})(0\%) &= 0 \\
 q_5 &= (2000 \text{ W})(0\%) &= 0 \\
 q_6 &= (2000 \text{ W})(0\%) &= 0
 \end{aligned}$$

The radiant portion of the cooling load is calculated using lighting heat gains for the current hour and past 23 h, the radiant fraction from Table 19 (67%), and radiant time series from Table 24, in accordance with Equation (39). From Table 24, select the RTS for medium-weight construction, assuming 50% glass and carpeted floors as is often found in modern office construction. Thus, the radiant cooling load for lighting is

$$\begin{aligned}
 Q_{r,10} &= r_0(0.67)q_{10} + r_1(0.67)q_9 + r_2(0.67)q_8 + r_3(0.67)q_7 + \dots + r_{23}(0.67)q_{11} \\
 &= (0.49)(0.67)(2000) + (0.17)(0.67)(2000) \\
 &\quad + (0.09)(0.67)(2000) + (0.05)(0.67)(1000) + (0.03)(0.67)(0) \\
 &\quad + (0.02)(0.67)(0) + (0.02)(0.67)(0) + (0.01)(0.67)(0) \\
 &\quad + (0.01)(0.67)(0) + (0.01)(0.67)(0) + (0.01)(0.67)(0) \\
 &\quad + (0.01)(0.67)(0) + (0.01)(0.67)(0) + (0.01)(0.67)(0) \\
 &\quad + (0.01)(0.67)(0) + (0.01)(0.67)(0) + (0.01)(0.67)(2000) \\
 &\quad + (0.01)(0.67)(2000) + (0.01)(0.67)(2000) \\
 &\quad + (0.01)(0.67)(2000) + (0.00)(0.67)(2000) \\
 &\quad + (0.00)(0.67)(2000) + (0.00)(0.67)(2000) \\
 &\quad + (0.00)(0.67)(2000) \\
 &= 1092 \text{ W}
 \end{aligned}$$

The total lighting cooling load at the designated hour is thus

$$Q_{wall} = Q_{c,10} + Q_{r,10} = 660 + 1092 = 1752 \text{ W}$$

### COMPARISON WITH PREVIOUS METHODS

Some users of this chapter during the past eight editions may have been disappointed that it did not contain (nor was it accompanied by) fully developed multiple-room, multiple-system calculation computer programs for immediate use by HVAC

designers. Nor have the several attempts to create and present hand-calculation procedures been acceptable in practice, as they were simply incapable of dealing realistically with contemporary demands. As ASHRAE evolves in the 21st century, the issue of practical load calculation procedures clearly demands computer operation.

Who should provide the computer applications for this purpose? While it could be argued that ASHRAE itself is the best source of experience and talent to generate such tools, the nature of ASHRAE as a technical society prevents this type of activity. Instead, ASHRAE has provided technically reliable mechanisms for both the heat balance and the radiant time series procedures to be accurately implemented, as the most scientifically correct methodologies available, anticipating that various qualified private enterprises will take these frameworks and complete their development into practical applications for HVAC designers.

The user may question what benefits may be expected now that the TFM, TETD/TA, and CLTD/CLF procedures presented in earlier chapter versions have been superseded (*not* invalidated or discredited). The primary benefit will be improved accuracy, with reduced dependency upon purely subjective input (such as determining a proper time-averaging period for TETD/TA, or ascertaining appropriate safety factors to add to the “rounded off” TFM results). As a generic example, the space sensible cooling load for the traditional little ASHRAE store building (used for example purposes since the 1940s) was calculated by means of the heat balance procedure and independently calculated by application of the radiant time series procedure, with each set of results plotted as one of the load profile curves of Figure 13. Also plotted on this chart are the corresponding curves produced by

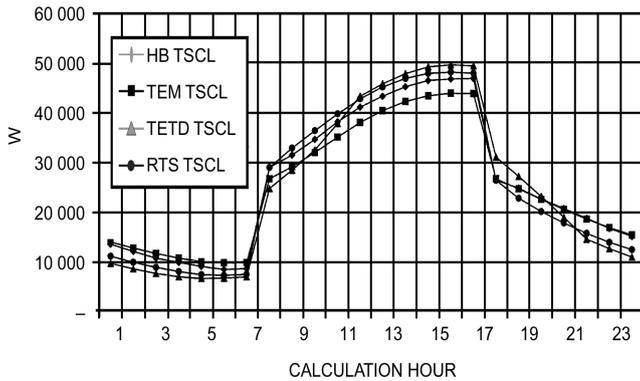

Fig. 13 Cooling Load Profile Comparison

the TFM and TETD/TA methodologies in the 1997 edition of this chapter. The user may draw his or her own conclusions from this chart.

## HEATING LOAD PRINCIPLES

Techniques for estimating design heating load for commercial, institutional, and industrial applications are essentially the same as for those estimating design cooling loads for such uses, except that (1) temperatures outside the conditioned spaces are generally lower than the space temperatures maintained; (2) credit for solar heat gains or for internal heat gains is not included; and (3) the thermal storage effect of building structure or content is ignored. Heat losses (negative heat gains) are thus considered to be instantaneous, heat transfer essentially conductive, and latent heat treated only as a function of replacing space humidity lost to the exterior environment.

This simplified approach is justified because it evaluates “worst case” conditions that can reasonably occur during a heating season. The worst case is the load that must be met under design interior and exterior conditions, including infiltration and/or ventilation, but with no solar effect (at night or on cloudy winter days) and before the periodic presence of people, lights, and appliances has an offsetting effect.

**Safety Factors and Load Allowances.** Before mechanical cooling became a usual procedure, buildings included much less insulation, large operable windows, and generally more infiltration-prone assemblies than the energy-efficient and much tighter buildings typical of today. Allowances of 10 to 20% of the net calculated heating load for piping losses to unheated spaces and 10 to 20% more for a warm-up load were common practice, along with occasional other safety factors reflecting the experience and/or concern of the individual designer. Such measures are rarely used today, with the uncompensated net heating load normally considered as having an adequate margin for error. Armstrong et al. (1992a, 1992b) provide a design method to deal with warm-up and cool-down load.

**Cooling Needs During Noncooling Months.** Perimeter spaces exposed to high solar heat gain often justify mechanical cooling during sunlit portions of traditional heating months, as do completely interior spaces with significant internal heat gain. Such spaces can also have significant heating loads during nonsunlit hours or after periods of nonoccupancy when adjacent spaces have cooled below interior design temperatures. The loads involved can be estimated conventionally to offset or to compensate for them and prevent overheating, but they have no direct relationship to design heating loads for the spaces in question.

**Other Considerations.** Calculation of design heating load estimates for this general category of applications has essentially

become a subset of the more involved and complex estimation of cooling loads for such spaces. Chapter 31 discusses using the heating load estimate to predict or analyze energy consumption over time. Special provisions to deal with special problems are covered in the 1999 *ASHRAE Handbook—Applications* and the 2000 *ASHRAE Handbook—Systems and Equipment*.

**F**ENESTRATION is an architectural term that refers to the arrangement, proportion, and design of window, skylight, and door systems within a building. Fenestration components include glazing material, either glass or plastic; framing, mullions, muntins, dividers, and opaque door slabs; external shading devices; internal shading devices; and integral (between-glass) shading systems. For our purposes, **fenestration** and **fenestration systems** will refer to the basic assemblies and components of exterior window, skylight, and door systems within the building envelope. Fenestration can serve as a physical and/or visual connection to the outdoors, as well as a means to admit solar radiation. The solar radiation provides natural lighting, referred to as **daylighting**, and heat gain to a space. Fenestration can be fixed or operable, and operable units can allow natural ventilation to a space and egress in low-rise buildings.

Fenestration affects building energy use through four basic mechanisms—thermal heat transfer, solar heat gain, air leakage, and daylighting. The energy impacts of fenestration can be minimized by (1) using daylight to offset lighting requirements, (2) using appropriate glazings and shading strategies to control solar heat gain to supplement heating through passive solar gain and minimize cooling requirements, (3) using appropriate glazing to minimize conductive heat loss, and (4) specifying low air leakage fenestration products. In addition, natural ventilation strategies can reduce energy use for cooling and fresh air requirements.

Today designers, builders, energy codes, and energy-efficiency incentive programs [such as Energy Star ([www.energystar.gov](http://www.energystar.gov)) and the LEED Green Building Program ([www.usgbc.org](http://www.usgbc.org))] are asking more and more from fenestration systems. Window, skylight, and door manufacturers are responding with new and improved products to meet those demands. With the advent of computer simulation software, designing to improve thermal performance of fenestration products has become much easier. Through participation in rating and certification programs (such as those of the National Fenestration Rating Council) that require the use of this software, fenestration manufacturers can take credit for these improvements through certified ratings that are credible to designers, builders, and code officials. A designer should consider architectural requirements, thermal performance, economic criteria, and human comfort when

selecting fenestration. Typically, a wide range of fenestration products are available that meet the specifications for a project. Refining the specifications to improve the energy performance and enhance a living or work space can result in lower energy costs, increased productivity, and improved thermal and visual comfort. Carmody et al. (1996) and CEA (1995) provide guidance for carrying out these requirements.

### FENESTRATION COMPONENTS

Fenestration consists of glazing, framing, and in some cases shading devices and insect screens.

#### Glazing

The glazing unit may have single glazing or multiple glazing. The most common glazing material is glass, although plastic is also used. The glass or plastic may be clear, tinted, coated, laminated, patterned, or obscured. **Clear** glass transmits more than 80% of the incident solar radiation and more than 75% of the visible light. **Tinted** glass is available in many colors, all of which differ in the amount of solar radiation and visible light they transmit and absorb. **Coatings** on glass affect the transmission of solar radiation, and visible light may affect the absorptance of room temperature radiation. Some coatings are highly reflective (such as mirrors), while others are designed to have a very low reflectance. Some coatings result in a visible light transmittance that is as much as 1.4 times higher than the solar heat gain coefficient (desirable for good daylighting while minimizing cooling loads). **Laminated** glass is made of two panes of glass adhered together. The interlayer between the two panes of glass is typically plastic and may be clear, tinted, or coated. **Patterned** glass is a durable ceramic frit applied to a glass surface in a decorative pattern. **Obscured** glass is translucent and is typically used in privacy applications.

#### Insulating Glazing Units

Insulating glazing units (IGUs) are hermetically sealed, multiple-pane assemblies consisting of two or more glazing layers held and bonded at their perimeter by a spacer bar typically containing a desiccant material. The desiccated spacer is surrounded on at least two sides by a sealant that adheres the glass to the spacer. Figure 1 shows the construction of a typical IGU.

The preparation of this chapter is assigned to TC 4.5, Fenestration.

**Glazing.** Common types of glass used in IGUs are clear, tinted, and low emissivity (low-e). Due to its energy efficiency, daylighting, and comfort benefits, low-e coated glass is now used in more than 30% of all the fenestration products installed in the United States. Tinted and reflective glazing can also be used to reduce solar heat gain through fenestration products. Low-e coatings can also be applied to thin plastic films for use in IGUs. There are two types of low-e coating: **high-solar-gain** and **low-solar-gain**. The first of these primarily reduces heat conduction through the glazing system and is intended for cold climates. The second, for hot climates, reduces solar heat gain by blocking admission of the infrared portion of the solar spectrum. There are two ways of achieving low-solar-gain low-e performance. The first is with a special multilayer solar infrared reflecting coating. The second is with a solar infrared absorbing outer glass. To protect the inner glazing and the building interior from the absorbed heat from this outer glass, a cold-climate-type low-e coating is also used to reduce conduction of heat from the outer pane to the inner one. In addition, argon and krypton gas are used in lieu of air in the gap between the panes in combination with low-e glazing to further reduce energy transfer. Some manufacturers construct IGUs with one or more suspended, low-e coated plastic films between the glass panes and with a spacer that has better insulating properties and a dual sealant that improves the seal around the gas spaces.

**Spacer.** The spacer serves to separate the panes of glass and to provide the surface for primary and secondary sealant adhesion. Several types of spacers are used in IGU construction today. Each type provides different heat transfer properties depending on the spacer material and geometry.

Heat transfer at the edge of the IGU is greater than at the center of the IGU due to greater heat flow through the spacer system. Spacer systems have been developed to minimize the heat flow at the edge of the IGU. These spacer systems are referred to as **warm edge spacers**. In IGU construction, warm edge spacer designs reduce edge heat transfer by substituting materials that have lower thermal conductivity than aluminum (e.g., stainless steel, galvanized steel, tin plated steel, polymers, or foamed silicone). Traditional spacers are often made of aluminum.

Fusing or bending the corners of the spacer minimizes moisture and hydrocarbon vapor transmission into the air space through the corners. Desiccants such as molecular sieve or silica gel are also used to absorb moisture that was initially trapped in the IGU during assembly or gradually diffuses through the seals after construction.

**Sealant(s).** Several different sealant configurations are being used successfully in modern IGU construction. In all sealant configurations, the primary seal minimizes moisture and hydrocarbon

transmission. In dual-seal construction, the secondary seal provides structural integrity between the lites of the IGU. A secondary seal ensures long-term adhesion and greater resistance to solvents, oils, and short-term water immersion. In typical dual-seal construction, the primary seal is made of compressed polyisobutylene (PIB), and the secondary seal is made of silicone, polysulfide, or polyurethane. Single-seal construction depends on a single sealant to provide adhesion of the glass to the spacer as well as minimizing moisture and hydrocarbon transmission. Single-seal construction is generally more cost-efficient than dual-seal systems. A third type of sealant used in IGU construction takes advantage of advanced cross-linking polymers that provide both low moisture transmission and equivalent structural properties to dual-seal systems. These sealants are typically referred to as dual seal equivalent (DSE) materials.

**Desiccants.** Typical desiccants include molecular sieve, silica gel, or a matrix of both materials. Desiccants are used to absorb moisture that was initially trapped in the IGU during assembly or that gradually diffused through the seals after construction.

**Gas Fill.** The hermetically sealed space between glass panes in an IGU is most often filled with air. In some cases, argon and krypton gas are used in lieu of air in the space between the panes to further reduce the energy transfer.

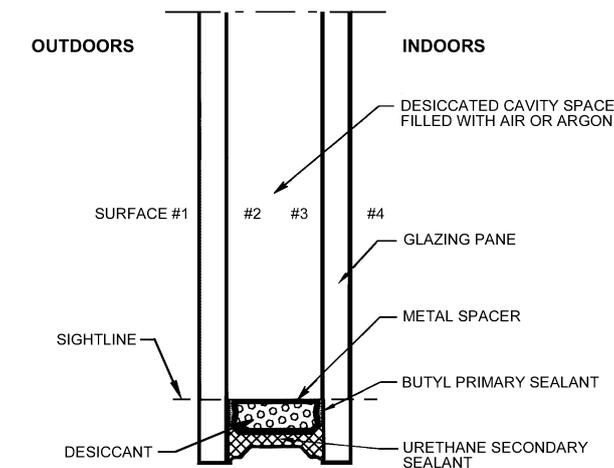

Fig. 1 Insulating Glazing Unit (IGU) Construction Detail

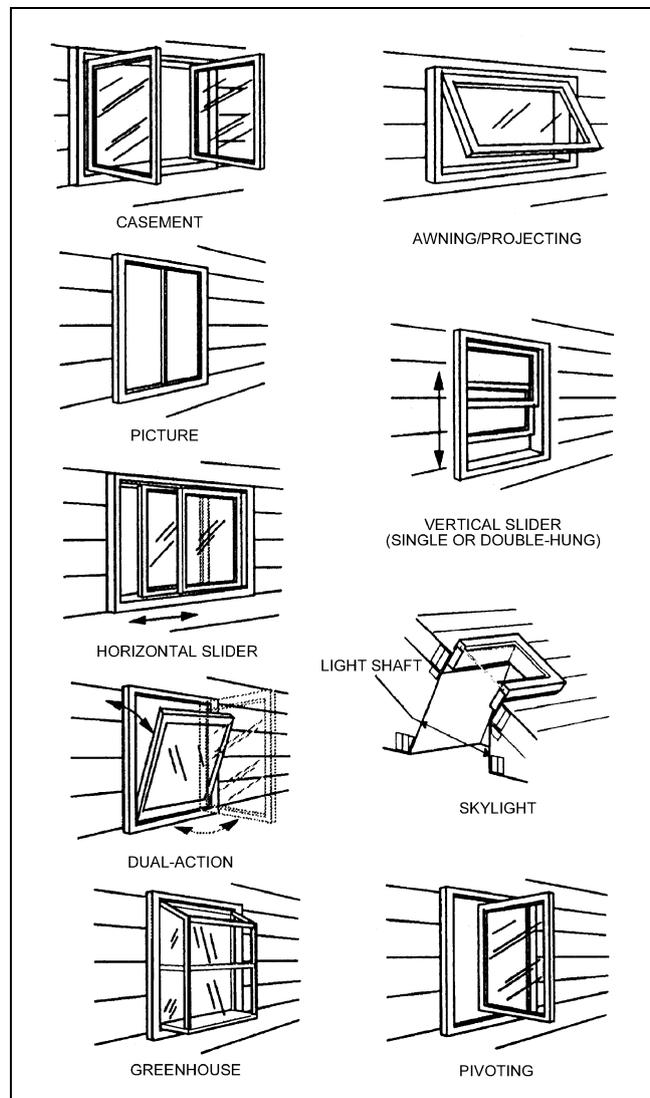

Fig. 2 Types of Residential Windows

### Framing

The three main categories of window framing materials are wood, metal, and polymers. **Wood** has good structural integrity and insulating value but low resistance to weather, moisture, warpage, and organic degradation (from mold and insects). **Metal** is durable and has excellent structural characteristics, but it has very poor thermal performance. The metal of choice in windows is almost exclusively aluminum, due to ease of manufacture, low cost, and low mass, but aluminum has a thermal conductivity roughly 1000 times that of wood or polymers. The poor thermal performance of metal-frame windows can be improved with a thermal break (a nonmetal component that separates the metal frame exposed to the outside from the surfaces exposed to the inside). **Polymer** frames are made of extruded vinyl or poltruded fiberglass (glass-reinforced polyester). Their thermal and structural performance is similar to that of wood, although vinyl frames for large windows must be reinforced.

Manufacturers sometimes combine these materials as clad units (e.g., vinyl-clad aluminum, aluminum-clad wood, vinyl-clad wood) to increase durability, improve thermal performance, or improve aesthetics. In addition, curtain wall systems for commercial buildings may be structurally glazed, and the exterior “framing” is simply rubber gaskets or silicone.

Residential windows can be categorized by operator type, as shown in Figure 2. Traditionally there are several basic window types: casements, fixed picture windows, horizontal and vertical sliders, pivoting, awning, or projecting windows, dual acting windows, and special applications such as skylights and greenhouse or garden window inserts. The glazing system can be mounted either directly in the frame (a direct-glazed or direct-set window, which is not operable) or in a sash that moves in the frame (for an operating window). In operable windows, a weather-sealing system between the frame and sash reduces air and water leakage.

### Shading

Shading devices are available in a wide range of products that differ greatly in their appearance and energy performance. Shading devices include interior and exterior blinds, integral blinds, interior and exterior screens, shutters, draperies, and roller shades. Shading devices on the exterior of the glazing reduce solar heat gain more effectively than interior devices. However, interior devices are easier to operate and adjust. Some products help insulate the indoors from the outdoors, while others redirect incoming solar radiation to minimize visual and thermal discomfort. Overhangs and vegetation can be effective shading too.

## DETERMINING FENESTRATION ENERGY FLOW

Energy flows through fenestration via (1) conductive and convective heat transfer caused by the temperature difference between outdoor and indoor air, (2) net long-wave (above 2500 nm) radiative exchange between the fenestration and its surrounding and between glazing layers, and (3) short-wave (below 2500 nm) solar radiation incident on the fenestration product, either directly from the sun or reflected from the ground or adjacent objects. Simplified calculations are based on the observation that the temperatures of the sky, ground, and surrounding objects (and hence their radiant emission) correlate with the exterior air temperature. The radiative interchanges are then approximated by assuming that all the radiating surfaces (including the sky) are at the same temperature as the outdoor air. With this assumption, the basic equation for the instantaneous energy flow  $Q$  through a fenestration is

$$Q = UA_{pf}(t_{out} - t_{in}) + (\text{SHGC})A_{pf}E_t \quad (1)$$

where

$$\begin{aligned} Q &= \text{instantaneous energy flow, W} \\ U &= \text{overall coefficient of heat transfer (U-factor), W/(m}^2 \cdot \text{K)} \\ t_{in} &= \text{interior air temperature, } ^\circ\text{C} \\ t_{out} &= \text{exterior air temperature, } ^\circ\text{C} \\ A_{pf} &= \text{total projected area of fenestration, m}^2 \\ \text{SHGC} &= \text{solar heat gain coefficient, nondimensional} \\ E_t &= \text{incident total irradiance, W/m}^2 \end{aligned}$$

The quantities  $U$  and SHGC are instantaneous performance indices. The principal justification for Equation (1) is its simplicity, achieved by collecting all the linked radiative, conductive, and convective energy transfer processes into  $U$  and SHGC. These quantities vary because (1) convective heat transfer rates vary as fractional powers of temperature differences or free-stream speeds, (2) variations in temperature due to the weather or climate are small on the absolute temperature scale ( $^\circ\text{R}$ ) that controls radiative heat transfer rates, (3) fenestration systems always involve at least two thermal resistances in series, and (4) solar heat gain coefficients depend on solar incident angle and spectral distribution.

In the discussion of this chapter,  $Q$  is divided into two parts:

$$Q = Q_{th} + Q_{sol} \quad (2)$$

where

$$\begin{aligned} Q_{th} &= \text{instantaneous energy flow due to indoor-outdoor temperature difference (thermal energy flow)} \\ Q_{sol} &= \text{instantaneous energy flow due to solar radiation (solar energy flow)} \end{aligned}$$

The section on U-Factor (Thermal Transmittance) deals with  $Q_{th}$ , while the section on Solar Heat Gain and Visible Transmittance discusses  $Q_{sol}$ . In the latter section, both the effects of direct solar radiation and those of solar radiation scattered by the sky or ground are included.

Equation (1) presents a fenestration as it might appear on a building plan: a featureless, planar object filling an opening in the building envelope. Real fenestrations, however, are composite three-dimensional objects that may consist of frames, sashes, mullions, and other structural elements, as well as glazing systems. The latter in turn may contain structural spacers as well as glazing layers. There may in addition be shading elements, either as separate attachments or integrated into the glazing system.

The heat transfer through such an assembly of elements is calculated by dividing the fenestration area into parts, each of which has an energy flow that is more simply calculated than the total:

$$Q = \sum_v A_v q_v \quad (3)$$

where

$$\begin{aligned} q_v &= \text{energy flux (energy flow per unit area) of the } v\text{th part} \\ A_v &= \text{area of the } v\text{th part} \end{aligned}$$

This subdivision is applied to each of the terms in Equation (2) separately; for example, the thermal heat transfer through glazings and frames is frequently different, so that it is useful to make the following separation:

$$Q_{th} = A_f q_f + A_g q_g \quad (4)$$

where the subscript  $f$  refers to the frame, and  $g$  refers to the glazing (both for thermal energy flow). Similarly, solar radiation will have a different effect on the frame and the glazed area of a fenestration (since the former is generally opaque), so that

$$Q_{sol} = A_{op} q_{op} + A_s q_s \quad (5)$$

where the subscript *op* refers to the (opaque) frame (for solar energy flow), and *s* refers to the (solar-transmitting) glazing. This division into frame and glazing areas can be and usually is different for the solar and thermal energy flows. Subdivisions of this sort, when Equation (3) is compared with Equation (1), effectively make the overall U-factor and solar heat gain coefficient area-averaged quantities. This area averaging is described explicitly in the appropriate sections below. Note that in more complicated fenestrations, where the glazing portion may contain opaque shading elements, the opaque portion is that part that can never under any conditions admit solar radiation in any form other than heat. A window with a closed, perfectly opaque blind would not be considered an opaque element because sometimes the blind may be open. A section of curtain wall consisting of wall or frame elements with an exterior cover of glass (for uniform appearance) would be an opaque element in spite of its transparent covering.

A second type of subdivision occurs when, for a given part of the fenestration system, energy flow is driven by physical processes that are more complicated than those assumed in Equation (1). For example, the heat transfer through a glazing consists of a "contact" (i.e., glass-to-air) part and a radiative part, and the latter ( $q_R$ ) may depend on radiant temperatures that are different from the air temperatures in Equation (1):

$$q = q_C + q_R \quad (6)$$

## U-FACTOR (THERMAL TRANSMITTANCE)

In the absence of sunlight, air infiltration, and moisture condensation, the first term in Equation (1) represents the rate of thermal heat transfer through a fenestration system. Most fenestration systems consist of transparent multipane glazing units and opaque elements comprising the sash and frame (hereafter called **frame**). The glazing unit's heat transfer paths include a one-dimensional center-of-glass contribution and a two-dimensional edge contribution. The frame contribution is primarily two-dimensional.

Consequently, the total rate of heat transfer through a fenestration system can be calculated knowing the separate heat transfer contributions of the center glass, edge glass, and frame. (When present, glazing dividers, such as decorative grilles and muntins, also affect heat transfer, and their contribution must be considered.) The overall U-factor is estimated using area-weighted U-factors for each contribution by

$$U_o = \frac{U_{cg}A_{cg} + U_{eg}A_{eg} + U_{pf}A_{pf}}{A_{pf}} \quad (7)$$

where the subscripts *cg*, *eg*, and *f* refer to the center-of-glass, edge-of-glass, and frame, respectively.  $A_{pf}$  is the area of the fenestration product's rough opening in the wall or roof less installation clearances. When a fenestration product has glazed surfaces in only one direction (typical windows), the sum of the areas equals the projected area. Skylights, greenhouse/garden windows, bay/bow windows, etc., because they extend beyond the plane of the wall/roof, have greater surface area for heat loss than a window with a similar glazing option and frame material; consequently, U-factors for such products are expected to be greater.

## DETERMINING FENESTRATION U-FACTORS

### Center-of-Glass U-Factor

Heat flow across the central glazed portion of a multipane unit must consider both convective and radiative transfer in the gas space. Convective heat transfer is estimated based on high-aspect-

ratio, natural convection correlations for vertical and inclined air layers (El Sherbiny et al. 1982, Shewen 1986, Wright 1996). Radiative heat transfer (ignoring gas absorption) is quantified using a more fundamental approach. Computational methods solving the combined heat transfer problem have been devised (Rubin 1982a, 1982b, Hollands and Wright 1982).

Especially for single glass, U-factors depend strongly on indoor and outdoor film coefficients. The U-factor for single glass is

$$U = \frac{1}{1/h_o + 1/h_i + L/1000k} \quad (8)$$

where

- $h_o, h_i$  = outdoor and indoor respective glass surface heat transfer coefficients, W/(m<sup>2</sup>·K)
- $L$  = glass thickness, mm
- $k$  = thermal conductivity, W/(m·K)

Values for  $U_{cg}$  at standard indoor and outdoor conditions depend on such glazing construction features as the number of glazing lights, the gas-space dimensions, the orientation relative to vertical, the emissivity of each surface, and the composition of the fill gas. Several computer programs can be used to estimate glazing unit heat transfer for a wide range of glazing construction (Arasteh et al. 1994, Finlayson and Arasteh 1993, Wright 1995c). The National Fenestration Rating Council calls for WINDOW 4.1 (LBL 1994) as a standard calculation method for the center glazing. In Canada, the VISION program (Wright 1995b) is used to determine center-glazing properties for the Canadian Standards Association (CSA *Standard* A440.2).

Figure 3 shows the effect of gas space width on  $U_{cg}$  for vertical double- and triple-paned glazing units. U-factors are plotted for air, argon, and krypton fill gases and for high (uncoated) and low (coated) values of surface emissivity. Gas space widths greater than 13 mm have no significant effect on  $U_{cg}$ , but greater glazing unit thicknesses decrease  $U_o$  since the length of the shortest heat flow path through the frame increases. A low-emissivity coating combined with krypton gas fill offers significant potential for reducing heat transfer in narrow gap-width glazing units.

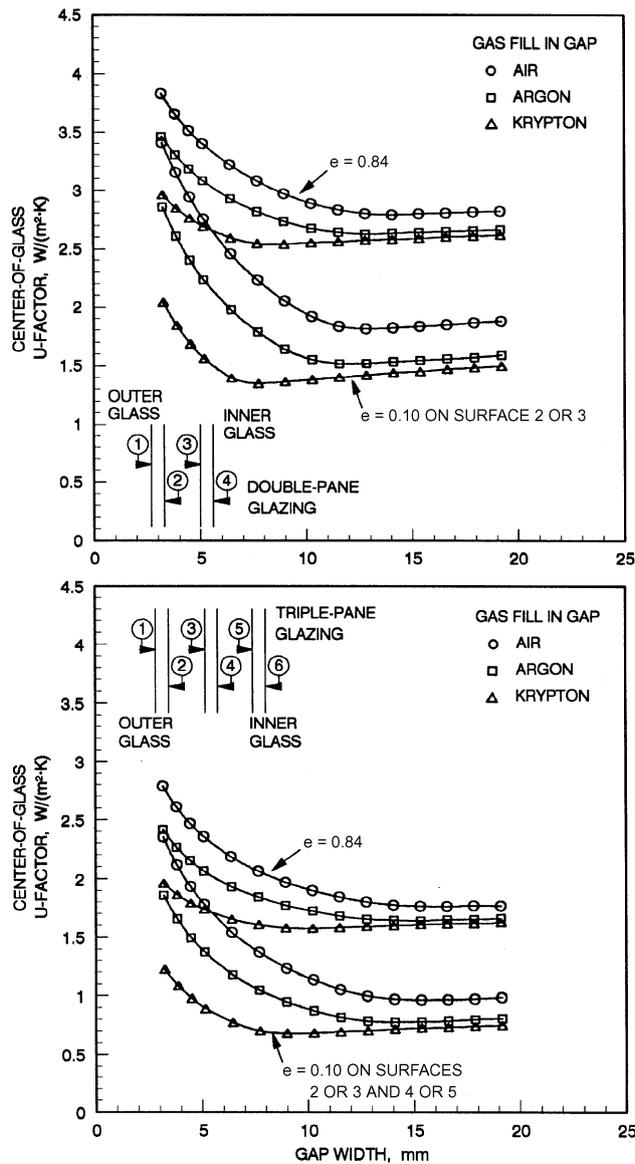

### Edge-of-Glass U-Factor

Insulating glazing units usually have continuous spacer members around the glass perimeter to separate the glazing and provide an edge seal. Aluminum spacers greatly increase conductive heat transfer between the contacted inner and outer glazing, thereby degrading the thermal performance of the glazing unit locally. The edge-of-glass area is typically taken to be a band 65 mm wide around the sightline. The width of this area is determined from the extent of two-dimensional heat transfer effects in current computer models, which are based on conduction-only analysis. In reality, due to convective and radiative effects, this area may extend beyond 65 mm (Beck et al. 1995, Curcija and Goss 1994, Wright and Sullivan 1995b), and it will depend on the type of insulating glazing unit and its thickness.

In low-conductivity frames, the heat flow at the edge-of-glass and frame area is through the spacer, and so the type of spacer has a greater impact on the edge-of-glass and frame U-factor. In metal frames, the edge-of-glass and frame U-factor varies little with the type of spacer (metal or insulating) because there is a significant heat flow through the highly conductive frame near the edge-of-glass area.

### Frame U-Factor

Fenestration frame elements consist of all structural members exclusive of the glazing units and include sash, jamb, head, and sill members; meeting rails and stiles; mullions; and other glazing dividers. Estimating the rate of heat transfer through the frame is

**Fig. 3 Center of Glass U-Factor for Vertical Double- and Triple-Pane Glazing Units**

complicated by (1) the variety of fenestration products and frame configurations, (2) the different combinations of materials used for frames, (3) the different sizes available, and, to a lesser extent, (4) the glazing unit width and spacer type. Internal dividers or grilles have little impact on the fenestration U-factor, provided there is at least a 3 mm gap between the divider and each panel of glass.

Computer simulations found that frame heat loss in most fenestration is controlled by a single component or controlling resistance, and only changes in this component significantly affect frame heat loss (EEL 1990). For example, the frame U-factor for thermally broken aluminum fenestration products is largely controlled by the depth of the thermal break material in the heat flow direction. For aluminum frames without a thermal break, the inside film coefficient provides most of the resistance to heat flow. For vinyl- and wood-framed fenestrations, the controlling resistance is the shortest distance between the inside and outside surfaces, which usually depends on the thickness of the sealed glazing unit.

Carpenter and McGowan (1993) experimentally validated frame U-factors for a variety of fixed and operable fenestration product

types, sizes, and materials using computer modeling techniques. Table 1 lists frame U-factors for a variety of frame and spacer materials and glazing unit thicknesses. Frame and edge U-factors are normally determined by two-dimensional computer simulation. The National Fenestration Rating Council requires that frame and edge U-factors be determined using the THERM (Arasteh et al. 2000) and FRAME (EEL 1995) computer programs. The Canadian Standards Association requires that frame and edge U-factors be determined using FRAME.

### Curtain Wall Construction

A curtain wall is an exterior building wall that carries no roof or floor loads and consists entirely or principally of glass and other surfacing materials supported by a framework. A curtain wall typically has a metal frame. To improve the thermal performance of standard metal frames, manufacturers provide both traditional thermal breaks as well as thermally improved products. The traditional thermal break type is poured and debridged, where urethane is poured into a metal U-channel in the frame and then the bottom of the channel is removed by machine. For this system to work well, there must be a thermal break between the interior and the exterior for all of the frame components, including those in any operable sash. Skip debridging (incomplete pour and debridging used for increased structural strength) can significantly degrade the U-factor. Bolts that penetrate the thermal break also degrade performance, but to a lesser degree. Griffith et al. (1998) showed that stainless steel bolts spaced 300 mm on center increased the frame U-factor by 18%. The paper also concluded that, in general, the isothermal planes method referenced in Chapter 25 provides a conservative approach to determining U-factors.

Thermally improved curtain wall products are a more recent development. In these products, most of the metal frame tends to be located on the interior with only a metal cap exposed on the exterior. Plastic spacers isolate the glazing assembly from both the metal cap on the exterior and the metal frame on the interior. These products can have significantly better thermal performance than standard metal frames, but it is important to minimize the number and area of the bolts that penetrate from exterior to interior.

### INDOOR AND OUTDOOR SURFACE HEAT TRANSFER COEFFICIENTS

Part of the overall thermal resistance of a fenestration system is due to the convective and radiative heat transfer between the exposed surfaces and the environment. Surface heat transfer coefficients  $h_o$  and  $h_i$  at the outer and inner glazing surfaces, respectively, combine the effects of radiation and convection.

The wind speed and orientation of the building are important in determining  $h_o$ . This relationship has long been studied, and many correlations have been proposed for  $h_o$  as a function of wind speed. However, no universal relationship has been accepted, and limited field measurements at low wind speeds by Klems (1989) show significant difference with values used by others.

Convective heat transfer coefficients are usually determined at standard temperature and air velocity conditions on each side. Wind speed can vary from less than 0.2 m/s for calm weather, free convection conditions, to over 29 m/s for storm conditions. A standard value of 29 W/(m<sup>2</sup>·K) corresponding to a 6.7 m/s wind is often used to represent winter design conditions. At near-zero wind speed,  $h_o$  varies with outside air and surface temperature, orientation to vertical, and air moisture content. At low wind speeds, the overall surface heat transfer coefficient can be as low as 6.8 W/(m<sup>2</sup>·K) (Yazdanian and Klems 1993).

For natural convection at the inner surface of a vertical fenestration product, the inner surface coefficient  $h_i$  depends on the indoor air and glass surface temperatures and on the emissivity of the glass inner surface. Table 2 shows the variation of  $h_i$  for winter ( $t_i = 21^\circ\text{C}$ )

**Table 1 Representative Fenestration Frame U-Factors in W/(m<sup>2</sup>·K)—Vertical Orientation**

Frame Material	Type of Spacer	Product Type/Number of Glazing Layers

Note: This table should only be used as an estimating tool for the early phases of design.  
<sup>a</sup>Depends strongly on width of thermal break. Value given is for 9.5 mm.  
<sup>b</sup>Single glazing corresponds to individual glazing unit thickness of 3 mm (nominal).  
<sup>c</sup>Double glazing corresponds to individual glazing unit thickness of 19 mm (nominal).  
<sup>d</sup>Triple glazing corresponds to individual glazing unit thickness of 34.9 mm (nominal).

<sup>e</sup>Glass thickness in curtainwall and sloped/overhead glazing is 6.4 mm.  
<sup>f</sup>Single glazing corresponds to individual glazing unit thickness of 6.4 mm (nominal).  
<sup>g</sup>Double glazing corresponds to individual glazing unit thickness of 25.4 mm (nominal).  
<sup>h</sup>Triple glazing corresponds to individual glazing unit thickness of 44.4 mm (nominal).

		1.2	17	4	6.72	40	16	4.08
		1.8	17	4	6.53	40	16	3.81

Notes:  
 Glazing ID refers to fenestration assemblies in Table 4.  
 Winter conditions: room air temperature  $t_i = 21^\circ\text{C}$ , outdoor air temperature  $t_o = -18^\circ\text{C}$ , no solar radiation

Summer conditions: room air temperature  $t_i = 24^\circ\text{C}$ , outdoor air temperature  $t_o = 32^\circ\text{C}$ , direct solar irradiance  $E_D = 748 \text{ W/m}^2$   
 $h_i = h_{ic} + h_{iR} = 1.46(\Delta T/L)^{0.25} + e\Gamma(T_g^4 - T_i^4)/\Delta T$   
 where  $\Delta T = T_g - T_i$ , K;  $L$  = glazing height, m;  $T_g$  = glass temperature, K

and summer ( $t_i = 24^\circ\text{C}$ ) design conditions, for a range of glass types and heights. Designers often use  $h_i = 8.3 \text{ W/(m}^2\cdot\text{K)}$ , which corresponds to  $t_i = 21^\circ\text{C}$ , glass temperature of  $-9^\circ\text{C}$ , and uncoated glass with  $e_g = 0.84$ . For summer conditions, the same value [ $h_i = 8.3 \text{ W/(m}^2\cdot\text{K)}$ ] is normally used, and it corresponds approximately to glass temperature of  $35^\circ\text{C}$ ,  $t_i = 24^\circ\text{C}$ , and  $e_g = 0.84$ . For winter conditions, this most closely approximates single glazing with clear glass that is 600 mm tall, but it overestimates the value as the glazing unit conductance decreases and height increases. For summer conditions, this value approximates all types of glass that are 600 mm tall but, again, is less accurate as the glass height increases. If the room surface of the glass has a low-e coating, the  $h_i$  values are about halved at both winter and summer conditions.

Heat transfer between the glazing surface and its environment is driven not only by the local air temperatures but also by the radiant temperatures to which the surface is exposed. The radiant temperature of the indoor environment is generally assumed to be equal to the indoor air temperature. While this is a safe assumption where a

small fenestration product is exposed to a large room with surface temperatures equal to the air temperature, it is not valid in rooms where the fenestration product is exposed to other large areas of glazing surfaces (e.g., greenhouse, atrium) or to other cooled or heated surfaces (Parmelee and Huebscher 1947).

The radiant temperature of the outdoor environment is frequently assumed to be equal to the outdoor air temperature. This assumption may be in error, since additional radiative heat loss occurs between a fenestration and the clear sky (Duffie and Beckman 1980). Therefore, for clear-sky conditions, some effective outdoor temperature  $t_{o,e}$  should replace  $t_o$  in Equation (1). For methods for determining  $t_{o,e}$ , see, for example, work by AGSL (1992). Note that a fully cloudy sky is assumed in ASHRAE design conditions.

The air space in an insulating glass panel made up of glass with no reflective coating on the air space surfaces has a coefficient  $h_s$  of  $7.4 \text{ W/(m}^2\cdot\text{K)}$ . When a reflective coating is applied to an air space surface,  $h_s$  can be selected from Table 3 by first calculating the effective air space emissivity  $e_{s,e}$  by Equation (9):

**Table 3 Air Space Coefficients for Horizontal Heat Flow**

Air Space Thickness, mm	Air Space Temp., °C	Air Temp. Diff., °C	Air Space Coefficient $h_s$ , W/(m <sup>2</sup> ·K)

$$e_{s,e} = \frac{1}{1/e_o + 1/e_i - 1} \tag{9}$$

where  $e_o$  and  $e_i$  are the hemispherical emissivities of the two air space surfaces. Hemispherical emissivity of ordinary uncoated glass is 0.84 over a wavelength range of 0.4 to 40 μm.

**REPRESENTATIVE U-FACTORS FOR FENESTRATION PRODUCTS**

Table 4 lists computed U-factors for a variety of generic fenestration products. The table is based on ASHRAE-sponsored research involving laboratory testing and computer simulation of various fenestration products. In the past, test data were used to provide more accurate results for specific products (Hogan 1988). Computer simulations (with validation by testing) are now accepted as the standard method for accurate product-specific U-factor determination. The simulation methodologies are specified in the National Fenestration Rating Council's NFRC 100 or Canadian Standards Association (CSA) *Standard A440.2* and are based on algorithms published in ISO *Standard 15099*. The *International Energy Conservation Code (ICC 2000)* and various state energy codes in the United States, the *National Energy Code* in Canada, and ASHRAE *Standards 90.1* and *90.2* all cite these standards. Fenestration needs to be rated in accordance with the NFRC or CSA standards for code compliance. The use of Table 4 should be limited to that of an estimating tool for the early phases of design.

Values in Table 4 are listed at winter design conditions for vertical installation and for skylights and other sloped installations with glazing surfaces that are sloped 20° from the horizontal. Data are based on center-of-glass and edge-of-glass component U-factors and assume that there are no dividers. However, they apply only to the specific design conditions described in the footnotes in the table, and they are typically used only to determine peak load conditions for sizing heating equipment. While these U-factors have been determined for winter conditions, they can also be used to estimate heat gain during peak cooling conditions, since conductive gain, which is one of several variables, is usually a small portion of the total heat gain for fenestration in direct sunlight. Glazing designs and framing materials may be compared in choosing a fenestration system that needs a specific winter design U-factor.

Table 4 lists 48 glazing types. (A subset of these types is included in Table 13, which lists solar heat gain coefficients and visible light transmittance.) The multiple glazing categories are appropriate for sealed glazing units and the addition of storm sash to other glazing units. No distinction is made between flat and domed units such as skylights. For acrylic domes, use an average gas-space width to determine the U-factor. Note that garden window and sloped/pyramid/barrel vault skylight U-factors are approximately twice those of other similar products. While this is partially due to the difference in slope in the case of the sloped/pyramid/barrel vault skylights, it is largely because these products project out from the surface of the wall or roof. For instance, the skylight surface area, which includes the curb, can vary from 13 to 240% greater than the rough opening area, depending on the size and mounting method. Unless otherwise noted, all multiple-glazed units are filled with dry air. Argon units are assumed to be filled with 90% argon (Elmahdy and Yusuf 1995). U-factors for CO<sub>2</sub>-filled units are similar to argon fills. For spaces up to 13 mm, argon/SF<sub>6</sub> (sulfur hexafluoride) mixtures up to 70% SF<sub>6</sub> are generally the same as argon fills. The use of krypton gas can provide U-factors lower than those for argon for glazing spaces less than 13 mm.

Table 4 provides data for six values of hemispherical emissivity and for 6.4 and 12.7 mm gas space widths. The emissivity of various low-e glasses varies considerably between manufacturers and processes. When the emissivity is between the listed values, interpolation may be used. When manufacturers' data are not available for

Notes:  
 1. All heat transmission coefficients in this table include film resistances and are based on winter conditions of -18°C outdoor air temperature and 21°C indoor air temperature, with 6.7 m/s outdoor air velocity and zero solar flux. With the exception of single glazing, small changes in the indoor and outdoor temperatures will not significantly affect overall U-factors. The coefficients are for vertical position except skylight values, which are for 20° from horizontal with heat flow up.  
 2. Glazing layer surfaces are numbered from the outdoor to the indoor. Double, triple, and quadruple refer to the number of glazing panels. All data are based on 3 mm glass, unless otherwise noted. Thermal conductivities are: 0.917 W/(m·K) for glass, and 0.19 W/(m·K) for acrylic and polycarbonate.  
 3. Standard spacers are metal. Edge-of-glass effects assumed to extend over the 65 mm band around perimeter of each glazing unit.

4. Product sizes are described in Figure 4, and frame U-factors are from Table 1.  
 5. Use  $U = 3.40 \text{ W/(m}^2\cdot\text{K)}$  for glass block with mortar but without reinforcing or framing.  
 6. The use of this table should be limited to that of an estimating tool for the early phases of design.

7. Values for triple- and quadruple-glazed garden windows are not listed as these are not common products.  
 8. Minor differences exist between the data in this table and U-factors determined using NFRC 100-91 because the data in this table are generated using modified heat transfer correlations for glazing cavities (Wright 1996) and indoor fenestration surfaces (Curcija and Goss 1995b).

low-e glass, assume that glass with a pyrolytic (hard) coating has an emissivity of 0.40 and that glass with a sputtered (soft) coating has an emissivity as low as 0.36. Tinted glass does not change the winter U-factor. Also, some reflective glass may have an emissivity less than 0.84. Values listed are for insulating glass units using aluminum edge spacers. If an insulated or nonmetallic spacer is used, the U-factors are approximately 0.17 W/(m<sup>2</sup>·K) lower.

Fenestration product types are subdivided first by vertical versus sloped installation and then into two general categories—manufactured and site-assembled. “Manufactured” is intended to represent products delivered as a complete unit to the site. These products are typically installed in low-rise residential and small commercial/institutional/industrial buildings. For vertical sliders, horizontal sliders, casement, awning, pivoted, and dual-action windows, and for sliding and swinging glass doors, use the operable category. For picture windows, use the fixed category. For products that project out from the surface of the wall, use the garden window category. For skylights, use the sloped skylight category.

“Site-assembled” is intended to represent products where frame extrusions are assembled on site into a fenestration product and then glazing is added on site. These products are typically installed in high-rise residential and larger commercial/institutional/industrial buildings. Curtain walls are typically made up of vision (transparent portion) and spandrel (opaque portion) panels. Table 4 contains representative U-factors for the vision panel (including mullions) for these assemblies. The spandrel portion of curtain walls usually consists of a metal pan filled with insulation and covered with a sheet of glass or other weatherproof covering. Although the U-factor in the center of the spandrel panel can be quite low, the metal pan is a thermal bridge, significantly increasing the U-factor of the assembly. Two-dimensional simulation validated by testing of a curtain wall having an aluminum frame with a thermal break found that the U-factor for the edge of the spandrel panel (the 65 mm band around the perimeter adjacent to the frame) was 40% of the way toward the U-factor of the frame. The U-factor was 0.34 W/(m<sup>2</sup>·K) for the center of the spandrel, 2.56 for the edge of the spandrel, and 6.02 for the

frame (Carpenter and Elmahdy 1994). Two-dimensional heat transfer analysis or physical testing is recommended to determine the U-factor of spandrel panels. Use the sloped/overhead glazing category for sloped glazing panels comparable to curtain walls.

Physical testing of double-glazed units showed U-factors of 5.7 W/(m<sup>2</sup>·K) for a thermally broken aluminum pyramidal skylight and 7.4 W/(m<sup>2</sup>·K) for an aluminum-frame half-round barrel vault (both normalized to a rough opening of 2.4 m by 2.4 m). Until more conclusive results are available, U-factors for these systems can be estimated by multiplying the “site-assembled sloped/overhead glazing” values in Table 4 by the ratio of total product surface area (including curbs) to rough opening area. These ratios range from 1.2 to 2.0 for low-slope skylights, 1.4 to 2.1 for pyramid assemblies sloped at 45°, and 1.7 to 2.9 for semicircular barrel vault assemblies. An example calculation is provided in Example 4.

The U-factors in Table 4 are based on the definitions of the six product types, frame sizes, and proportion of frame to glass area shown in Figure 4. Four of the products are manufactured fenestration products. The operable category glazing units are 1.35 m<sup>2</sup> in area, and the overall size corresponds to a 900 mm by 1500 mm fenestration product. The fixed (nonoperable) category is about 1.44 m<sup>2</sup> in area, and the overall size corresponds to a 1200 mm by 1200 mm window. The garden window category is 1.35 m<sup>2</sup> in projected area (3.15 m<sup>2</sup> in surface area) and 1500 mm wide by 900 mm high by 380 mm deep. The manufactured skylight category is a nominal 0.72 m<sup>2</sup> in area, corresponding to a 600 mm by 1200 mm skylight. The nominal dimensions of a roof-mounted skylight correspond to centerline spacing of roof framing members; consequently, the rough opening dimensions are 570 mm by 1180 mm. The curtain wall and sloped/overhead glazing categories are a nominal 1.44 m<sup>2</sup> in area, representing repeating 1200 mm by 1200 mm panels. The nominal dimensions correspond to centerline spacing of the head and sill and vertical mullions.

Six frame types are listed (although not all for any one category) in order of improving thermal performance. The most conservative assumption is to use the frame category of aluminum frame without

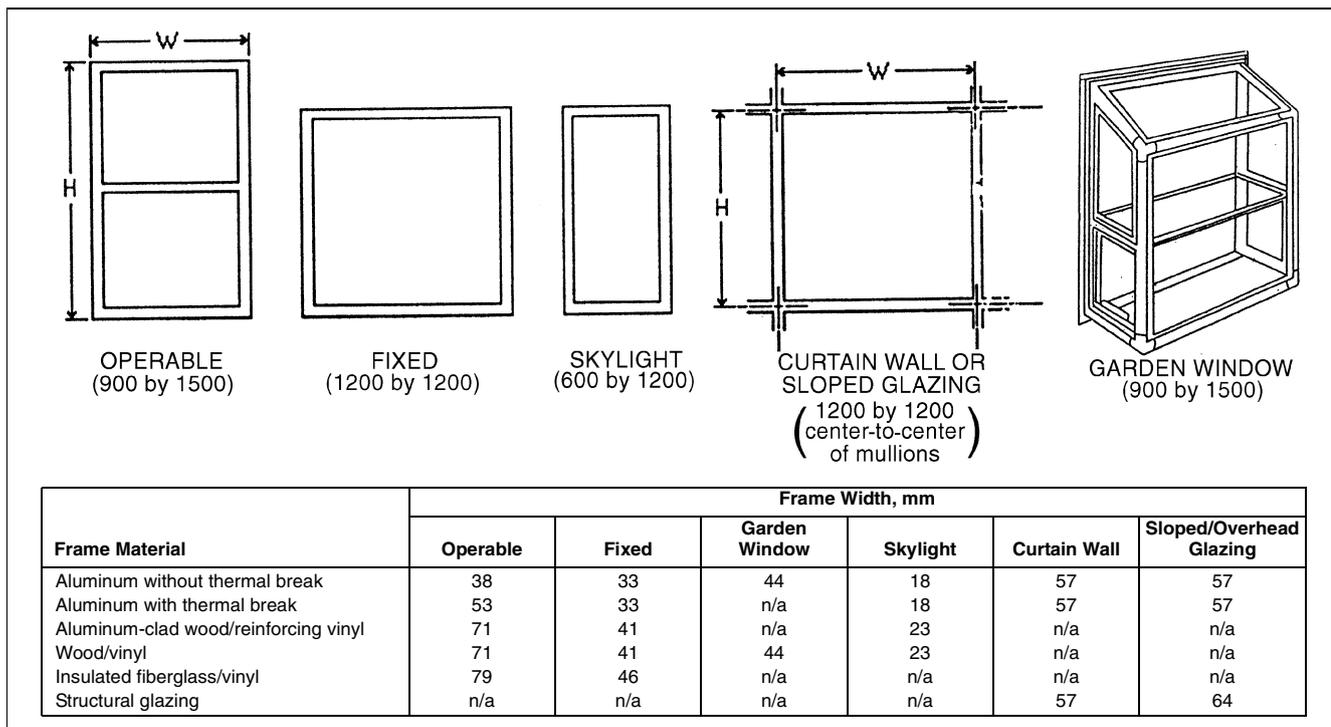

Fig. 4 Standard Fenestration Units

Table 5 Glazing U-Factors for Various Wind Speeds

6.0	5.03	5.08	
6.5	5.95	5.50	

a thermal break (although there are products on the market that have higher U-factors). The aluminum frame with a thermal break is for frames having at least a 10 mm thermal break between the inside and outside for all members including both the frame and the operable sash, if applicable. (Products are available with significantly wider thermal breaks, which achieve considerable improvement.) The reinforced vinyl/aluminum clad wood category represents vinyl-frame products, such as sliding glass doors or large windows that have extensive metal reinforcing within the frame and wood products with extensive metal, usually on the exterior surface of the frame. Both of these factors provide short circuits, which degrade the thermal performance of the frame material. The wood/vinyl frame is meant to represent the improved thermal performance that is possible if the thermal short circuits from the previous frame category do not exist. Insulated fiberglass/vinyl represents fiberglass or vinyl frames that do not have metal reinforcing and whose frame cavities are filled with insulation. For several site-assembled product types, there is a structural glazing frame category that is intended to represent products where sheets of glass are butt-glazed to each other using a sealant only, and none of the framing members is exposed to the exterior. For glazing with a steel frame, use aluminum frame values. For aluminum window with wood trim or vinyl cladding, use the values for aluminum. Frame type refers to the primary unit. Thus, when storm sash is added over another fenestration product, use the values given for the nonstorm product.

To estimate the overall U-factor of a fenestration product that differs significantly from the assumptions given in Table 4 and/or Figure 4, first determine the area that is frame/sash, center-of-glass, and edge-of-glass (based on a 65 mm band around the perimeter of each glazing unit). Next, determine the appropriate component U-factors. These can be taken either from the standard values listed in italics in Table 4 for glass, from the values in Table 1 for frames, or from some other source such as test data or computed factors. Finally, multiply the area and the component U-factors, sum these products, and then divide by the rough opening in the building envelope where this product will fit to obtain the overall U-factor  $U_o$ .

Table 5 provides approximate data to convert the overall U-factor at one wind condition to a U-factor at another.

### REPRESENTATIVE U-FACTORS FOR DOORS

Doors are often an overlooked component in the thermal integrity of the building envelope. Although swinging and revolving doors represent a small portion of the shell in residential, commercial, and institutional buildings, their U-factor is usually many times higher than that of the walls or ceilings. In some storage and

industrial buildings, loading bay doors (overhead doors) represent a significant area of high heat loss. Table 6 contains representative U-factors for swinging, overhead, and revolving doors determined through computer simulation (Carpenter and Hogan 1996). These are generic values, and product-specific values determined in accordance with standards should be used whenever available. NFRC 100, Section B, and CSA *Standard* A453 give procedures for evaluating the performance of swinging doors. Overhead doors are often evaluated in accordance with National Association of Garage Door Manufacturers (NAGDM) *Standard* 105. Where these standards are cited in codes, they must be used for compliance.

Swinging doors can be divided into two categories: slab and stile-and-rail. A stile-and-rail door is a swinging door with a full-glass insert supported by horizontal rails and vertical stiles. The stiles and rails are typically either solid wood members or extruded aluminum or vinyl, as shown in Figure 5. Most residential doors are slab type with either solid wood, steel, or fiberglass skin over foam insulation in a wood frame with aluminum sill. The edges of the

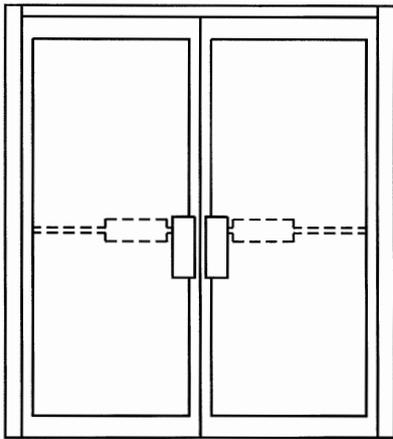

Fig. 5 Details of Stile-and-Rail Door

steel skin door are normally wood to provide a thermal break. In commercial construction, doors are either steel skin over foam insulation in a steel frame (i.e., utility doors) or a full glass door made up of aluminum stiles, rails, and frame (i.e., entrance doors). The most important factors affecting door U-factor are material construction, glass size, and glass type. Frame depth, slab width, and number of panels have a minor effect on door performance. Sidelites and double doors have U-factors similar to a single door of the same construction. For wood slab doors in a wood frame, the glazing area does not have much effect on the U-factor. For the insulated steel slab in a wood frame, however, glazing area has a strong effect on U-factor. Typical commercial insulated slab doors have a U-factor approximately twice that of residential insulated doors, the prime reason being thermal bridging of the slab edge and the steel frame. Stile-and-rail doors, even if thermally broken, have U-factors 50% higher than a full-glass commercial steel slab door.

There are three generic types of overhead doors: roll-up, uninsulated sectional, and insulated sectional. Metal roll-up doors consist of small metal plates of approximately 65 mm in height that “roll up” around a metal rod to open. Sectional doors consist of a series of 600 mm high sections that travel in a track to open. There is a wide range in the design of insulated overhead doors. Factors affecting heat transfer include width of insulation, thermal break design (if any), and design of interior skin. For the uninsulated sectional door, there is very little difference between the center value and the total value: essentially the value of single glazing. The center of the insulated door has low U-factors, but thermal bridging at the door and section edges significantly increases the total U-factor. For doors without thermally broken edges, the total value is 2.5 to 3.3 times greater than the center value. The addition of a good thermal break design reduces this increase to a 1.6 multiplier.

Many commercial buildings use revolving entrance doors. Most of these doors are of similar design: single glazing in an aluminum frame without thermal break. The door, however, can be in two positions: closed (X shaped as viewed from above) or open (+ shaped). At nighttime, these doors are locked in the X position, effectively creating a double-glazed system. During the daytime, the door revolves and is often left positioned so that there is only one glazing between the inside and outside (+ position). U-factors are given in Table 6 for both positions.

## EXAMPLES

**Example 1.** Estimate the U-factor for a manufactured fixed fenestration product with a reinforced vinyl frame and double-glazing with a sputter-type low-e coating ( $e = 0.10$ ). The gap is 13 mm wide and argon-filled, and the spacer is metal.

**Solution:** Locate the glazing system type in the first column of Table 4 (ID = 23), then find the appropriate product type (fixed) and frame type (reinforced vinyl). The U-factor listed (in the tenth column of U-factors) is  $1.89 \text{ W}/(\text{m}^2 \cdot \text{K})$ .

**Example 2.** Estimate a representative U-factor for a wood-framed, 970 mm by 2080 mm swinging French door with eight 280 mm by 400 mm panes (true divided panels), each consisting of clear double-glazing with a 6.5 mm air space and a metal spacer.

**Solution:** Without more detailed information, assume that the dividers have the same U-factor as the frame and that the divider edge has the same U-factor as the edge-of-glass. Calculate the center-of-glass, edge-of-glass, and frame areas:

$$A_{cg} = 8[(280 - 130)(400 - 130)]/10^6 = 0.324 \text{ m}^2$$

$$A_{eg} = 8(280 \times 400)/10^6 - 0.324 = 0.572 \text{ m}^2$$

$$A_f = (970 \times 2080)/10^6 - 8(280 \times 400)/10^6 = 1.122 \text{ m}^2$$

Select the center-of-glass, edge-of-glass, and frame U-factors. These component U-factors are 3.29 and 3.63  $\text{W}/(\text{m}^2 \cdot \text{K})$  (from Table 4, glazing ID = 4, U-factor columns 1 and 2) and 2.90  $\text{W}/(\text{m}^2 \cdot \text{K})$  (from Table 1, wood frame, metal spacer, operable, double-glazing), respectively. From Equation (7),

$$U_o = \frac{(3.12 \times 0.324) + (3.63 \times 0.572) + (2.90 \times 1.122)}{(0.97 \times 2.08)} \\ = 3.14 \text{ W}/(\text{m}^2 \cdot \text{K})$$

**Example 3.** Estimate the overall average U-factor for a multifloor curtain wall assembly that is part vision glass and part opaque spandrel. The typical floor-to-floor height is 3.6 m, and the building module is 1.2 m as reflected in the spacing of the mullions both horizontally and vertically. For a representative section 1.2 m wide and 3.6 m tall, one of the modules is glazed and the other two are opaque. The mullions are aluminum frame with a thermal break 80 mm wide and centered on the module. The IGU is double glazing with a pyrolytic low-e coating ( $e = 0.40$ ) and has a 13 mm gap filled with air and a metal spacer. The spandrel panel has a metal pan backed by  $R = 3.5 \text{ m}^2 \cdot \text{K}/\text{W}$  insulation and no intermediate reinforcing members.

**Solution:** It is necessary to calculate the U-factor for the glazed module and for the opaque spandrel modules and then to do an area-weighted average to determine the average U-factor for the overall curtain wall assembly.

First, calculate the overall U-factor for the glazed module. Calculate the center-of-glass, edge-of-glass, and frame areas. The glazed area is 1120 mm by 1120 mm (1200 mm module, 1200 mm of mullions on each edge).

$$A_{cg} = (1120 - 130)(1120 - 130)/10^6 = 0.9801 \text{ m}^2$$

$$A_{eg} = (1120 \times 1120)/10^6 - 0.9801 = 0.2743 \text{ m}^2$$

$$A_f = [(1200 \times 1200)/10^6 - (1120 \times 1120)]/10^6 = 0.1856 \text{ m}^2$$

Select the center-of-glass, edge-of-glass, and frame U-factors. These component U-factors are 2.27 and 3.04  $\text{W}/(\text{m}^2 \cdot \text{K})$  (from Table 4, ID = 13, columns 1 and 2) and 9.94  $\text{W}/(\text{m}^2 \cdot \text{K})$  (from Table 1, aluminum frame with a thermal break, metal spacer, curtain wall, double glazing), respectively. From Equation (7),

$$U_{\text{glazing module}} = \frac{(2.27 \times 0.9801) + (3.04 \times 0.2743) + (9.94 \times 0.1856)}{(1.2 \times 1.2)} \\ = 3.41 \text{ W}/(\text{m}^2 \cdot \text{K})$$

Then, calculate the overall U-factor for the two opaque spandrel modules. The center-of-spandrel, edge-of spandrel, and frame areas are the same as the glazed module. The frame U-factor is the same. Calculate the center-of-spandrel U-factor. In this particular case, the R-value of the insulation does not need to be rated as there are no intermediate framing members penetrating it and providing thermal short circuits. When the resistance of the insulation ( $3.5 \text{ m}^2 \cdot \text{K}/\text{W}$ ) is

added to the exterior air film resistance of  $0.03 \text{ m}^2 \cdot \text{K}/\text{W}$  and the interior air film resistance of  $0.12 \text{ m}^2 \cdot \text{K}/\text{W}$  (from Table 1, Chapter 25), the total resistance is  $3.65 \text{ m}^2 \cdot \text{K}/\text{W}$  and the U-factor is  $1/3.65 = 0.274 \text{ W}/(\text{m}^2 \cdot \text{K})$ . The edge-of-spandrel U-factor is 40% of the way to the frame U-factor, which is  $0.274 + [0.40(9.94 - 0.274)] = 4.14 \text{ W}/(\text{m}^2 \cdot \text{K})$ .

$$U_{\text{opaque spandrel module}} = \frac{(0.274 \times 0.9801) + (4.14 \times 0.2743) + (9.94 \times 0.1856)}{(1.2 \times 1.2)} = 2.26 \text{ W}/(\text{m}^2 \cdot \text{K})$$

Finally, calculate the overall average U-factor for the curtain wall assembly, including the one module of vision glass and the two modules of opaque spandrel.

$$U_{\text{curtain wall}} = \frac{[3.41 \times (1.2 \times 1.2)] + [2.26 \times 2 \times (1.2 \times 1.2)]}{3 \times (1.2 \times 1.2)} = 2.64 \text{ W}/(\text{m}^2 \cdot \text{K})$$

Note that even with double glazing having a low-e coating and with R-20 in the opaque areas, this curtain wall with metal pans only has an overall R-value of approximately  $0.38 \text{ m}^2 \cdot \text{K}/\text{W}$ .

**Example 4.** Estimate the U-factor for a semicircular barrel vault that is 6 m wide (3 m tall) and 10 m long mounted on a 150 mm curb. The barrel vault has an aluminum frame without a thermal break. The glazing is double with a 13 mm gap width filled with air and a low-e coating ( $e = 0.20$ ).

**Solution:** An approximation can be made by multiplying the U-factor for a site-assembled sloped/overhead glazing product having the same frame and glazing features by the ratio of the surface area (including the curb) of the barrel vault to the rough opening area in the roof that the barrel vault fits over. First, determine the surface area (including the curb) of the barrel vault:

$$\begin{aligned} \text{Area of the curved portion of the barrel vault} &= (\pi \times \text{diameter}/2) \times \text{length} \\ &= (3.14 \times 6/2) \times 10 = 94.25 \text{ m}^2 \end{aligned}$$

$$\begin{aligned} \text{Area of the two ends of the barrel vault} &= 2\pi(\text{radius})^2/2 = \pi r^2 \\ &= 3.14 \times 3^2 = 28.27 \text{ m}^2 \end{aligned}$$

$$\begin{aligned} \text{Area of the curb} &= \text{perimeter} \times \text{curb height} \\ &= (6 + 10 + 6 + 10) \times 0.150 = 4.8 \text{ m}^2 \end{aligned}$$

$$\begin{aligned} \text{Total surface area of the barrel vault} &= 94.25 + 28.27 + 4.8 = 127.3 \text{ m}^2 \end{aligned}$$

Second, determine the rough opening area in the roof that the barrel vault fits over:

$$\begin{aligned} &= \text{length} \times \text{width} \\ &= 6 \times 10 = 60 \text{ m}^2 \end{aligned}$$

Third, determine the ratio of the surface area to the rough opening area:

$$= 127.3/60 = 2.12$$

Fourth, determine the U-factor from Table 4 of a site-assembled sloped/overhead glazing product having the same frame and glazing features. The U-factor is  $4.06 \text{ W}/(\text{m}^2 \cdot \text{K})$  (ID = 17, 12th column on the second page of Table 4).

Fifth, determine the estimated U-factor of the barrel vault.

$$\begin{aligned} U_{\text{barrel vault}} &= U_{\text{sloped overhead glazing}} \times \text{surface area/rough opening for the barrel vault} \\ &= 4.06 \times 2.12 = 8.61 \text{ W}/(\text{m}^2 \cdot \text{K}) \end{aligned}$$

## SOLAR HEAT GAIN AND VISIBLE TRANSMITTANCE

Fenestration solar heat gain has two components. First is directly transmitted solar radiation. The quantity of radiation entering the fenestration directly is governed by the solar transmittance of the glazing system. Multiplying the incident irradiance by the glazing area and its solar transmittance yields the solar heat enter-

ing the fenestration directly. The second component is the absorbed solar radiation, radiation that is removed from the main beam and absorbed in the glazing and framing materials of the window, some of which is subsequently conducted to the interior of the building.

### DETERMINING INCIDENT SOLAR FLUX

#### Solar Radiation

The flux of solar radiation on a surface normal (perpendicular) to the sun's rays above the earth's atmosphere at the mean earth-sun distance of  $149.5 \times 10^6 \text{ km}$  (Allen 1973) is defined as the solar constant  $E_{sc}$ . The currently accepted value is  $1367 \text{ W}/\text{m}^2$  (Iqbal 1983). Because the earth's orbit is slightly elliptical, the extraterrestrial radiant flux  $E_o$  varies from a maximum of  $1413 \text{ W}/\text{m}^2$  on January 3, when the earth is closest to the sun (aphelion), to a minimum of  $1332 \text{ W}/\text{m}^2$  on July 4, when the earth-sun distance reaches its maximum (perihelion).

The earth's orbital velocity also varies throughout the year, so **apparent solar time**, as determined by a solar time sundial, varies somewhat from the **mean time** kept by a clock running at a uniform rate. This variation, called the **equation of time**, is given in Table 7. The conversion between local standard time and solar time involves two steps. First the equation of time is added to the local standard time, and then a longitude correction is added. This longitude correction is four minutes of time per degree difference between the local (site) longitude and the longitude of the **local standard meridian** for that time zone. Standard meridians are found every  $15^\circ$  from  $0^\circ$  at Greenwich, England (Greenwich Meridian). In the United States and Canada, these values are  $60^\circ$  for Atlantic Standard Time,  $75^\circ$  for Eastern Standard Time,  $90^\circ$  for Central Standard Time,  $105^\circ$  for Mountain Standard Time,  $120^\circ$  for Pacific Standard Time,  $135^\circ$  for Alaska Standard Time, and  $150^\circ$  for Hawaii-Aleutian Standard Time.

Equation (10) relates apparent solar time (AST) to local standard time (LST) as follows:

$$\text{AST} = \text{LST} + \text{ET}/60 + (\text{LSM} - \text{LON})/15 \quad (10)$$

where

AST = apparent solar time, decimal hours

LST = local solar time, decimal hours

ET = equation of time, decimal minutes

LSM = local standard time meridian, decimal  $^\circ$  of arc

LON = local longitude, decimal  $^\circ$  of arc

Because the earth's equatorial plane is tilted at an angle of  $23.45^\circ$  to the orbital plane, the **solar declination**  $\delta$  (the angle between the

Note: Data are for 21st day of each month during the base year of 1964.

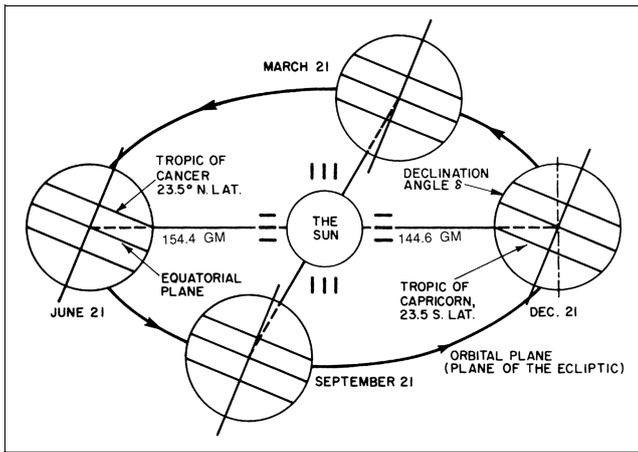

Fig. 6 Motion of Earth around Sun

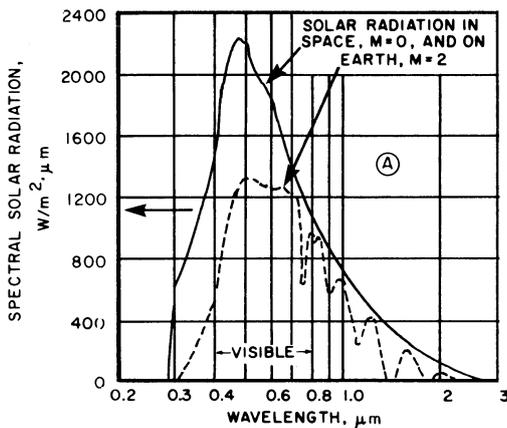

Fig. 7 Terrestrial and Extraterrestrial Solar Spectral Irradiances

earth-sun line and the equatorial plane) varies through out the year, as shown in Figure 6, Table 7, and Equation (11). This variation causes the changing seasons with their unequal periods of daylight and darkness. The following equation can be used to estimate the declination from the day of year  $\eta$ , but it is more accurate to look up the actual declination in an astronomical or nautical almanac for the actual year and date in question.

$$\delta = 23.45 \sin \{ [360(284 + \eta)] / 365 \} \quad (11)$$

The spectral distribution of solar radiation beyond the earth's atmosphere (Figure 7) resembles the radiant energy emitted by a blackbody at about 6000 K. The peak solar spectral irradiance of  $2130 \text{ W}/(\text{m}^2 \cdot \text{K})$  is reached at  $0.451 \mu\text{m}$  ( $451 \text{ nm}$ ) in the green portion of the visible spectrum.

In passing through the earth's atmosphere, the sun's radiation is reflected, scattered, and absorbed by dust, gas molecules, ozone, water vapor, and water droplets (fog and clouds). The extent of this depletion at any given time is determined by atmospheric composition and length of the atmospheric path traversed by the sun's rays. This length is expressed in terms of the air mass  $m$ , which is the ratio of the mass of atmosphere in the actual earth-sun path to the mass that would exist if the sun were directly overhead at sea level ( $m = 1.0$ ). For most purposes, the air mass at any time equals the cosecant of the solar altitude multiplied by the ratio of the existing barometric pressure to standard pressure. Beyond the atmosphere,  $m = 0$ .

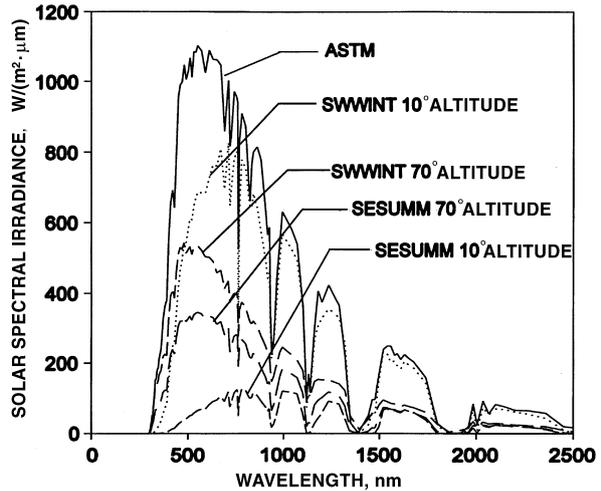

Fig. 8 Comparison of Standard Air Mass  $m = 1.5$  Solar Spectrum with Direct Beam Spectra Through Atmospheres Characteristic of southwest in winter (SWWINT) and southeastern U.S. in summer (SESUMM) for two solar altitude angles (McCluney 1996)

Table 8 Portions of Total Solar Spectral Irradiance Contained in Portions of Visible Spectrum

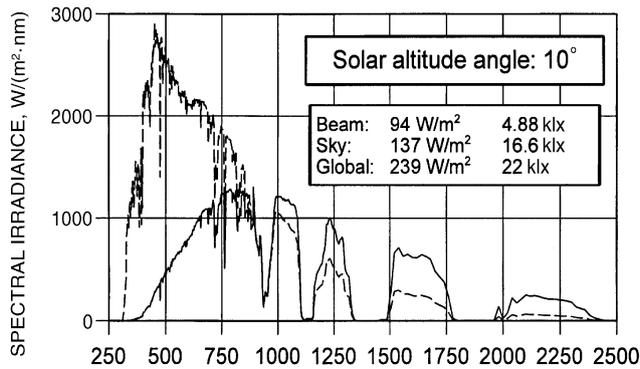

Wavelength, nm		Percent Irradiance	Percent Illuminance
Start	End		
370	770	54.4	100.0
380	760	52.2	100.0
390	750	50.2	99.9
400	740	47.4	99.9
410	730	44.9	99.8
420	720	41.9	99.8
430	710	39.5	99.8
440	700	36.7	99.8
450	690	35.3	99.5
460	680	31.1	99.1

Note: The integrated total irradiance =  $950 \text{ W}/\text{m}^2$  and illuminance =  $100 \text{ klx}$ .

Most ultraviolet solar radiation is absorbed by the ozone in the upper atmosphere, while part of the radiation in the short-wave portion of the spectrum is scattered by air molecules, imparting the blue color to the sky. Water vapor in the lower atmosphere causes the characteristic absorption bands observed in the solar spectrum at sea level (Figure 7). For a solar altitude  $\beta$  of  $41.8^\circ$  (air mass  $m = 1.5$ ), the total solar direct beam flux on a clear day at sea level can be divided into spectral regions as follows. Less than 3% of the total is in the ultraviolet, 47% is in the visible region, and the remaining 50% is in the infrared (ASTM Standard E 891). The maximum spectral irradiance occurs at  $0.61 \mu\text{m}$ , and little solar energy (less than 5% of the spectrum) exists at wavelengths beyond  $2.1 \mu\text{m}$ .

It is interesting to see what fraction of the total solar irradiance lies in the visible part of the spectrum. Since the limits of the visible portion vary from observer to observer (and because the eye is not very sensitive to radiation at the spectral limits of vision), the fractions of total irradiance and illuminance found between different spectral limits at the edge of the visible portion of the spectrum can be calculated. The results are shown in Table 8 for the ASTM air mass  $m = 1.5$  terrestrial spectrum shown in Figure 8.

The solar spectral distribution shown in Figure 7 for  $m = 0$  is the World Radiation Center's 1985 standard extraterrestrial spectrum for a solar constant of  $1367 \text{ W}/\text{m}^2$  (Wehrli 1985). The one for  $m = 1.5$  in Figure 8 is from ASTM Standard E 891. This latter takes no account of monthly variations in irradiance caused by changes in the

**Fig. 9 Comparison of Direct and Diffuse Solar Spectra for Low Solar Altitude Angle**

earth-sun distance and by variations in the atmosphere's constituent particulates and gases.

When variations in atmospheric constituents and air mass are considered, the solar spectral distribution is seen to vary, as illustrated in Figure 8, for two different atmospheric conditions and for two solar altitude angles, and in Figure 9 for both direct and diffuse radiation components and a low sun angle. It is clear that the spectral distribution for low sun angle beam radiation is significantly shifted toward longer wavelengths. This shift can be seen visually as a reddening of the sun near to the horizon. Clear sky diffuse radiation is generally shifted toward the blue end of the spectrum.

Upon passage through the atmosphere, extraterrestrial solar radiation is reduced in magnitude due to absorption by atmospheric gases and particulates. The strength of this absorption varies with wavelength, and the terrestrial solar spectrum exhibits definite "dips" in regions of strong absorption, called **absorption bands**. The most prominent atmospheric gases contributing to this effect are listed below:

- **Ozone.** Strongest absorption in the ultraviolet, some in the visible. Concentration variable.
- **H<sub>2</sub>O.** Strongest absorption in near and far IR. Highly variable.
- **CO<sub>2</sub>.** Strongest absorption in near and far IR. Slightly variable.
- **O<sub>2</sub>, CH<sub>4</sub>, N<sub>2</sub>O, CFCs.** Strongest absorption mostly in the IR. Concentration almost constant.
- **NO<sub>2</sub>.** Strongest absorption in the visible. Highly variable in polluted areas.

The effect of aerosols and other particulates on terrestrial solar radiation can be significant. Diffuse sky radiation is solar beam radiation that has been multiply scattered out of the direct beam and downward through the atmosphere to the earth's surface. This scattering is produced by 30 different atmospheric molecules (of which the above are the most significant optically) and by larger particles of different types, including aerosols of water, dust, smoke, and particulates of other kinds.

More information on atmospheric optics can be found in Chapter 44 of the Optical Society of America's *Handbook of Optics* (Bass 1995) and in Iqbal (1983).

Glazing systems exhibiting strong spectral selectivity (strong changes in their optical properties over the solar spectrum) will selectively pass more or less radiation in different parts of the spectrum. This effect can cause substantial changes in the solar heat gain coefficient of the glazing system when the shape of the solar spectrum shifts appreciably. This in turn can cause errors in solar heat gain predictions when the actual solar radiation on a fenestration system has a spectrum that is different from the standard spectrum used to determine the solar heat gain coefficient of that system

(McCluney 1996). These errors are typically 5 to 10% but can be substantially greater in special cases.

Some short-wavelength radiation scattered by air molecules, dust, and other particulates in the atmosphere reaches the earth in the form of diffuse sky radiation  $E_d$ . Since this diffuse radiation comes from all parts of the sky, its irradiance is difficult to predict and varies as moisture and particulate content and sun angle change throughout any given day. For completely overcast conditions, the diffuse component accounts for all solar radiant heat gain of fenestrations.

The total short-wavelength irradiance  $E_t$  reaching a terrestrial surface is the sum of the direct solar radiation  $E_D$ , the diffuse sky radiation  $E_d$ , and the solar radiation  $E_r$  reflected from surrounding surfaces. The irradiance on the fenestration aperture of the direct beam component  $E_D$  is the product of the direct normal irradiation  $E_{DN}$  and the cosine of the angle of incidence  $\theta$  between the incoming solar rays and a line normal (perpendicular) to the surface:

$$E_t = E_{DN} \cos \theta + E_d + E_r \quad (12)$$

A method for computing all the factors on the right side of Equation (12) is presented in the sections on Direct Normal Irradiance and Diffuse and Ground-Reflected Radiation. Perez et al. (1986), Gueymard (1987), *Solar Energy* (1988), and Gueymard (1993) give more detailed models, which separate the diffuse sky radiation into different components. Gueymard (1995) provides a comprehensive spectrally based model for calculating the spectral and broadband totals of all three terms in Equation (12), for cloudless sky conditions. The Gueymard model allows user input of the concentrations of a variety of atmospheric constituents, including particulates.

The importance of the diffuse component is illustrated in Figure 9, which shows that at low sun angles the diffuse component contains more radiant flux than the direct beam component, even on a clear day, and that the spectral distributions of the two components are quite different. Although the total irradiances are relatively modest for both of these components, they are not insignificant for annual energy performance calculations.

Vertical windows receive considerable quantities of diffuse sky radiation over the course of a year. The diffuse component is an important part of solar radiant heat gain.

### Determining Solar Angle

The sun's position in the sky is conveniently expressed in terms of the solar altitude  $\beta$  above the horizontal and the solar azimuth  $\phi$  measured from the south (Figure 10). These angles, in turn, depend on the local latitude  $L$ ; the solar declination  $\delta$ , which is a function of the date [Table 7 or Equation (11)]; and the apparent solar time, expressed as the hour angle  $H$ , where

$$H = 15(\text{AST} - 12) \quad (13)$$

Equations (14) and (15) relate  $\beta$  and  $\phi$  to the three angles just mentioned:

$$\sin \beta = \cos L \cos \delta \cos H + \sin L \sin \delta \quad (14)$$

$$\cos \phi = \frac{\sin \beta \sin L - \sin \delta}{\cos \beta \cos L} \quad (15)$$

Figure 10 shows the solar position angles and incident angles for horizontal and vertical surfaces. Line OQ leads to the sun, the north-south line is NOS, and the east-west line is EOW. Line OV is perpendicular to the horizontal plane in which the solar azimuth  $\phi$  (angle HOS) and the surface azimuth  $\Psi$  (angle POS) are located. Angle HOP is the surface solar azimuth  $\gamma$ , defined as

$$\gamma = \phi - \Psi \quad (16)$$

The solar azimuth  $\phi$  is positive for afternoon hours and negative for morning hours. Likewise, surfaces that face west have a positive

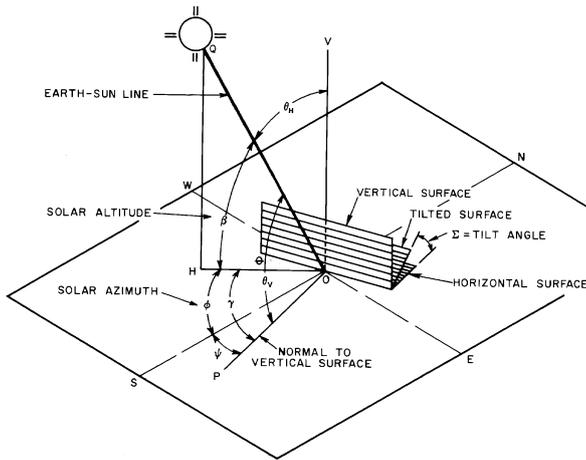

Fig. 10 Solar Angles for Vertical and Horizontal Surfaces

Table 9 Surface Orientations and Azimuths, Measured from South

Orientation	N	NE	E	SE	S	SW	W	NW
Surface azimuth ψ	180°	-135°	-90°	-45°	0	45°	90°	135°

surface azimuth ψ; those facing east have a negative surface azimuth (Table 9). If ψ is greater than 90° or less than -90°, the surface is in the shade. Table 9 gives values in degrees for the surface azimuth ψ, applicable to the orientations of interest.

The angle of incidence θ for any surface is defined as the angle between the incoming solar rays and a line normal to that surface. For the horizontal surface shown in Figure 10, the incident angle θ<sub>H</sub> is QOV; for the vertical surface, the incident angle θ<sub>V</sub> is QOP.

For any surface, the incident angle θ is related to β, γ, and the tilt angle of the surface Σ by

$$\cos\theta = \cos\beta \cos\gamma \sin\Sigma + \sin\beta \cos\Sigma \quad (17)$$

where Σ = tilt angle of surface from horizontal.

When the surface is horizontal, Σ = 0° and

$$\cos\theta_H = \sin\beta \quad (18)$$

For a vertical surface, Σ = 90° and

$$\cos\theta_V = \cos\beta \cos\gamma \quad (19)$$

**Direct Normal Irradiance**

At the earth's surface on a clear day, direct normal irradiation, or solar irradiance E<sub>DN</sub>, is represented by

$$E_{DN} = \frac{A}{\exp(B/\sin\beta)} \quad (20)$$

where

A = apparent solar irradiation at air mass m = 0 (Table 7)

B = atmospheric extinction coefficient (Table 7)

Values of A and B vary during the year because of seasonal changes in the dust and water vapor content of the atmosphere and because of the changing earth-sun distance. Equation (20) does not give the maximum value of E<sub>DN</sub> that can occur in each month but yields values that are representative of conditions on cloudless days for a relatively dry and clear atmosphere. For very clear atmospheres, E<sub>DN</sub> can be 15% higher than indicated by Equation (20), using values of A and B in Table 7.

For locations where clear, dry skies predominate (e.g., at high elevations) or, conversely, where hazy and humid conditions are frequent, values found by using Equation (20) and Table 7 should be

Table 10 Solar Reflectances of Foreground Surfaces

Foreground Surface	Incident Angle					
	20°	30°	40°	50°	60°	70°

Adapted from Threlkeld (1962)

multiplied by the Clearness Numbers in Threlkeld and Jordan (1958), reproduced as Figure 5 in Chapter 32 of the 1999 ASHRAE Handbook—Applications. This broadband model should only be used for determining fenestration solar gain when the glazing system is not strongly spectrally selective and when its angular selectivity closely matches that of single-pane glass.

**Diffuse and Ground-Reflected Radiation**

The following equations can be used to generate E<sub>d</sub> and E<sub>r</sub>, where all angles are in degrees. The solar azimuth φ and the surface azimuth ψ are measured in degrees from south; angles to the east of south are negative, and angles to the west of south are positive. Values of A, B, and C are given in Table 7 for the 21st day of each month. Values for other dates can be obtained by interpolation.

The ratio Y of sky diffuse radiation on a vertical surface to sky diffuse radiation on a horizontal surface is given by

$$Y = 0.55 + 0.437 \cos\theta + 0.313 \cos^2\theta \quad \text{for } \cos\theta > -0.2$$

$$Y = 0.45 \quad \text{for } \cos\theta \leq -0.2 \quad (21)$$

Diffuse irradiance E<sub>d</sub> is given by

$$E_d = CYE_{DN} \quad \text{for vertical surfaces} \quad (22)$$

$$E_d = CE_{DN} \frac{1 + \cos\Sigma}{2} \quad \text{for surfaces other than vertical} \quad (23)$$

Ground-reflected irradiance E<sub>r</sub> is given by

$$E_r = E_{DN}(C + \sin\beta)\rho_g \frac{1 - \cos\Sigma}{2} \quad \text{for surfaces at all orientations} \quad (24)$$

where ρ<sub>g</sub> is ground reflectivity, often taken to be 0.2 for typical mixture of ground surfaces. For other surfaces, Table 10 lists angle-dependent solar reflectances.

**Example 5.** Find the solar azimuth and altitude at 3:00 P.M. central daylight savings time on June 21 in St. Louis, MO.

**Solution:** Central daylight savings time of 3:00 P.M. re-expressed in decimal hours at local standard time is LST = 14.0. The latitude and longitude of St. Louis, MO, are 38.6°N and 90.2°W, respectively. The local standard meridian of the central time zone is 90°W. The equation of time (Table 7) is -1.4 min. From Equation (10), apparent solar time (AST) = 14.0 - 1.4/60 + (90 - 90.2)/15 = 13.9633. From Equation (13), H = 15 × (13.9633 - 12) = 29.45°. Table 7 gives the solar declination δ on June 21 as 23.45°.

Thus, by Equation (14),

$$\sin\beta = \cos(38.6^\circ) \cos(23.45^\circ) \cos(29.45^\circ) + \sin(38.6^\circ) \sin(23.45^\circ) = 0.873$$

$$\beta = 60.76^\circ$$

Using Equation (15),

$$\cos\phi = \frac{\sin(60.76) \sin(38.6) - \sin(23.45)}{\cos(60.76) \cos(38.6)} = 0.384$$

$$\phi = 67.4^\circ$$

**Example 6.** For the conditions of Example 5, find the incident angle at a window facing west.

**Solution:** From Example 5,  $\phi = 67.4^\circ$ . From Table 9,  $\psi = 90^\circ$ . From Equation (16),  $\gamma = 67.4^\circ - 90^\circ = -22.6^\circ$ .

A negative surface solar azimuth  $\gamma$  indicates that the sun is south of the normal to the surface. Thus, using Equation (19),

$$\begin{aligned} \cos\theta &= \cos(60.76^\circ) \cos(-22.6^\circ) = 0.451 \\ \theta &= 63.2^\circ \end{aligned}$$

**Example 7.** Find the direct, diffuse, and ground-reflected components of the solar irradiation on the window in Example 6.

**Solution:** From Example 5,  $\sin\beta = 0.873$ , and from Table 7,  $A = 1088 \text{ W/m}^2$  and  $B = 0.205$ . Therefore, from Equation (20),

$$E_{DN} = 1088 / [\exp(0.205/0.873)] = 860.3 \text{ W/m}^2$$

$$E_{DN} \cos(\theta) = 860.3 \times 0.451 = 388 \text{ W/m}^2$$

From Table 7,  $C = 0.134$ . From Equation (21),  $Y = 0.55 + 0.437 \times 0.451 + 0.313 \times (0.451)^2 = 0.811$ . From Equation (22),

$$E_d = (0.134)(0.811)(860.3) = 93.5 \text{ W/m}^2$$

From Equation (24), assuming a ground reflectivity  $\rho_g$  of 0.2,

$$E_r = (860.3)(0.134 + 0.873)(0.2)/2 = 86.6 \text{ W/m}^2$$

### Thermal Infrared Radiation

Any material above a temperature of absolute zero emits electromagnetic radiation. The rate of emission depends upon the temperature of the material and can be expressed in a simple equation, called the Stefan-Boltzmann law:

$$E_b = \sigma T^4 \tag{25}$$

where

- $E_b$  = hemispherical total emissive power of black body,  $\text{W/m}^2$
- $T$  = temperature, K
- $\sigma$  = Stefan-Boltzmann constant,  $\text{W}/(\text{m}^2 \cdot \text{K}^4)$

The **emissivity**  $e$  of a surface is the ratio of the emission of thermal radiant flux from the surface to the flux that would be emitted by a blackbody emitter at the same temperature. Given the temperature and emissivity of a surface, the emitted irradiance spectrum can be computed from

$$E = e\sigma T^4$$

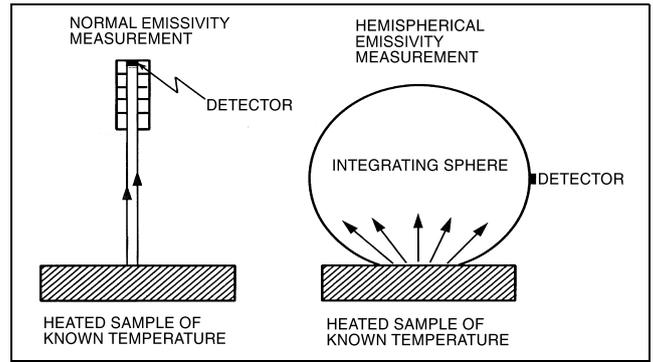

where  $E$  is the emitted irradiance in units of flux per unit area,  $e$  is the emissivity of the surface,  $\sigma$  is the Stefan-Boltzmann constant, and  $T$  is the absolute temperature of the surface.

The maximum value of **hemispherical emissivity**  $e$  for any material is 1.0, in which case the surface emits the theoretical maximum amount of radiation possible. In this case, the surface is called a **blackbody**, and the radiation emitted by the surface is called **blackbody radiation**.

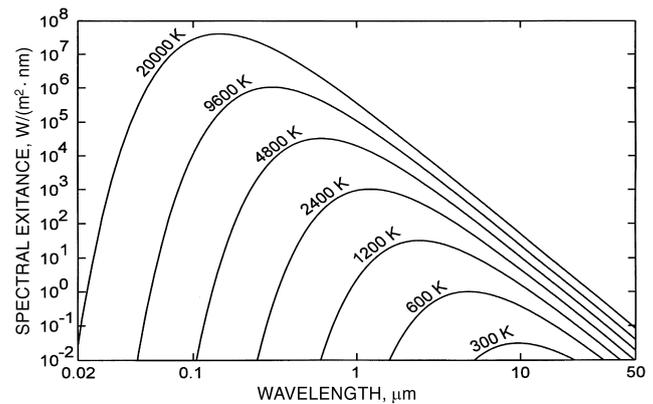

Occasionally, a related quantity called **normal emissivity** is used. The relationship between them is illustrated in Figure 11. The spectral distribution of blackbody radiation is illustrated in Figure 12 for temperatures ranging from 300 K (room temperature) to 20 000 K.

### OPTICAL PROPERTIES

Solar radiation (including both direct rays from the sun and diffuse rays from the sky, clouds, and surrounding objects) incident on a fenestration system is partly transmitted and partly reflected by the

**Fig. 11** Illustration of Difference Between Normal and Hemispherical Emissivity

**Fig. 12** Spectral Distributions of Blackbody Radiation at Different Source Temperatures

glazings of that system. An additional fraction is absorbed within the glazings and/or the coatings on their surfaces. The fraction of incident flux that is reflected is called the **reflectance**  $R$ , the fraction absorbed is called the **absorptance**  $\mathcal{A}$ , and the fraction transmitted is the **transmittance**  $T$ . The sum of the transmittance  $T$ , absorptance  $\mathcal{A}$ , and reflectance  $R$  of a glazing layer is unity:

$$T + R + \mathcal{A} = 1 \tag{26}$$

However, this is complicated by the fact that radiation incident on a surface can have nonconstant distributions over the directions of incidence and over the wavelength (or frequency) scale. Thus, when measuring one or more of the optical properties, the wavelength distribution and direction of incident (and emerging) radiation must be specified.

### Angular Dependence

The concept of solid angle is needed to understand angular dependence. A solid angle is defined and enclosed by all rays joining a point to a closed curve. For a closed curve on a sphere of radius  $R$ , the solid angle  $\varpi$  is the ratio of the projected area  $A$  on the sphere to the square of  $R$ . A sphere has a solid angle of  $4\pi$  steradians ( $4\pi \text{ sr}$ ); a hemisphere has a  $2\pi \text{ sr}$  solid angle.

Radiation incident on a point in a surface comes to that point from many directions in some solid angle. For a cone of half angle  $\alpha$ , the solid angle defined by the circular top and point bottom of that cone is given by

$$\varpi = 2\pi (1 - \cos \alpha) \tag{27}$$

In measuring transmittance or reflectance, a sample is illuminated over a specified solid angle. The reflected or transmitted flux is then collected within another solid angle. The size of a conical solid angle and the direction of its axis need to be specified to obtain meaningful results. A conical solid angle is bounded by a right circular cone.

ASTM *Standards* E 903, E 1084, E 971, and E 972, as well as NFRC 300, which refers to ASTM *Standard* E 971, refer to **conical-hemispherical** measurements of optical properties. The reason is that for most thermal or HVAC design calculations, only the total flux transmitted into a **hemispherical** solid angle, due to the direct solar beam incident in a small **conical** solid angle, is of interest. All transmitted solar irradiance is considered heat gain in these applications, regardless of the directional distribution of the transmitted radiation.

For complex fenestrations (those with nonspecular components), for many daylighting applications, and for some passive solar space-heating applications, the directional distribution of transmitted radiation is of interest. In such cases, it is important to know what is called the **biconical transmittance and reflectance** of fenestration systems, defined for conical solid angles of incidence and emergence (see Figure 13).

Biconical optical properties are needed (1) to treat diffuse sky as well as direct beam radiation, (2) to handle the directional distribution of the flux entering a room through a window, and (3) to calculate the angle-dependent optical and solar gain properties of multiple-pane window systems and complex glazing systems, including those with integral or attached shading devices.

**Spectral Dependence**

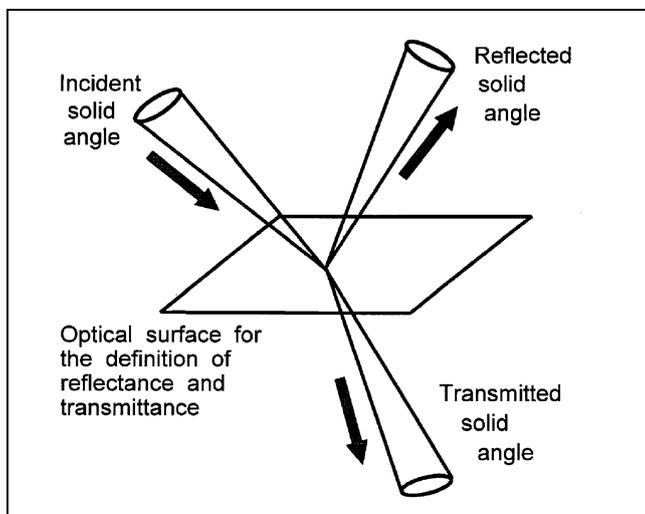

Frequency and wavelength are related through

$$\lambda f = c \tag{28}$$

where

- $\lambda$  = wavelength, m
- $f$  = frequency, Hz
- $c$  = speed of light =  $3.0 \times 10^8$  m/s in air at standard atmospheric pressure

The wavelength dependence of radiometric quantities is denoted with a subscript  $\lambda$  attached to the optical quantity, thus  $\phi_\lambda$ ,  $E_\lambda$ , and  $L_\lambda$ . The wavelength dependency of optical properties is denoted by the functional notation, thus  $\alpha(\lambda)$ ,  $\rho(\lambda)$ ,  $\tau(\lambda)$ , and  $e(\lambda)$ .

**Fig. 13 Geometry for Definition of Biconical Transmittance and Reflectance**

All solar radiant flux becomes heat when it is absorbed by materials such as glazings, window frames, and room surfaces. This includes radiation in the UV, visible, and IR portions of the spectrum. Recall from Equation (26) that the sum of the transmittance, reflectance, and absorptance is 1.0.

There is an additional relationship among the optical properties that is of interest and importance. It is called Kirchhoff's law (McCluney 1994a):

$$\mathcal{A}(\lambda, \theta, \phi) = e(\lambda, \theta, \phi) \tag{29}$$

where  $\theta$  and  $\phi$  are angles defining the directional dependence of the spectral absorptance  $\mathcal{A}(\lambda)$  and the spectral emissivity  $e(\lambda)$ . A consequence of Equations (26) and (29) is that for opaque materials a good absorber is a good emitter and a poor reflector, and vice versa, but only on a wavelength-by-wavelength basis or over a defined wavelength interval. A surface appearing to be an excellent reflector in the visible portion of the spectrum may have a high emissivity (and low reflectance) over most of the infrared spectrum, or vice versa.

**Source Spectra.** Radiation incident on a surface has a distribution not only over direction within some solid angle but also over a range of wavelengths. The latter distribution is called a **spectrum**. For terrestrial applications, it is only after the extraterrestrial solar spectrum has been modified by passage through the atmosphere that it is of interest (Figures 8 and 9).

**SOLAR-OPTICAL PROPERTIES OF GLAZING**

The solar-optical properties of a glazing are the wavelength-integrated (or total) transmittance, reflectance, and absorptance of the glazing to incident solar radiation. If the spectral optical properties [ $T(\lambda)$ ,  $R(\lambda)$ ,  $\mathcal{A}(\lambda)$ ] of the glazing and the spectral irradiance  $E(\lambda)$  incident on the glazing are known, the solar optical properties can be calculated from

$$p = \frac{\int_{\lambda_{min}}^{\lambda_{max}} p(\lambda) E(\lambda) d\lambda}{\int_{\lambda_{min}}^{\lambda_{max}} E(\lambda) d\lambda} \tag{30}$$

where  $p$  stands for transmittance, reflectance, or absorptance, and the limits of integration are those values of wavelength outside of which the solar spectral irradiance is negligibly small.

If  $E(\lambda)$  in Equation (30) is a standard solar spectral irradiance distribution, then the optical property resulting from this equation is called the **solar optical property**. If the spectral properties  $p(\lambda)$  are available only at a set of discrete wavelengths  $\lambda_k$  (e.g., measured data), then the following discrete sum approximation of Equation (30) can be calculated:

$$p = \sum_{k=1}^M w_k p(\lambda_k) \tag{31}$$

where  $w_k = \frac{E(\lambda_k)}{\sum_{k=1}^M E(\lambda_k) \Delta\lambda_k}$  is the spectral weight for the wavelength

$\lambda_k$  and where  $\Delta\lambda_k = 1/2(\lambda_{k+1} - \lambda_{k-1})$ .

Unless explicitly stated otherwise, solar-optical properties used in this chapter are calculated using the tabulated ASTM *Standard* E 891 solar spectrum and Equation (31).

Many window glazings do not have strong spectral selectivity over the solar spectrum, so their spectral optical properties can be

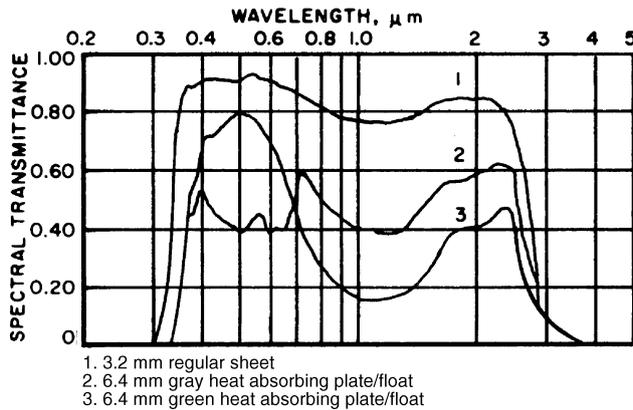

considered constant, even if the source spectrum changes substantially. In these cases, the transmitted spectral irradiance can be determined by multiplying the incident irradiance by the solar transmittance.

Figure 14 shows the spectral transmittance at normal incidence of typical architectural glasses. The approximate transmittance of total incident solar radiation through clear float glass at an incident angle of 0° ranges from 86% for 2.4 mm thick glass to 84% for 3.2 mm thick glass to 78% for 6.4 mm thick glass. Actual transmittance varies with the amount of iron or other absorbers in the glass. Low iron content glass has a relatively constant spectral transmittance over the entire solar spectrum.

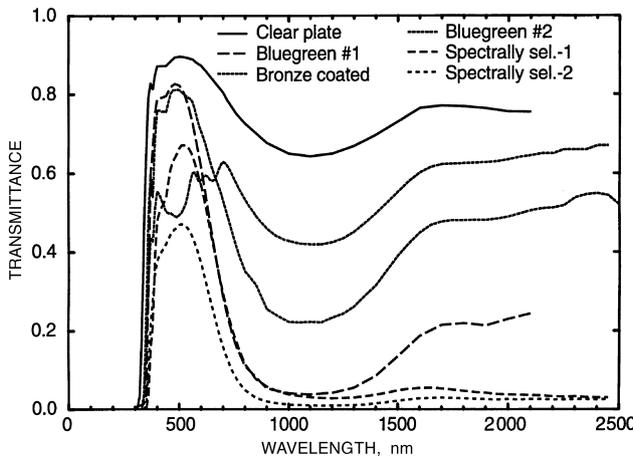

Figure 15 shows the normal incidence spectral transmittances of several common commercially available glazings. Figure 16 shows the normal incidence spectral transmittances and exterior reflectances of a variety of additional coated and tinted glasses, indicating the strong spectral selectivity that is now available from some glass and window manufacturers.

**Angular Dependence of Glazing Optical Properties**

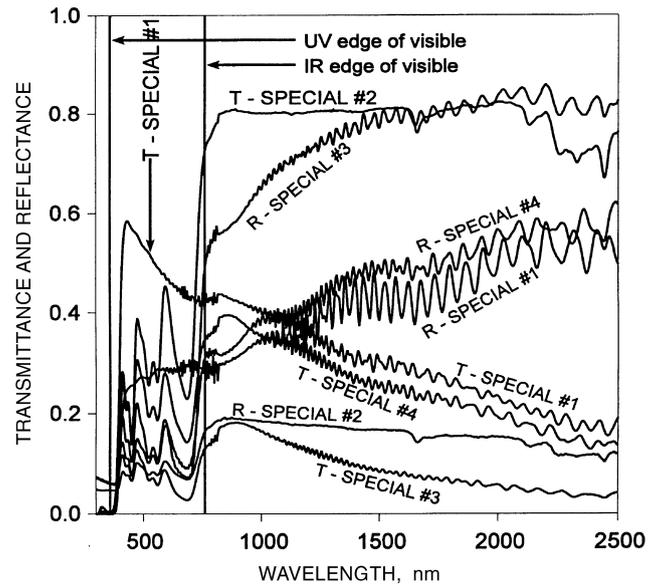

As Figure 17 shows, the optical properties of a single sheet of clear glass depend on the angle of incidence. This variation is small for incident angles below 40° but becomes significant at larger angles.

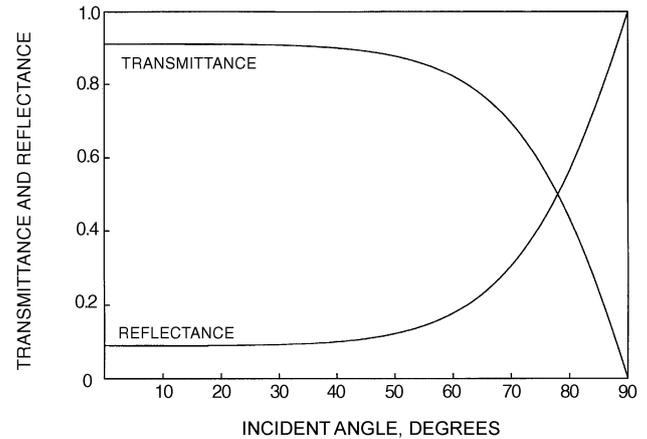

**Fig. 14 Spectral Transmittance for Typical Architectural Glass**

**Fig. 15 Spectral Transmittances of Commercially Available Glazings**  
(McCluney 1993)

refractive index  $n = 1.55$ , thickness  $t = 3.2$  mm, absorptivity  $\alpha = 0.01/m$

**Fig. 18 Variations with Incident Angle of Solar-Optical Properties for (A) Double-Strength Sheet Glass, (B) Clear Plate Glass, and (C) Heat-Absorbing Plate Glass**

Figure 18 compares the properties of glasses of different thickness and composition. As the incident angle increases from zero, transmittance diminishes, reflectance increases, and absorptance first increases because of the lengthened optical path and then decreases as more incident radiation is reflected. While the shapes of the property curves are superficially similar, note that both the magnitude of the transmittance at normal incidence and the angle at which the transmittance changes significantly vary with glass type and thickness. The three curves all have slightly different shapes. For coated glasses or for multiple-pane glazing systems, this difference is more pronounced. One cannot assume that all glazings or glazing systems have a universal angular dependence. This is one of the inadequacies of the shading coefficient methodology for determining solar heat gain that led to its elimination from this edition.

In North America, peak summertime solar gains occur with east- and west-facing vertical windows at angles of incidence ranging from about 25 to 55°. The peak solar gain for horizontal glazings occurs typically at small angles of incidence. For north- and south-facing vertical glazings, peak summertime solar gains occur at angles of incidence greater than about 40° (McCluney 1994b).

Angles of incidence important for annual energy performance calculations range from 5° to over 80° for east- and west-facing vertical windows and for horizontal glazings. This range is only slightly diminished for south-facing windows. For north-facing windows, the direct beam solar gains are small and their angles of incidence range from 62 to 86° (McCluney 1994b).

**Optical Properties of Single Glazing Layers**

The optical properties of a single layer of glazing material are outlined in Figure 19. The layer has a thickness  $d$  and is characterized by a surface reflectivity and transmissivity,  $\rho$  and  $\tau$ , for each of the two surfaces (denoted  $f$  and  $b$  in the figure) and an absorptivity,  $\alpha$ , which is a volumetric property of the material (assumed of uniform composition). In general,  $\tau$  and  $\rho$  are characteristics of the interface between the material and the adjacent medium; they may in principle be different for the two surfaces (e.g., for a coated surface, or where a material layer is adjacent to another material rather than air). All three properties, transmissivity, reflectivity, and absorptivity, depend on the wavelength of the incident radiation, and  $\tau$  and  $\rho$  also depend on the incident angle  $\theta$  of the radiation incident on the layer.

The transmittance  $T$  and the front reflectance  $R^f$  of a **layer** (as opposed to a **surface**) contain the effects of multiple reflections between the two surfaces of the layer, as indicated in Figure 19, as well as the effects of absorption during the passage through the layer

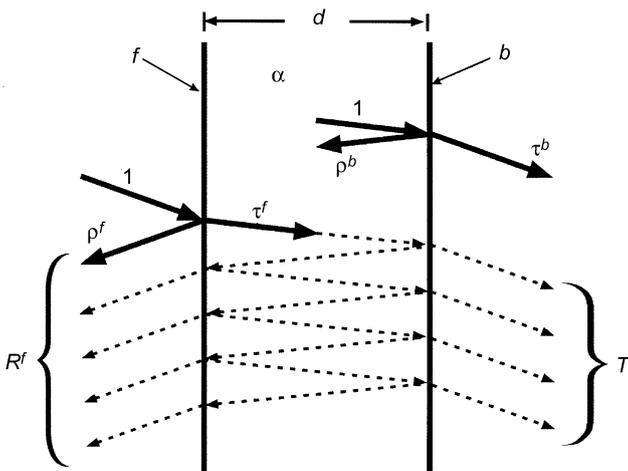

Fig. 19 Optical Properties of a Single Glazing Layer

(one or more times), due to the volume absorptivity  $\alpha$ . The same is true of the back reflectance  $R^b$ , which is the reflectance of the layer for radiation incident on back side  $b$  and which is not illustrated in the figure. For non-normal incidence, surface reflectances are in general different for the two possible polarizations of light, conventionally denoted  $s$  (TE) and  $p$  (TM). We distinguish these below by a subscript  $\mu (= s, p)$  on the surface reflectance. [A pre-subscript is used where there is a possibility of confusion with later notational additions.] The transmittance and reflectances are given by

$${}_{\mu}T(\theta, \lambda) = \frac{\tau_{\mu}^f(\theta, \lambda)\tau_{\mu}^b(\theta, \lambda)e^{-\frac{\alpha(\lambda)d}{\cos\zeta}}}{1 - \rho_{\mu}^f(\theta, \lambda)\rho_{\mu}^b(\theta, \lambda)e^{-\frac{2\alpha(\lambda)d}{\cos\zeta}}} \quad (32)$$

$${}_{\mu}R^f(\theta, \lambda) = \rho_{\mu}^f(\theta, \lambda) + \rho_{\mu}^b(\theta, \lambda){}_{\mu}T(\theta, \lambda)e^{-\frac{\alpha(\lambda)d}{\cos\zeta}} \quad (33)$$

$${}_{\mu}R^b(\theta, \lambda) = \rho_{\mu}^b(\theta, \lambda) + \rho_{\mu}^f(\theta, \lambda){}_{\mu}T(\theta, \lambda)e^{-\frac{\alpha(\lambda)d}{\cos\zeta}} \quad (34)$$

where  $\zeta$  is the angle at which radiation incident at angle  $\theta$  propagates within the glazing layer (the refracted angle). Since sunlight is unpolarized, the transmittance and reflectances of an isolated glazing layer are then calculated from

$$T(\theta, \lambda) = \frac{1}{2}[{}_sT(\theta, \lambda) + {}_pT(\theta, \lambda)] \quad (35)$$

$$R^f(\theta, \lambda) = \frac{1}{2}[{}_sR^f(\theta, \lambda) + {}_pR^f(\theta, \lambda)] \quad (36)$$

$$R^b(\theta, \lambda) = \frac{1}{2}[{}_sR^b(\theta, \lambda) + {}_pR^b(\theta, \lambda)] \quad (37)$$

The transmittance is the same for incident radiation incident (of a given polarization) on either surface, as can be seen from the symmetry of Equation (32) in the indices  $f$  and  $b$ . Front and back reflectances, however, may differ. The angular and wavelength dependence of these quantities is emphasized in the equations through explicit function reference [e.g.,  $T(\theta, \lambda)$ ]. This dependence will not always be made explicit (in the interest of brevity of equations) but should not be forgotten.

The transmittance and reflectances are the basic measurable quantities for an isolated glazing layer in air. Measurements on glazing layers are typically made at normal incidence, and the properties at other angles must be inferred from these measurements. A systematic compilation of these measured properties for most glazings manufactured in the United States is maintained by the National Fenestration Rating Council, Silver Spring, MD, and is available on the World Wide Web at <http://www.nfrc.org> or at <http://windows.lbl.gov/software/> [see also LBL (1994) and NFRC (2000a)].

It follows from conservation of energy that the average absorptance of the layer must be defined as the fraction of the incident radiation that is neither transmitted nor reflected by the layer. Note that when the layer surfaces have different properties, this results in different absorptances for front and back incidence. It also produces an angular dependence in the layer absorptance  $a$  that is not present in the absorptivity  $\alpha$ :

$${}_{\mu}a^f(\theta, \lambda) = 1 - {}_{\mu}T(\theta, \lambda) - {}_{\mu}R^f(\theta, \lambda) \quad (38a)$$

$${}_{\mu}a^b(\theta, \lambda) = 1 - {}_{\mu}T(\theta, \lambda) - {}_{\mu}R^b(\theta, \lambda) \quad (38b)$$

and, since these are linear relations,

$$a^f(\theta, \lambda) = 1 - T(\theta, \lambda) - R^f(\theta, \lambda) \quad (38c)$$

$$a^b(\theta, \lambda) = 1 - T(\theta, \lambda) - R^b(\theta, \lambda) \quad (38d)$$

for the unpolarized quantities. A lowercase symbol is used here in anticipation of the discussion of multilayer glazing systems below.

### Uncoated Glazings

For uncoated glazings, the interface reflectivities  $\rho$  of the two surfaces are the same and may be determined from the Fresnel equations:

$$\rho_s(\theta, \lambda) = \left( \frac{\sin(\theta - \zeta)}{\sin(\theta + \zeta)} \right)^2 \quad (39a)$$

$$\rho_p(\theta, \lambda) = \left( \frac{\tan(\theta - \zeta)}{\tan(\theta + \zeta)} \right)^2 \quad (39b)$$

where  $\zeta$  is the refracted angle and may be calculated from Snell's law and the real part of the refractive index  $n$  relative to air:

$$\sin \theta = n \sin \zeta \quad \text{and} \quad \zeta = \arcsin\left(\frac{\sin \theta}{n}\right) \quad (40)$$

At normal incidence, the two polarizations are indistinguishable, and Equation (39) reduces to

$$\rho(0, \lambda) = \frac{[n(\lambda) - 1]^2}{[n(\lambda) + 1]^2} \quad \text{and} \quad n(\lambda) = \frac{1 + \sqrt{\rho(0, \lambda)}}{1 - \sqrt{\rho(0, \lambda)}} \quad (41)$$

and since

$$\tau_\mu(\theta, \lambda) + \rho_\mu(\theta, \lambda) = 1 \quad (42)$$

for any surface, a measurement of the spectral transmittance and reflectance at normal incidence may be used with Equations (32) and (33) to determine the refractive index and absorptance as a function of wavelength. Note that  $n$  is also wavelength-dependent, although for most glazing materials the dependence is weak over the solar spectrum. Once these quantities are known, the equations may be used to calculate the properties at all angles.

### ASHRAE "Standard" Glass

In the discussion of single glazing, and historically in the context of the solar heat gain factor and shading coefficient methodology, ASHRAE has used as a calculation standard the properties of "one-eighth-inch, clear double-strength glass" (DSG). The wavelength-averaged properties of this standard glazing are calculated from the following equations:

$$T_{\text{DSG}}(\theta) = \sum_{n=0}^5 (ts)_n \cos^n \theta \quad (43)$$

$$a_{\text{DSG}}^f(\theta) = a_{\text{DSG}}^b(\theta) = \sum_{n=0}^5 (as)_n \cos^n \theta \quad (44)$$

where the coefficients  $(ts)_n$  and  $(as)_n$  are given in Table 11. The hemispherical average quantities may be calculated by averaging Equations (43) and (44), which yields

$$\langle T_{\text{DSG}} \rangle_D = 2 \sum_{n=0}^5 \frac{(ts)_n}{n+2} \quad (45)$$

**Table 11** Coefficients for Double-Strength Glass (DSG) for Calculation of Transmittance and Absorptance

$n$	$(as)_n$	$(ts)_n$
0	0.01154	-0.00885
1	0.77674	2.71235
2	-3.94657	-0.62062
3	8.57881	-7.07329
4	-8.38135	9.75995
5	3.01188	-3.89922

$$\langle a_{\text{DSG}}^f \rangle_D = \langle a_{\text{DSG}}^b \rangle_D = 2 \sum_{n=0}^5 \frac{(as)_n}{n+2} \quad (46)$$

### Determining the Properties of Uncoated Glazing Layers from Normal Incidence Measurements

For uncoated glazings, the front and back transmissivities, reflectivities, transmittances, reflectances, and isolated-layer absorptances are equal, the two polarizations are indistinguishable, and at normal incidence Equations (32) and (33) become

$$T(0, \lambda) = \frac{[\tau(0, \lambda)]^2 e^{-\alpha(\lambda)d}}{1 - [\rho(0, \lambda)]^2 e^{-2\alpha(\lambda)d}} \quad (47)$$

$$R(0, \lambda) = \rho(0, \lambda)[1 + T(0, \lambda)e^{-\alpha(\lambda)d}] \quad (48)$$

while Equation (42) becomes

$$\tau(0, \lambda) + \rho(0, \lambda) = 1 \quad (49)$$

These three equations can be solved to yield  $\rho(0, \lambda)$  and  $\alpha(\lambda)$ :

$$\rho(0, \lambda) = \frac{P - \sqrt{P^2 - 4[2 - R(0, \lambda)]R(0, \lambda)}}{2[2 - R(0, \lambda)]} \quad (50)$$

where

$$P = [T(0, \lambda)]^2 - [R(0, \lambda)]^2 + 2R(0, \lambda) \quad (51)$$

$$\alpha(\lambda) = -\frac{1}{d} \ln \left[ \frac{R(0, \lambda) - \rho(0, \lambda)}{\rho(0, \lambda)T(0, \lambda)} \right] \quad (52)$$

The real part of the refractive index (relative to air) is then calculated by solving Equation (41):

$$n(\lambda) = \frac{1 + \sqrt{\rho(0, \lambda)}}{1 - \sqrt{\rho(0, \lambda)}} \quad (53)$$

Thus, given spectroscopic measurements of the transmittance and reflectance at normal incidence of an uncoated glazing layer, one can determine the basic parameters needed for a complete calculation of the optical properties of that layer.

**Example 8.** Construct an approximate model of the optical properties of a single layer of uncoated 3 mm clear glass, suitable for use in calculations involving selective glazings that have different properties in the visible and NIR regions. Use this model to calculate the properties under the conditions of Example 5.

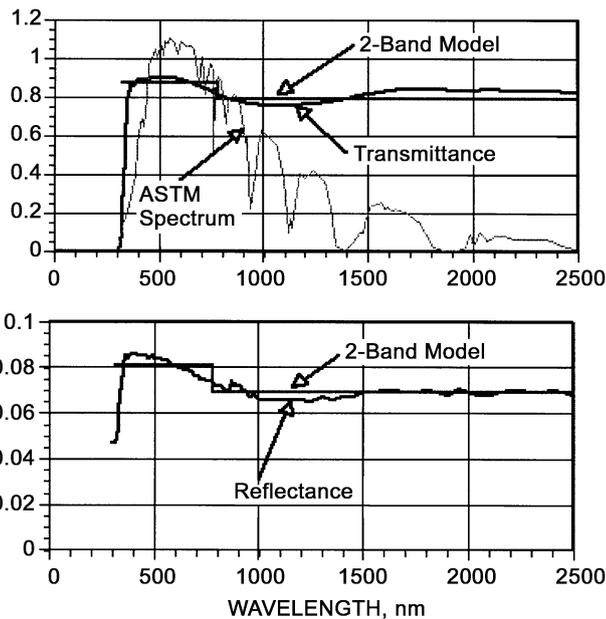

**Solution:** The spectral transmittance and reflectance of clear 3 mm glass are shown in Figure 20. [The source of these data is "generic" clear glass in the NFRC (2000b) spectral data library.] It can be seen

that the variation with wavelength is not very great, and although a single average transmittance and reflectance would be adequate, for use with spectrally selective glazings it is better to construct the “2-band” model also shown in the figure, which characterizes the properties separately for the visible region (320 to 780 nm wavelength) and the NIR region (780 to 2500 nm). About 99% of the ASTM solar spectrum lies within these two regions. The corresponding normal incidence properties are  $T(0,vis) = 0.876$ ,  $R(0,vis) = 0.081$ ,  $T(0,NIR) = 0.791$ , and  $R(0,NIR) = 0.069$ .

From Equation (51), one then calculates  $P(vis) = 1.922$  and  $P(NIR) = 1.758$ . Equation (50) yields surface reflectances of  $\rho(0,vis) = 0.44$  and  $\rho(0,NIR) = 0.041$ , and Equation (53) gives refractive indices for the two wavelength regions of  $n(vis) = 1.530$  and  $n(NIR) = 1.507$ . From Equation (52), we obtain the values  $\alpha(vis) = 0.0149$  and  $\alpha(NIR) = 0.0508$ . These are the parameters necessary for calculating the optical properties.

For the conditions of Example 5, the incident angle is found in Example 6 to be  $63.2^\circ$ . At this incident angle, Equation (40) gives refracted angles of  $\zeta(vis) = 35.7^\circ$  and  $\zeta(NIR) = 36.3^\circ$ . For polarization  $s$ , Equation (39a) gives  $\rho_s(63.2^\circ,vis) = 0.218$ ,  $\rho_s(63.2^\circ,NIR) = 0.210$ , and for polarization  $p$ , Equation (39b) gives  $\rho_p(63.2^\circ,vis) = 0.0066$ , and  $\rho_p(63.2^\circ,NIR) = 0.0072$ . Putting these values into Equations (32) through (34) gives for the transmittances and reflectances for each polarization:  ${}_sT(63.2^\circ,vis) = 0.604$ ,  ${}_sR(63.2^\circ,vis) = 0.343$ ,  ${}_sT(63.2^\circ,NIR) = 0.533$ ,  ${}_sR(63.2^\circ,NIR) = 0.303$ ,  ${}_pT(63.2^\circ,vis) = 0.934$ ,  ${}_pR(63.2^\circ,vis) = 0.012$ ,  ${}_pT(63.2^\circ,NIR) = 0.816$ , and  ${}_pR(63.2^\circ,NIR) = 0.012$ .

Note that the reflected radiation is almost completely polarized. The unpolarized quantities are then calculated from Equations (35) and (36):  $T(63.2^\circ,vis) = 1/2(0.604 + 0.934) = 0.769$  and  $R(63.2^\circ,vis) = 1/2(0.343 + 0.012) = 0.178$ , and, similarly,  $T(63.2^\circ,NIR) = 0.674$  and  $R(63.2^\circ,NIR) = 0.157$ .

**Coated Glazings**

While in principle the equations in the preceding sections could be used to calculate the properties of coated glazings, this is not currently practical. To obtain the necessary basic information about the structure of complex coatings would require spectrophotometric measurements at angles other than normal incidence. The instruments for making such measurements are not widely available nor are there yet standardized procedures for making the measurements and extracting coating properties from them.

Until such capabilities are available, the following approximate procedure should be used to model coated glazings (Finlayson and Arasteh 1993). Coated glazing properties should vary from these estimates by no more than  $\pm 20\%$  at  $60^\circ$  incidence (Rubin et al. 1999).

The spectral transmittance and reflectances at any incident angle are approximated from those at normal incidence by

$$T(\theta, \lambda) = T(0, \lambda)T_{REF}(\theta) \tag{54}$$

$$R^i(\theta, \lambda) = R^i(0, \lambda)[1 - R_{REF}(\theta)] + R_{REF}(\theta) \quad (i = f, b) \tag{55}$$

where

$$T_{REF}(\theta) = \sum_{m=0}^4 (TA)_m \cos^m \theta \tag{56}$$

and

$$R_{REF}(\theta) = \sum_{m=0}^4 (RA)_m \cos^m \theta - T_{REF}(\theta) \tag{57}$$

The constants in Equations (56) and (57) are selected from the entries in Table 12 appropriate to the value of the spectrally averaged transmittance at normal incidence,  $T(0)$ . Since Equations (54) and (55) make wavelength-independent modifications to the properties at normal incidence, the spectral averaging may be done first, yielding

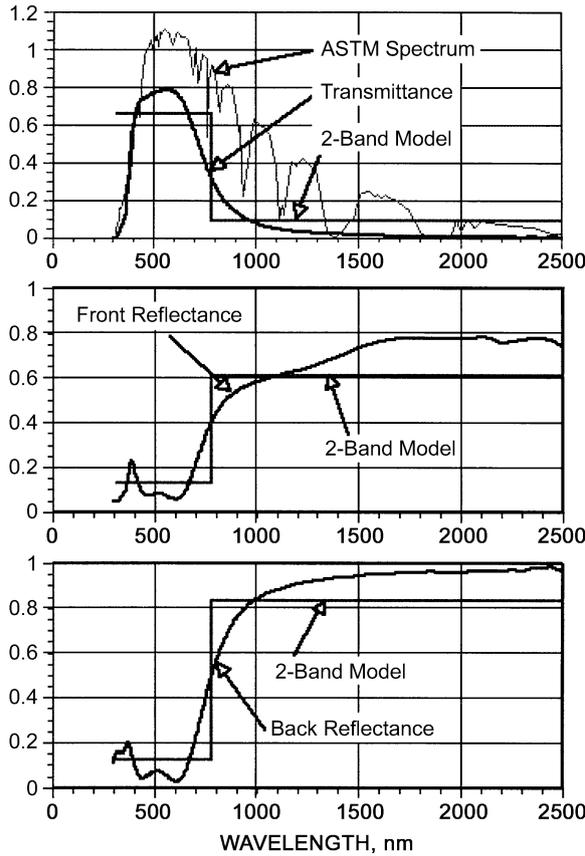

$$T(\theta) = T(0)[T_{REF}(\theta)] \tag{58}$$

$$R^i(\theta) = R^i(0)[1 - R_{REF}(\theta)] + R_{REF}(\theta) \quad (i = f, b) \tag{59}$$

**Example 9.** Construct an approximate model of the optical properties of a single layer of 3 mm clear glass with a selective low-emissivity coating on surface 2. Use this model to calculate the properties under the conditions of Example 5.

**Solution:** The spectral transmittance and reflectances of selective 3 mm glass at normal incidence are shown in Figure 21. [The source of these data is “EE-170-3.CIG” glass in the NFRC (2000b) spectral data library.] The 2-band model shown in the figure has the following normal-incidence spectral properties:  $T(0,vis) = 0.657$ ,  $R^f(0,vis) = 0.132$ ,  $R^b(0,vis) = 0.122$ ,  $T(0,NIR) = 0.088$ ,  $R^f(0,NIR) = 0.614$ , and  $R^b(0,NIR) = 0.830$ . It can be seen from Figure 21 that this model crudely represents the difference in glazing optical properties for the two spectral regions.

For the crude optical model available for coated glass, the angular dependence enters only through  $T_{REF}$  and  $R_{REF}$ . Following the method of Example 11 to average the spectral properties, one finds that the spectral average transmittance at normal incidence for this glazing,  $T(0)$ , is 0.379. Since this is less than 0.645, constants for computing these two functions using Equations (56) and (57) are taken from the lower two rows of Table 12. At an incident angle of  $63.2^\circ$  (from Example 6), these functions are  $T_{REF}(63.2^\circ) = 0.810$  and  $R_{REF}(63.2^\circ) = 0.081$ . The transmittance and reflectances are then calculated for each wavelength region using Equations (58) and (59):

**Fig. 21 Transmittance and Reflectance at Normal Incidence of a Selective Low-e Glass Approximated by a 2-Band Model of Spectrally Weighted Transmittance and Reflectance**

$$T(63.2^\circ, \text{vis}) = 0.532, R^f(63.2^\circ, \text{vis}) = 0.202, R^b(63.2^\circ, \text{vis}) = 0.193,$$

$$T(63.2^\circ, \text{NIR}) = 0.071, R^f(63.2^\circ, \text{NIR}) = 0.646, \text{ and}$$

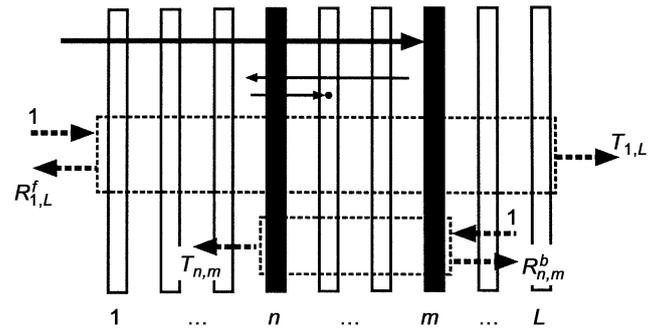

$$R^b(63.2^\circ, \text{NIR}) = 0.844$$

### Optical Properties of Multiple-Layer Glazing Systems

For the optical properties of glazing systems consisting of multiple glazing layers, interreflections may occur between layers, which means that the effect of a particular layer on the overall properties may depend on its position within the assembly as well as on the transmittance and reflectances of the particular layer. We must therefore expand the glazing layer considerations above to apply to the overall properties of systems and subsystems of glazing layers. The notation for doing this is illustrated in Figure 22.

In the following section, polarization indices are omitted from the equations. In principle, these equations should be used to make separate calculations of the optical properties of the glazing system for each of the two polarizations,  $s$  and  $p$ , and the results should be averaged using Equations (35) through (37). This should be done if a highly accurate result is desired (and data are available). However, since accurate data on coated glazings are lacking and polarization effects are relatively small, the polarization-averaged quantities will be used for each layer. This is the approximation used in commonly available computer calculations such as Wright (1995b) and LBL (1994).

The position of each layer in a multilayer glazing system consisting of  $L$  layers is characterized by its layer number  $n$  as shown in Figure 22. (By convention, layer 1 is the layer closest to the sun.) The individual layer transmittances, reflectances, and absorptances for the  $n$ th layer (the properties of the layer when isolated in air) are

**Fig. 22 Multilayer Glazings Considered as Systems and Subsystems**

denoted by adding a single subscript to the property symbol:  $T_n$ ,  $R_n^f$ ,  $R_n^b$ ,  $a_n^f$  and  $a_n^b$ . The properties of a subsystem consisting of the layers  $n$  through  $m$ , inclusive ( $n$  and  $m$  may be written as capital letters  $N$  and  $M$  to avoid confusion and emphasize their role in specifying a subsystem), are denoted by symbols with two indices for transmittances and reflectances and by script capital letters for absorptances ( $\mathcal{A}$ ):

$T_n(\theta, \lambda)$  = isolated-layer transmittance of the  $n$ th layer (in an  $L$ -layer system)

$T_{N,M}(\theta, \lambda)$  = transmittances of the subsystem consisting of layers  $N$  through  $M$  (in an  $L$ -layer system)

and similarly for reflectances, while

$a_n^f(\theta, \lambda)$  = isolated-layer front absorptance for the  $n$ th layer (in an  $L$ -layer system)

$\mathcal{A}_{n:(N,M)}^f(\theta, \lambda)$  = actual front absorptance for the  $n$ th layer in the subsystem consisting of layers  $N$  through  $M$  (in an  $L$ -layer system); the fraction of the radiation incident on layer  $N$  that is absorbed in layer  $n$ , including effects of multiple reflections from layers  $N$  through  $M$

$\mathcal{A}_{n:(N,M)}^b(\theta, \lambda)$  = actual back absorptance for the  $n$ th layer in the subsystem consisting of layers  $N$  through  $M$  (in an  $L$ -layer system); the fraction of the (backward-going) radiation incident on layer  $M$  that is absorbed in layer  $n$ , including effects of multiple reflections from layers  $N$  through  $M$ .

A quantity such as  $T_{1,L}(\theta, \lambda)$  refers to the total overall system property. Note that  $\mathcal{A}_{n:(n,n)}^f(\theta, \lambda) = a_n^f$  and  $\mathcal{A}_{n:(n,n)}^b(\theta, \lambda) = a_n^b$ . (A subsystem consisting of one layer is the same as an isolated layer.)

The properties of any subsystem can be calculated by use of the following recursion relations and proceeding from left to right in Figure 22 (Finlayson and Arasteh 1993):

$$T_{n,m+1}(\theta, \lambda) = \frac{T_{n,m}(\theta, \lambda)T_{m+1}(\theta, \lambda)}{1 - R_{n,m}^b(\theta, \lambda)R_{m+1}^f(\theta, \lambda)} \quad (60)$$

$$R_{n,m+1}^f(\theta, \lambda) = R_{n,m}^f(\theta, \lambda) + \frac{[T_{n,m}(\theta, \lambda)]^2 R_{m+1}^b(\theta, \lambda)}{1 - R_{n,m}^b(\theta, \lambda)R_{m+1}^f(\theta, \lambda)} \quad (61)$$

$$R_{n,m+1}^b(\theta, \lambda) = R_{m+1}^b(\theta, \lambda) + \frac{[T_{m+1}(\theta, \lambda)]^2 R_{n,m}^b(\theta, \lambda)}{1 - R_{n,m}^b(\theta, \lambda)R_{m+1}^f(\theta, \lambda)} \quad (62)$$

where it is always the case that  $m \geq n$ , and a subsystem consisting of one layer is the same as an isolated layer [e.g.,  $T_{n,n}(\theta, \lambda) \equiv T_n(\theta, \lambda)$ ]. These equations allow one to build up the properties of the  $L$ -layer system by beginning with the isolated properties of the first layer and successively adding additional layers. The absorptance of the  $n$ th layer in the system is then calculated from

$$\mathcal{A}_{n:(1,L)}^f(\theta, \lambda) = \frac{T_{1,n-1}(\theta, \lambda) a_n^f(\theta, \lambda)}{1 - R_{1,n-1}^b(\theta, \lambda) R_{n,L}^f(\theta, \lambda)} + \frac{T_{1,n}(\theta, \lambda) R_{n+1,L}^f(\theta, \lambda) a_n^b(\theta, \lambda)}{1 - R_{1,n}^b(\theta, \lambda) R_{n+1,L}^f(\theta, \lambda)} \quad (63)$$

or

$$\mathcal{A}_{n:(1,L)}^b(\theta, \lambda) = \frac{T_{n+1,L}(\theta, \lambda) a_n^b(\theta, \lambda)}{1 - R_{1,n}^b(\theta, \lambda) R_{n+1,L}^f(\theta, \lambda)} + \frac{T_{n,L}(\theta, \lambda) R_{1,n-1}^f(\theta, \lambda) a_n^f(\theta, \lambda)}{1 - R_{1,n}^f(\theta, \lambda) R_{n+1,L}^b(\theta, \lambda)} \quad (64)$$

Note that in Equations (63) and (64), combinations of subscripts will arise for the first and last layer absorptances that refer to non-existent layers (the layer before the first or after the last). Rather than write separate equations for these special cases, we define the non-existent layers to have transmittance of one and reflectance of zero:

$$T_{1,0} = T_{L+1,L} = 1 \\ R_{L+1,L}^f = R_{L+1,L}^b = R_{1,0}^f = R_{1,0}^b = 0 \quad (65)$$

**Example 10.** Calculate the properties of a double-glazed unit having the coated glass of Example 9 as an outer glass and the clear glass of Example 8 as an inner glass, under the conditions of Example 5.

**Solution:** From Example 9, the optical properties of the outer glazing, which is layer 1, at  $63.2^\circ$  (Example 6) are  $T_1(63.2^\circ, \text{vis}) = 0.532$ ,  $R_1^f(63.2^\circ, \text{vis}) = 0.202$ , and  $R_1^b(63.2^\circ, \text{vis}) = 0.193$  for the visible region and  $T_1(63.2^\circ, \text{NIR}) = 0.071$ ,  $R_1^f(63.2^\circ, \text{NIR}) = 0.646$ , and  $R_1^b(63.2^\circ, \text{NIR}) = 0.844$  for the NIR region. From Example 8, the corresponding (unpolarized) values for the inner glazing (layer 2) are  $T_2(63.2^\circ, \text{vis}) = 0.769$  and  $R_2^f(63.2^\circ, \text{vis}) = R_2^b(63.2^\circ, \text{vis}) = 0.178$  for the visible region, and  $T_2(63.2^\circ, \text{NIR}) = 0.674$  and  $R_2^f(63.2^\circ, \text{NIR}) = R_2^b(63.2^\circ, \text{NIR}) = 0.157$  for the NIR region.

Inserting these values into Equation (60) gives the following for the glazing system's overall transmittance:

$$T_{1,2}(63.2^\circ, \text{vis}) = \frac{T_1(63.2^\circ, \text{vis}) T_2(63.2^\circ, \text{vis})}{1 - R_1^b(63.2^\circ, \text{vis}) R_2^f(63.2^\circ, \text{vis})} \\ = \frac{(0.532)(0.769)}{1 - (0.193)(0.178)} = 0.424$$

and

$$T_{1,2}(63.2^\circ, \text{NIR}) = \frac{T_1(63.2^\circ, \text{NIR}) T_2(63.2^\circ, \text{NIR})}{1 - R_1^b(63.2^\circ, \text{NIR}) R_2^f(63.2^\circ, \text{NIR})} \\ = \frac{(0.071)(0.674)}{1 - (0.844)(0.157)} = 0.055$$

Similarly, Equation (61) gives  $R_{1,2}^f(63.2^\circ, \text{vis}) = 0.202 + (0.532)^2 \times (0.178) / [1 - (0.193)(0.178)] = 0.254$  and  $R_{1,2}^f(63.2^\circ, \text{NIR}) = 0.446$  for the front reflectances in the two spectral regions, and Equation (62) gives the back reflectances,  $R_{1,2}^b(63.2^\circ, \text{vis}) = 0.178 + (0.769)^2 \times (0.193) / [1 - (0.193)(0.178)] = 0.296$  and  $R_{1,2}^b(63.2^\circ, \text{NIR}) = 0.600$ . In order to calculate the layer absorptances in the glazing system, we must first calculate the isolated-layer absorptances for both glazings using Equations (38c) and (38d):

$$a_1^f(63.2^\circ, \text{vis}) = 1 - 0.532 - 0.202 = 0.266$$

$$a_1^b(63.2^\circ, \text{vis}) = 0.275$$

$$a_1^f(63.2^\circ, \text{NIR}) = 0.283$$

$$a_1^b(63.2^\circ, \text{NIR}) = 0.085$$

$$a_2^f(63.2^\circ, \text{vis}) = a_2^b(63.2^\circ, \text{vis}) = 0.053$$

$$a_2^f(63.2^\circ, \text{NIR}) = a_2^b(63.2^\circ, \text{NIR}) = 0.165$$

We then use Equations (63) and (65) to calculate the layer front absorptances in the glazing system:

$$\mathcal{A}_{1:(1,2)}^f(63.2^\circ, \text{vis}) = a_1^f(63.2^\circ, \text{vis}) \\ + \frac{T_1(63.2^\circ, \text{vis}) R_2^f(63.2^\circ, \text{vis}) a_1^b(63.2^\circ, \text{vis})}{1 - R_1^b(63.2^\circ, \text{vis}) R_2^f(63.2^\circ, \text{vis})} \\ = 0.266 + \frac{(0.532)(0.178)(0.275)}{1 - (0.193)(0.178)} = 0.293$$

$$\mathcal{A}_{2:(1,2)}^f(63.2^\circ, \text{vis}) = \frac{T_1(63.2^\circ, \text{vis}) a_2^b(63.2^\circ, \text{vis})}{1 - R_1^b(63.2^\circ, \text{vis}) R_2^f(63.2^\circ, \text{vis})} \\ = \frac{(0.532)(0.053)}{1 - (0.193)(0.178)} = 0.029$$

$$\mathcal{A}_{1:(1,2)}^f(63.2^\circ, \text{NIR}) = 0.285$$

$$\mathcal{A}_{2:(1,2)}^f(63.2^\circ, \text{NIR}) = 0.014$$

and Equations (64) and (65) to calculate the back absorptances:  $\mathcal{A}_{1:(1,2)}^b(63.2^\circ, \text{vis}) = 0.219$ ,  $\mathcal{A}_{2:(1,2)}^b(63.2^\circ, \text{vis}) = 0.061$ ,  $\mathcal{A}_{1:(1,2)}^b(63.2^\circ, \text{NIR}) = 0.066$ , and  $\mathcal{A}_{2:(1,2)}^b(63.2^\circ, \text{NIR}) = 0.279$ .

### Spectral Averaging of Glazing Properties

For calculating fenestration heat transfer, it is generally sufficient to use spectrally averaged glazing system properties as defined in Equation (30) or (31). While for special combinations of climate and location it may be desirable to carry out this averaging using variant solar spectra as weighting functions in these equations, as discussed in the section on Solar Radiation under Determining Incident Solar Flux, it is seldom either feasible or necessary to carry out heat transfer calculations using a detailed, time-dependent solar spectrum and the spectral glazing properties.

For multiple-layer glazing systems, the spectral averaging of Equation (30) or (31) should in general be applied to the system spectral properties at each angle [Equations (60) through (64)]. Since all glazing layer properties are to some extent both angle and wavelength dependent, and since these equations are nonlinear in the glazing properties, this is the only procedure that is valid in principle. In general, when a glazing property is used without a specific function reference to wavelength, it assumes that this averaging procedure has been carried out. For example, for a multiple-layer glazing,

$$T_{n,m}(\theta) = \frac{\int_{\lambda_{\min}}^{\lambda_{\max}} E_{STD}(\lambda) T_{n,m}(\theta, \lambda) d\lambda}{\int_{\lambda_{\min}}^{\lambda_{\max}} E_{STD}(\lambda) d\lambda} \quad (66)$$

where  $T_{n,m}(\theta, \lambda)$  has been obtained from the individual layer properties and the application of Equation (60). The analogous definitions apply for  $R_{n,m}^f(\theta)$ ,  $R_{n,m}^b(\theta)$ ,  $\mathcal{A}_{n:(1,L)}^f(\theta)$ , and  $\mathcal{A}_{n:(1,L)}^b(\theta)$  and the other wavelength-dependent quantities appearing in the

section on Optical Properties of Multiple-Layer Glazing Systems. Unless otherwise stated, the standard spectrum,  $E_{STD}(\lambda)$ , used in the calculation is the ASTM *Standard E 891* spectrum.

However, as explained in this section, many glazings have properties that vary little over the wavelength region spanned by the solar spectrum. For systems containing only these glazings, much computational labor can be saved by calculating the wavelength-averaged properties (as a function of incident angle) for each isolated glazing layer and using these properties in Equations (60) through (64). While this procedure is less accurate, it may prove adequate for systems involving clear and nearly clear glazings. In using it, one should, however, examine the spectral properties of the glazings to ensure that the potential errors in the approximation are understood. One should particularly note Figures 15, 16, 23, and 24. While clear architectural glazings are generally engineered to have constant spectral properties in the visible region to avoid objectionable coloration, this may not apply to the substantial part of the solar spectrum outside the visible region.

The values of  $T_{1,m}(\theta)$ ,  $R_{1,m}^f(\theta)$ , and  $R_{1,m}^b(\theta)$  are tabulated for a number of common single ( $m = 1$ ), double ( $m = 2$ ), and triple ( $m = 3$ ) glazing systems in Table 13, and these may be used in combination with the wavelength-averaged versions of Equations (63), (64), (38c), and (38d). One obtains the wavelength-averaged equation by simply dropping the references to wavelength in the equations. At the level of accuracy implied by the use of Table 13, it will be sufficient to use the wavelength-averaged properties listed in the table for layers or subsystems in Equations (63) and (64) to calculate the layer absorptances in the system. For example, if one were interested in a double-glazed system with a tinted and a clear glass, the properties listed in Table 13 for single-glazed clear and single-glazed tinted glass could be used for the layer properties in calculating the in-system layer absorptances. A problem arises for some low-e coated glazings, which are not listed in Table 13 as single glazings because they are never utilized that way (due to the fragility of the coating). In this case, one must use the formulas or consult the NFRC (2000b) data library and its associated (free) computer software to obtain the layer properties.

Even when some glazings have a significant spectral dependence, it may be possible to simplify the calculation by evaluating Equation (31) over only a small number of selected wavelengths. For example, a common situation is a glazing system consisting primarily of clear glazing layers but containing one “selective” or “hot climate” low-e glazing layer (see Figure 24 and associated text). This glazing layer will have very different properties in the visible and near-infrared parts of the solar spectrum. One could, therefore, calculate its spectral average separately over the two spectral regions and utilize the center wavelengths of the two regions in Equation (31)—a “two-band” model. If the other glazings in the system have properties that can be considered constant within each of the two spectral regions, a model of this type will generally produce adequate results.

**Example 11.** Calculate the spectral average properties of the glazings in Examples 8, 9, and 10. How do the results using a 2-band model compare with those for a single-band model? How do the results obtained from the formulas compare with those obtained by linearly interpolating the values in Table 13?

**Solution:** One must first calculate the spectral weights to be applied to the 2-band model. This is done by integrating the ASTM spectrum (numerically) to determine the fraction of energy contained in the visible (320 to 780 nm) and NIR (780 to 2500 nm) bands. Energy outside of either band is neglected (about 1.4% of the solar spectrum). These weights are  $w_{vis} = 0.512$  and  $w_{NIR} = 0.488$ . The spectral average properties are then calculated using Equation (31). For the selective glazing of Example 9, the spectral average properties at  $63.2^\circ$  are  $T_1(63.2^\circ) = (0.512)(0.532) + (0.488)(0.071) = 0.307$ ,  $R_1^f(63.2^\circ) =$

$0.419$ ,  $R_1^b(63.2^\circ) = 0.511$ ,  $a_1^f(63.2^\circ) = 0.274$ , and  $a_1^b(63.2^\circ) = 0.182$ . For the clear glazing of Example 8, the spectral average properties are  $T_2(63.2^\circ) = 0.723$ ,  $R_2^f(63.2^\circ) = R_2^b(63.2^\circ) = 0.168$ , and  $a_2^f(63.2^\circ) = a_2^b(63.2^\circ) = 0.107$ . For the double-glazed system of Example 10, the spectral average properties are  $T_{1,2}(63.2^\circ) = 0.244$ ,  $R_{1,2}^f(63.2^\circ) = 0.446$ ,  $R_{1,2}^b(63.2^\circ) = 0.444$ ,  $\mathcal{A}_{1:(1,2)}^f(63.2^\circ) = 0.289$ ,  $\mathcal{A}_{1:(1,2)}^b(63.2^\circ) = 0.144$ ,  $\mathcal{A}_{2:(1,2)}^f(63.2^\circ) = 0.022$ , and  $\mathcal{A}_{2:(1,2)}^b(63.2^\circ) = 0.167$ .

To obtain the results for a single-band model, we repeat the calculations of Example 10 using the spectral average quantities for the two glazing layers instead of the separate values for the visible and NIR bands. When we do this, we obtain the spectral average properties  $T_{1,2}(63.2^\circ) = 0.243$ ,  $R_{1,2}^f(63.2^\circ) = 0.436$ ,  $R_{1,2}^b(63.2^\circ) = 0.460$ ,  $\mathcal{A}_{1:(1,2)}^f(63.2^\circ) = 0.285$ ,  $\mathcal{A}_{1:(1,2)}^b(63.2^\circ) = 0.144$ ,  $\mathcal{A}_{2:(1,2)}^f(63.2^\circ) = 0.037$ , and  $\mathcal{A}_{2:(1,2)}^b(63.2^\circ) = 0.153$ . As can be seen, the results for the two methods are not identical but are relatively close together for this glazing system.

The exact glazing system used in this example is not listed in Table 13 (as will frequently be the case in practice), so we must locate the glazing system that is closest in properties. The emissivity of the selective coating on surface 2 of the outer glazing is 0.05, and the transmittance and reflectances for the insulating glass unit at normal incidence are  $T(0^\circ) = 0.331$ ,  $R^f(0^\circ) = 0.388$ , and  $R^b(0^\circ) = 0.396$ . The most similar unit listed in Table 13 is ID 25a, which has  $T(0^\circ) = 0.37$ ,  $R^f(0^\circ) = 0.35$ , and  $R^b(0^\circ) = 0.39$  (i.e., slightly lower front reflectance and therefore higher transmittance).

Near the required angle of incidence, the table values listed are  $T(60^\circ) = 0.29$ ,  $R^f(60^\circ) = 0.40$ ,  $R^b(60^\circ) = 0.43$  and  $T(70^\circ) = 0.22$ ,  $R^f(70^\circ) = 0.47$ , and  $R^b(70^\circ) = 0.50$ . (The subscripts 1,2 are understood from the system description.) Linear interpolation in angle yields the values  $[T_{1,2}(63.2^\circ)]_{25a} = 0.27$ ,  $[R_{1,2}^f(63.2^\circ)]_{25a} = 0.42$ , and  $[R_{1,2}^b(63.2^\circ)]_{25a} = 0.45$ .

Since the normal incidence transmittance of ID 25a in the table was about 0.04 higher than that of the glazing system in which we are interested (and the front reflectance correspondingly 0.04 lower), we might correct the above calculation by multiplying by the ratio of the normal incidence value for the desired glazing to that of table entry 25a. When we do this, we obtain the values  $[T_{1,2}(63.2^\circ)]_{table} = 0.27 \times 0.331/0.37 = 0.24$ ,  $[R_{1,2}^f(63.2^\circ)]_{table} = 0.42 \times 0.388/0.35 = 0.47$ , and  $[R_{1,2}^b(63.2^\circ)]_{table} = 0.45 \times 0.396/0.39 = 0.46$ . These values are quite close to the ones obtained above from use of the exact formulas.

## Angular Averaging of Glazing Properties

As stressed in the previous sections, the solar-optical properties of glazings depend on the incident angle of the radiation passing through the glazing. It is relatively simple to account for this dependence in the case of beam solar radiation, since at any particular time the radiation can be considered to be incident from a single direction, and from this direction the incident angle can be calculated as described in the section on Determining Solar Angle under Determining Solar Incident Flux. However, for the diffuse solar and ground-reflected radiation, the situation is more complicated. In principle, the energy flow through the glazing should be a sum over the individual energy flows resulting from incident radiation from each direction; for example, the radiant flux directly transmitted through an  $L$ -layer glazing due to sky and ground radiation would be

$$q_{trans} = \int \int \int_{\lambda hem} E_{sky, ground}(\theta, \phi, \lambda) T_{1,L}(\theta, \lambda) (\cos \theta) d\omega d\lambda \quad (67)$$

where  $\lambda$  denotes solar wavelengths and  $hem$  stands for hemispherical.  $E_{sky, ground}(\theta, \phi, \lambda)$  is the spectral radiance of the portion of the sky viewed in the direction  $(\theta, \phi)$  from the glazing, and  $d\omega$  is the infinitesimal element of solid angle corresponding to this direction. While such calculations can be carried out for specific sky conditions using detailed sky data or models, such as those cited in the text following Equation (12) in the section on Solar Radiation, the labor of such a calculation will be worthwhile only for very specific purposes. More generally, a drastic simplifying assumption, alluded to in Equation (12), is made. Both the sky and ground radiation are assumed to be **ideally diffuse** (i.e., to have a sky radiance that is

**Table 13 Visible Transmittance ( $T_v$ ), Solar Heat Gain Coefficient (SHGC), Solar Transmittance ( $T$ ), Front Reflectance ( $R^f$ ), Back Reflectance ( $R^b$ ), and Layer Absorptances ( $\mathcal{A}_n^f$ ) for Glazing and Window Systems (Continued)**

independent of direction). In addition, the spectral dependence is assumed to be the same as for beam solar radiation. These simplifications are implicit in the use of the quantities  $E_d$  and  $E_r$  in Equation (12). To calculate these quantities from one of the detailed sky or ground models mentioned in that section (or from detailed data), rather than from the simpler equations given elsewhere in this chapter, one would use the following equations:

$$E_d = \int \int_{\lambda_{sky}} \int E_{sky}(\theta, \phi, \lambda)(\cos \theta) d\omega d\lambda \quad (68)$$

$$E_r = \int \int_{\lambda_{ground}} \int E_{ground}(\theta, \phi, \lambda)(\cos \theta) d\omega d\lambda \quad (69)$$

Since these are assumed to be direction-independent quantities, and since for vertical glazings the sky and ground subtend equal solid angles, in most cases the fact that these quantities originate from distinct solid angle regions is ignored. More careful consideration must be given to these quantities for tilted glazings or for direction-dependent shading (such as overhangs and venetian blinds) when high accuracy in the results is desired.

The optical properties to be used with these quantities are then the **hemispherical averages** of the corresponding angle-dependent properties. For example, for an  $L$ -layer unshaded glazing, the average transmittance, front reflectance, and layer-specific overall front absorptance would be

$$\begin{aligned} \langle T_{1,L} \rangle_D &= \frac{\int \int_{hem} T_{1,L}(\theta)(\cos \theta) d\omega}{\int \int_{hem} (\cos \theta) d\omega} \\ &= 2 \int_0^{\pi/2} T_{1,L}(\theta)(\cos \theta)(\sin \theta) d\theta \quad (70) \end{aligned}$$

$$\begin{aligned} \langle R_{1,L}^f \rangle_D &= \frac{\int \int_{hem} R_{1,L}^f(\theta)(\cos \theta) d\omega}{\int \int_{hem} (\cos \theta) d\omega} \\ &= 2 \int_0^{\pi/2} R_{1,L}^f(\theta)(\cos \theta)(\sin \theta) d\theta \quad (71) \end{aligned}$$

$$\begin{aligned} \langle \mathcal{A}_{n:(1,L)}^f \rangle_D &= \frac{\int \int_{hem} \mathcal{A}_{n:(1,L)}^f(\theta)(\cos \theta) d\omega}{\int \int_{hem} (\cos \theta) d\omega} \\ &= 2 \int_0^{\pi/2} \mathcal{A}_{n:(1,L)}^f(\theta)(\cos \theta)(\sin \theta) d\theta \quad (72) \end{aligned}$$

**Table 14 Angular Weighting Function and Double Glazing System (Example 10) Transmittance Calculated for the Angular Mesh Used to Calculate Hemispherical Average Transmittance**

$\theta^\circ$	Angular Weight	$T_{1,2}(\theta)$
0	0.000	0.331
10	0.060	0.329
20	0.113	0.325
30	0.153	0.318
40	0.174	0.309
50	0.174	0.294
60	0.153	0.260
70	0.113	0.194
80	0.060	0.094
90	0.000	0.000

and similarly for the back reflectance and layer-specific absorptances. The simplified expression at the end of each equation follows from the fact that the quantities being averaged are independent of the angle  $\phi$ .

**Example 12.** Calculate the hemispherical average properties for the two glazings and the glazing system in Examples 8, 9, and 10, and compare the results with Table 13.

**Solution:** Equations (70) through (72) are used, and the integration is done numerically, using an angular grid of  $10^\circ$  intervals extending from  $0^\circ$  to  $90^\circ$ . To carry out this calculation, all of the properties in the three examples must be recalculated at each angle. A single-band model rather than a 2-band is used to reduce the calculational labor. Values of  $T_{1,2}(\theta)$  used in calculating  $\langle T_{1,2} \rangle_D$  are shown in Table 14, together with the angular weighting functions used in the numerical integration. The angular weighting functions are the values, at each angle, of  $2(\cos \theta)(\sin \theta)\Delta\theta$  at that angle, where  $\Delta\theta$  is the grid interval ( $10^\circ$ ) expressed in radians.

The resulting values are  $\langle T_1 \rangle_D = 0.335$ ,  $\langle R_1^f \rangle_D = 0.401$ ,  $\langle R_1^b \rangle_D = 0.496$ ,  $\langle a_1^f \rangle_D = 0.264$ , and  $\langle a_1^b \rangle_D = 0.169$  for the selective glazing of Example 9;  $\langle T_2 \rangle_D = 0.761$ ,  $\langle R_2^f \rangle_D = \langle R_2^b \rangle_D = 0.137$ , and  $\langle a_2^f \rangle_D = \langle a_2^b \rangle_D = 0.101$  for the clear glazing of Example 8;  $\langle T_{1,2} \rangle_D = 0.277$ ,  $\langle R_{1,2}^f \rangle_D = 0.405$ ,  $\langle R_{1,2}^b \rangle_D = 0.442$ , and  $\langle \mathcal{A}_{1:(1,2)}^f \rangle_D = 0.271$ ,  $\langle \mathcal{A}_{1:(1,2)}^b \rangle_D = 0.138$ ,  $\langle \mathcal{A}_{2:(1,2)}^f \rangle_D = 0.036$ , and  $\langle \mathcal{A}_{2:(1,2)}^b \rangle_D = 0.141$  for the double-glazing system of Example 10.

The corresponding values listed for system 25a in Table 13 are  $[\langle T_{1,2} \rangle_D]_{25a} = 0.31$ ,  $[\langle R_{1,2}^f \rangle_D]_{25a} = 0.39$ , and  $[\langle R_{1,2}^b \rangle_D]_{25a} = 0.42$ . When we correct them as in Example 11 for the differences between the glazing system of interest and ID 25a at normal incidence, we obtain  $[\langle T_{1,2} \rangle_D]_{table} = 0.31 \times 0.331/0.37 = 0.28$ ,  $[\langle R_{1,2}^f \rangle_D]_{table} = 0.39 \times 0.388/0.35 = 0.43$ , and  $[\langle R_{1,2}^b \rangle_D]_{table} = 0.42 \times 0.396/0.39 = 0.43$ . These are reasonably close to the values we obtained from the calculation using the more detailed equations.

### Spectrally Selective Glazing

The spectral range from 350 nm to over 50  $\mu\text{m}$  contains radiation from both the sun and sky incident upon fenestration systems as well as the longer wavelength **thermal radiation**. Thermal radiation is emitted by warm bodies both outside and inside the building. Figure 23 shows the human eye spectral response, the solar spectrum for an air mass  $m = 1.5$ , and a room temperature blackbody radiation spectrum. The blackbody radiation is scaled to compare with the solar spectrum. Spectral selectivity was defined previously as strong changes in the optical properties of a glazing system over the spectrum. Figure 23 illustrates the basic concept in terms of the spectral reflectance and Figure 24, the spectral transmittance of ideal low solar gain glazings. One can see in this figure the human eye spectral response (called the human photopic visibility function), an air mass 1.5 solar spectrum, and a room temperature ( $24^\circ\text{C}$ ) blackbody radiation spectrum. The latter has been scaled up to better compare it with the shape of the solar spectrum. What is clear

from this diagram is the separation of the solar spectrum from the emission spectrum characteristic of an interior room of a multiple-pane glazing system.

Almost all architectural glass is opaque to the long-wave radiation emitted by surfaces at temperatures below about 1200°C. This characteristic produces the **greenhouse effect**, by which solar radiation passing through a window is partially retained inside by the following mechanism. Radiation absorbed by surfaces within the room is emitted as long-wavelength radiation, and it cannot escape directly through the glass since it is opaque to all radiation beyond 4.5 μm. Instead, the radiation from the room surfaces falling on the glass is absorbed and re-emitted to both sides as determined by several parameters, such as the inside and outside film heat transfer coefficients, the surface emissivities, and other glazing properties.

A good reflector in the long-wavelength infrared portion of the spectrum can be a poor reflector and a good transmitter in the solar portion. Because of the conservation of energy ( $T + R + A = 1.0$ ), a high reflectance in the long-wavelength infrared portion of the spectrum means a low transmittance and absorptance. Because of Kirchhoff's law [Equation (29)], a low absorptance means a low emissivity as well. This is the principle of operation of the high-solar-gain (or cold-climate) **low-e coating** on window glass. Such a coating has high transmittance over the entire solar spectrum, producing high solar heat gain while being highly reflective to the long-wavelength infrared radiation emitted by the interior surfaces, reflecting this radiation back inward. The *low-e* in low-e coating refers to a low emissivity over the long-wavelength portion of the spectrum.

Another characteristic of glazing is that at a given wavelength, or over a defined range of wavelengths, the transmittance is the same in both directions. A glazing with a coating or consisting of multiple glazing layers will have one solar transmittance value, but it will have two reflectance values—one for radiation approaching each side of the system.

Figure 24 shows a hypothetical glazing system with improved performance for hot climates. In this case, the sharp **reflectance edge** that the ideal cold-climate low-e coating exhibited just past the end of the solar spectrum in Figure 23 is shifted closer to the edge of the visible portion of the spectrum, thereby increasing the solar near-infrared (NIR) reflectance of the glazing. This results, as seen in Figure 24, in a drop in the hot-climate transmittance to the right of the visible portion of the spectrum. The effect is to reflect the near-infrared portion of the solar spectrum outside, reducing

solar gain, while still admitting visible light in the wavelength region below 800 nm. This hot-climate, solar-gain-rejecting coating also exhibits low emissivity over the long-wavelength spectrum, and is therefore also properly termed a low-e coating. To distinguish the cold- from the hot-climate version, a glazing with this type of spectral response is often termed **selective low-e**. This is somewhat of a misnomer, because both hot- and cold-climate glazings are spectrally selective. Another terminology is **high-solar-gain low-e** glazing system for cold climates, contrasted with **low-solar-gain low-e** glazing system for hot climates.

The reduced infrared transmittance for the hot-climate glazing in Figure 24 is ideally achieved by high reflectance and low absorptance (meaning also low emissivity). It can also be accomplished with high infrared absorptance, if the flow of the absorbed solar radiation to the interior of the building can be reduced, introducing a second approach to the construction of a hot-climate, low-solar-gain glazing system. In this case, the outer pane of a multiple-pane glazing system is made to have good visible transmittance but high absorptance over the solar infrared spectrum. To protect the interior of the building from the heat of this absorbed radiation, additional glazings, gas spaces, and cold-climate type, low-e coatings are added.

By this means, radiation, conduction, and convection of heat from the hot outer pane to the interior ones and to the interior of the building are reduced because of the coating, the insulating gas space, and the additional panes. Such a glazing system for hot climates is insulated primarily *not* to protect the building from conductive heat losses in winter but to protect the interior from the solar radiant heat absorbed by the hot outer pane in summer. Several manufacturers offer this kind of nonreflecting spectrally selective glazing system for commercial buildings having large cooling loads. (If this glazing system is placed in a flip window, one that rotates open for cleaning and can be closed with either side facing outward, then flipping it over in winter can make it an effective trap for passive solar heating of the interior (McCluney and Jindra 2000). Such a system will have two different SHGC values, depending upon which way the window is flipped.

Figure 24 shows that glazings intended for hot climates should have (1) high transmittance over the visible portion of the spectrum to let daylight in for both illumination and view and (2) low transmittance over all other portions of the spectrum to reduce solar heat gain. In contrast, glazings intended for very cold climates should have high transmittance over the whole solar spectrum, from 380 nm

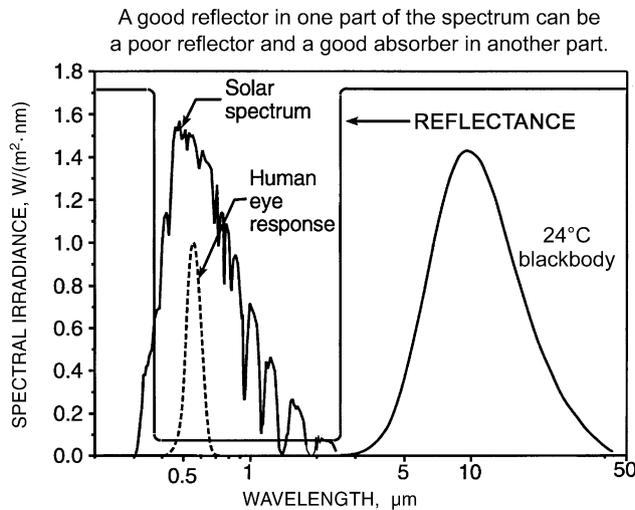

Fig. 23 Solar Spectrum, Human Eye Response Spectrum, Scaled Blackbody Radiation Spectrum, and Idealized Glazing Reflectance Spectrum

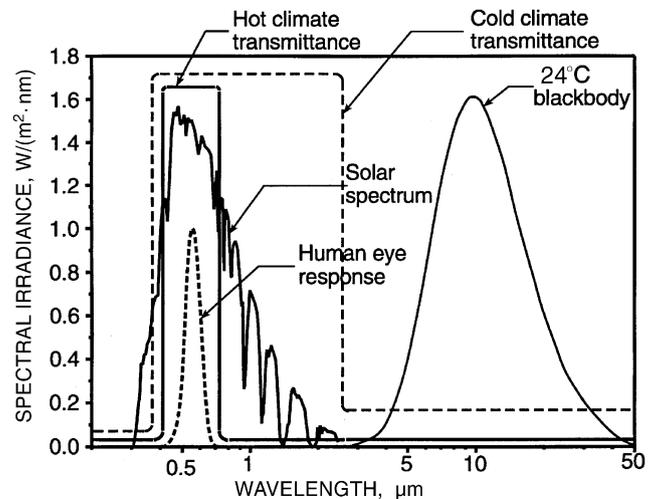

Fig. 24 Demonstration of Two Spectrally Selective Glazing Concepts, Showing Ideal Spectral Transmittances for Glazings Intended for Hot and Cold Climates

to over 3500 nm, for maximum admission of solar radiant heat gain and light. In addition, glazings for cold climates should have low transmittance over the long-wavelength portion of the spectrum in order to block the radiant heat emitted by the relatively warm interior surfaces of buildings, preventing its escape to the outside.

Extreme spectral selectivity in glazing systems in the visible portion of the spectrum can produce an unwanted color shift in the transmitted light. The color of the transmitted light and its color-rendering properties should be considered in the design.

### SOLAR HEAT GAIN COEFFICIENT

Fenestration solar heat gain has two components. First is the directly transmitted solar radiation. The quantity of radiation entering the fenestration directly is governed by the solar transmittance of the glazing system. Multiplying the incident irradiance by the glazing area and its solar transmittance yields the solar heat entering the fenestration directly. The second component is the inward-flowing portion of the absorbed solar radiation, radiation that is absorbed in the glazing and framing materials of the window and is subsequently conducted, convected, and radiated to the interior of the building.

The solar heat gain coefficient values presented in this chapter are based on a standard spectral irradiance distribution for air mass 1.5. This spectrum is recommended by the National Fenestration Rating Council (NFRC) for the purpose of rating fenestrations for instantaneous energy performance using defined environmental and incident irradiance conditions. The NFRC standard spectrum can be found in ASTM *Standard E 891*. For real solar gain calculation situations, and with glazing systems exhibiting spectral selectivity over the solar spectrum, the incident solar spectrum used should be altered from the representative one contained in this standard in order to be more realistic for the atmospheric conditions at the location and time of the calculation. Gueymard (1987a, 1987b, 1993a, 1993b, and 1995) has developed an algorithm to guide a computerized methodology for calculating realistic solar spectra that are sensitive to changes in the atmospheric constituents.

The ASTM standard spectrum is different from Parry Moon's (Moon 1940) air mass 2 spectrum used by the glazing industry in the past. Both are different from solar spectral distributions incident upon fenestrations with different atmospheric conditions and for different sun angles. These differences will have little impact on the SHGC of glazing systems containing only glazings with relatively flat spectral transmittances, that is, glazings that are not strongly spectrally selective. Glazings that do exhibit strong spectral selectivity (such as those shown in Figures 15 and 16), however, can have different SHGC values. The visible transmittances are less sensitive to solar spectral changes. However, for glazings with very strong spectral selectivity in the visible portion of the spectrum, such as those exhibiting strong color, the visible transmittance also can be sensitive to the shape of the incident spectrum.

Absorbed solar radiation, including ultraviolet, visible, and infrared radiation from the sun and sky, is turned into heat inside the absorbing material. In a window, the glazing system temperature rises as a result to some approximately equilibrium value at which the energy gains from absorbed radiation are balanced by equal losses. The absorbed solar radiation is dissipated through the mechanisms of conduction, convection, and radiation. Some heat goes outside the building, and the remainder goes inside, adding to the directly transmitted solar radiation. The magnitude of what is called the **inward-flowing fraction**  $N$  of the absorbed radiation depends on the nature of the air boundary layers adjacent to both sides of the glazing, including any gas between the panes of a multiple-pane glazing system ( $N_i$  is often used to distinguish the inward-flowing fraction from the outward-flowing fraction,  $N_o$ ). However, since only the inward-flowing fraction is used here, the subscript  $i$  is dropped for clarity.)

The concept of the solar heat gain coefficient is best illustrated for the case of a single glass pane in direct sunlight. Let  $E_D$  be the direct solar irradiance incident upon a single pane of glass,  $T$  be its solar transmittance,  $\mathcal{A}$  be the solar absorptance, and  $N$  be the inward-flowing fraction of the absorbed radiation. In this case, the total solar gain (heat flow per unit area)  $q_b$  that enters the space due to the incident solar radiation is

$$q_b = E_D(T + N\mathcal{A}) \quad (73)$$

in units of energy flux per unit area,  $W/m^2$ . Multiple glazings are discussed in the section on Calculation of Solar Heat Gain Coefficient.

The quantity in parenthesis in Equation (73) is called the **solar heat gain coefficient** or **SHGC**. It is the fraction of incident irradiance that enters through the glazing and becomes heat gain. It includes both the directly transmitted portion and the absorbed and re-emitted portion:

$$\text{SHGC} = T + N\mathcal{A} \quad (74)$$

The SHGC is needed to determine the solar radiant heat gain through a window's glazing system. The SHGC for certain defined conditions of spectrum and incident angle  $\theta$  should be included along with U-factor and other instantaneous performance properties in any manufacturer's description of a window's energy performance. Since the optical properties  $\mathcal{A}$  and  $T$  vary with the angle of incidence [defined as the angle between the rays incident on the glazing and the normal (perpendicular) to the glazing], according to Equation (74), the solar heat gain coefficient is also a function of angle of incidence. Once the incident irradiance and SHGC are known for a given angle of incidence, the solar gain (from direct beam radiation) can be computed with the following equation:

$$q_b = E_D \text{SHGC} \quad (75)$$

Optical properties also vary with wavelength. The quantities  $\mathcal{A}$  and  $T$  are spectral averages, as described by Equation (30).

### Calculation of Solar Heat Gain Coefficient

In the most general way, the solar heat gain  $q$  and the solar heat gain coefficient SHGC are defined as angle-dependent and spectrally dependent properties:

$$\begin{aligned} q(\theta) &= \int_{\lambda} E_D(\lambda) [T(\theta, \lambda) + N\mathcal{A}(\theta, \lambda)] d\lambda \\ &= \int_{\lambda} E_D(\lambda) \text{SHGC}(\theta, \lambda) d\lambda \end{aligned} \quad (76)$$

where the definition of Equation (74) implies an angle- and wavelength-dependent solar heat gain coefficient:

$$\text{SHGC}(\theta, \lambda) = T(\theta, \lambda) + N\mathcal{A}(\theta, \lambda) \quad (77)$$

This can in turn be used to define a wavelength-averaged solar heat gain coefficient:

$$\text{SHGC}(\theta) = \frac{\int_{\lambda} E_D(\lambda) [T(\theta, \lambda) + N\mathcal{A}(\theta, \lambda)] d\lambda}{\int_{\lambda} E_D(\lambda) d\lambda} \quad (78)$$

where

$E_D(\lambda)$  = incident solar spectral irradiance

$T(\theta, \lambda)$  = spectral transmittance of the glazing system

$\mathcal{A}(\theta, \lambda)$  = total spectral absorptance of the glazing system

Starting with this edition of the Handbook, Equations (76) through (78) indicate the preferred way of determining the solar gain of glazing systems and calculating the solar heat gain coefficient. At least two computer programs are available to assist in the calculation (Arasteh et al. 1994, AGSL 1992). This approach has been adopted by the National Fenestration Rating Council in NFRC 200 for the rating, certification, and labeling of windows for energy performance and by the Canadian Standards Association (CSA *Standard* A440.2). The method is valid for strongly spectrally selective glazing systems as well as for nonselective ones. In these programs, the overall system optical properties at a given incident angle are calculated for each wavelength and the results averaged following Equation (31). The ASTM *Standard* E 891 spectrum is used in the averaging. The wavelength-averaged properties (at a given incident angle) can then be used in Equation (76).

When a glazing system is not strongly spectrally selective, the solar-weighted spectral broadband values of the optical properties can be used, and the integral over wavelength shown in Equations (76) and (78) is not needed. In this case, and for a general unshaded glazing system, which may consist of several glazing layers, each glazing layer will have its own individual inward-flowing fraction of the absorbed radiation for that layer. Let the glazings be numbered from the outside inward, and  $k$  be the glazing index. Then, the SHGC is given by

$$\text{SHGC}(\theta) = T_{1,L}^f(\theta) + \sum_{k=1}^L N_k \mathcal{A}_{k:(1,L)}^f(\theta) \quad (79)$$

where

$T_{1,L}^f(\theta)$  = front transmittance of the glazing system

$L$  = number of glazing layers

$\mathcal{A}_{k:(1,L)}^f$  = absorptance of layer  $k$

$N_k$  = inward-flowing fraction for layer  $k$

The wavelength-independent quantities in this equation are obtained by the averaging procedure of Equation (66). Conversely, the wavelength-dependent form of Equation (79) is obtained by adding the wavelength dependence to the indicated angle dependence; the  $N_k$  and the layer decomposition are independent of wavelength.

The solar heat gain coefficient is a combination of the solar-optical properties discussed in the section on Solar Optical Properties of Glazings and a new set of quantities  $N_k$ , which account for the fact that of the energy absorbed in a given layer, the fraction that reaches the interior space will depend on the location of the layer. The  $N_k$  are thermal in origin; they depend on the heat transfer properties of the assembly rather than on its optical properties.

The inward-flowing fractions can be calculated from simplified heat transfer models, using the following equation:

$$N_k = \frac{U}{h_{o,k}} \quad (80)$$

where

$U$  = U-factor of the glazing

$h_{o,k}$  = effective heat transfer coefficient between the exterior environment and the  $k$ th glazing layer

The effective heat transfer coefficient can be calculated in a one-dimensional model as the reciprocal of the sum of the thermal resistances of all elements between layer  $k$  and the exterior (see Chapter 3). For example, for single glazing,

$$N = \frac{U}{h_o} \quad (81)$$

where  $U$  is the U-factor of the glazing and  $h_o$  is the exterior heat transfer coefficient (see Chapter 3). For double glazing, the two inward-flowing fractions are

$$N_1 = \frac{U}{h_o}, \quad N_2 = \frac{h_o + U}{h_o} \quad (82)$$

where the numeric subscripts obey the usual layer numbering convention (1 is the exterior glazing).

In more complicated multilayer glazing systems, it is advisable to perform a detailed heat transfer analysis of the system to determine the values of  $N_k$ , since the effective heat transfer coefficients and  $U$  depend (weakly) on the glazing layer temperatures and other environmental conditions (e.g., Finlayson and Arasteh 1993, LBL 1994, and Wright 1995c).

### Diffuse Radiation

For incident radiation that is diffuse, the hemispherical average solar heat gain coefficient must be used. This may be calculated either by a direct hemispherical averaging of Equation (79) using the analog of Equation (70) as follows:

$$\begin{aligned} \langle \text{SHGC}(\theta) \rangle_D &= \frac{\iint_{hem} \text{SHGC}(\theta)(\cos\theta)d\omega}{\iint_{hem} (\cos\theta)d\omega} \\ &= 2 \int_0^{\pi/2} \text{SHGC}(\theta)(\cos\theta)d\theta \end{aligned} \quad (83)$$

or equivalently by simply using the hemispherically averaged solar-optical properties in Equation (79):

$$\langle \text{SHGC} \rangle_D = \langle T_{1,L}^f \rangle_D + \sum_{k=1}^L N_k \langle \mathcal{A}_{k:(1,L)}^f \rangle_D \quad (84)$$

In any case,  $N_k$  is unaffected in the averaging process, since it does not depend on the incident angle or the wavelength. Considerations of the solar spectrum discussed previously in the sections on Spectral Averaging of Glazing Properties and Angular Averaging of Glazing Properties also apply to the solar heat gain coefficient.

### Solar Gain Through Frame and Other Opaque Elements

Figure 25 illustrates the mechanisms by which a window provides solar gain. It is assumed that all of the directly transmitted solar radiation is absorbed at indoor surfaces, where it is converted to heat. Solar gain also enters a building through opaque elements such as the frame and any mullion or dividers that are part of the fenestration system because a portion of the solar energy absorbed at the surfaces of these elements is redirected to the indoor side by heat transfer.

The solar heat gain coefficient of the fenestration system can be calculated while accounting for solar gain through the opaque elements by area-weighting the solar heat gain coefficients of the glazing, frame, and  $M$  divider elements. Thus,

$$\text{SHGC} = \frac{\text{SHGC}_g A_g + \text{SHGC}_f A_f + \sum_{i=1}^M A_i \text{SHGC}_i}{A_g + A_f + \sum_{i=1}^M A_i} \quad (85)$$

where  $SHGC_g$ ,  $SHGC_f$ , and  $SHGC_i$  are the solar heat gain coefficients of the glazed area, frame, and  $i$ th divider, respectively.  $A_g$ ,  $A_f$ , and  $A_i$  are the corresponding projected areas.

In some cases, it is useful to have an overall SHGC for the opaque elements only, which is defined by

$$SHGC_{op} = \frac{SHGC_f A_f + \sum_{i=1}^M A_i SHGC_i}{A_{op}} \quad (86)$$

where

$$A_{op} = A_f + \sum_{i=1}^M A_i$$

$SHGC_f$  can be estimated (Wright 1995a) using

$$SHGC_f = \alpha_f^s \left( \frac{U_f}{h_f} \right) \left( \frac{A_f}{A_{surf}} \right) \quad (87)$$

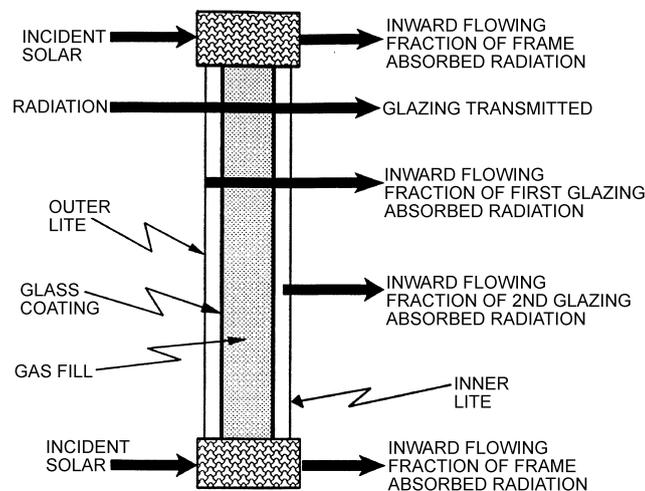

where  $\alpha_f^s$  is the solar absorptivity of the outdoor surface of the frame,  $U_f$  is the frame U-factor, and  $h_f$  is the heat transfer coefficient (radiative plus convective) between the frame and the outdoor environment. The projected-to-surface area ratio ( $A_f/A_{surf}$ ) corrects for the fact that  $U_f$  is based on projected area  $A_f$  and  $h_f$  is based on the exposed outdoor frame surface area  $A_{surf}$ .  $SHGC_i$  can be calculated in the same way:

$$SHGC_i = \alpha_i^s \left( \frac{U_i}{h_i} \right) \left( \frac{A_i}{A_{surf,i}} \right) \quad (88)$$

The outdoor side heat transfer coefficients  $h_f$  and  $h_i$  can be estimated using ASHRAE (1996):

$$h_f \text{ or } h_i = h_{co} + 4\sigma e_f T_{out}^3 \quad (89)$$

where  $h_{co}$  is the convective heat transfer coefficient between the frame (or divider) surface and the outdoor environment,  $e_f$  is the emissivity (long-wave) of the outdoor frame (or divider) surface,  $T_{out}$  is the outdoor absolute temperature, and  $\sigma$  is the Stefan-Boltzmann constant.

**Fig. 25 Components of Solar Radiant Heat Gain with Double-Pane Window, Including Both Frame and Glazing Contributions**

### Shading Coefficient—A Historical Perspective

Before modern complex windows were marketed in quantity, the determination of fenestration solar gain was substantially simpler. Frame and edge effects were largely ignored, and attention focused on the glazing, which was typically made up of single-pane clear or tinted glass. ASHRAE provided a method for calculating the incident solar beam irradiance for any direction of incidence and tabulated the resulting solar gains through single-pane clear glass in units of flux per unit area in tables of what were called **solar heat gain factors** (SHGFs). These factors, having units of  $W/m^2$ , are to be distinguished from the solar heat gain coefficient, which is dimensionless. Solar heat gain factors provide the total solar radiant heat gain through a standard single-glazing system, including both the directly transmitted radiant component and the inward flowing fraction of the radiation absorbed in the glazing system.

The engineer's job is relatively easy with this method. One first figures out the angle of direct beam incidence on the glass for a typical peak solar gain date and time. This is done by (1) using equations provided in the section on Determining Solar Angle under Determining Incident Solar Flux or (2) by looking up the data for a latitude close to that of the building being designed for a chosen glazing orientation and for a given time of day expected to produce peak solar gain, in Tables 16 through 22 in Chapter 29 of the 1997 *ASHRAE Handbook—Fundamentals*. These tables provide the solar heat gain factor for clear single-pane glass (the so-called **standard reference glazing**, having  $T = 0.86$ ,  $R = 0.08$ , and  $a = 0.06$  at normal incidence) under these conditions.

The next step is simply a matter of multiplying the solar heat gain factor by the area of the glazing, producing the solar gain expected, in W. This provides directly the solar gain for single-pane clear glass.

In order to deal with windows having shades or tinted glass, the concept of a **shading coefficient** was introduced. The idea behind the shading coefficient was to find a multiplicative factor for the shaded glass that allowed the engineer to correct the previously determined solar gain number through clear glass to the proper value for the window with a shade or tint. This could be done because the commonly used shading systems (interior shades and drapes) were assumed not to have strongly varying angular properties, leaving the single glazing as the only determinant of angular dependence. Spectral variation was not considered. This concept was later extended to tinted glazings, which often do not violate the basic underlying assumptions, and to glass blocks and single-glazed windows with interior venetian blinds, for which the application is more dubious.

The shading coefficient was defined to be the ratio of the solar heat gain coefficient of a glazing system at a particular angle of incidence and incident solar spectrum to that for standard reference glazing at the same angle of incidence and spectral distribution:

$$SC = \frac{SHGC(\theta)_{test}}{SHGC(\theta)_{ref}} \quad (90)$$

For single-pane clear and many single-pane tinted glazings, this ratio remains constant as the solar spectral shape varies and as the angle of incidence varies. Thus, a single number can be used to convert from the reference SHGC to the SHGC for the tinted glazing at the angle of incidence selected. Due to its lack of sensitivity to angle of incidence, the same SC value works for beam radiation at any angle of incidence, as well as for diffuse radiation. This meant that the complicated calculation of solar heat gain transmission through glass could be done once and tabulated, a quantity appearing in previous editions of this Handbook as the SHGF. For other systems, the SHGF obtained from the table could simply be multiplied by the SC, a great simplification. The value of the SC for standard reference glass is 1.0, but the SHGC for this glass is 0.87 at normal inci-

dence, using ASHRAE standard summer conditions, and for the standard ASTM solar spectrum. This was useful for dealing with glazings of different thicknesses (and was later extended to tinted glazings). Because the principal property causing angular dependence in single glazing is reflectance, angular properties do not depend strongly on thickness, so that the SC defined by Equation (90) remains approximately constant. While tinted glazings, having different spectral transmission from the reference glazing, have a very different SHGC, this difference does not depend strongly on angle, so again SC is approximately constant. Since it is easiest to determine the transmittance of a glazing at normal incidence, it became standard practice to calculate the SC for clear and tinted single glazing from the following relation:

$$SC = \frac{SHGC}{0.87} \quad (91)$$

This equation applies only to the glazing portion of single-pane tinted or clear windows. It does not include frame effects. It may still be used to determine the SC of commercially available, single, uncoated glazing products from the solar heat gain coefficient (or vice versa) published by the manufacturer.

### Solar Heat Gain Coefficient, Visible Transmittance, and Spectrally Averaged Solar-Optical Property Values

Table 13 lists the visible transmittance, solar transmittance, front and back reflectance, and solar heat gain coefficients for common glazing and window systems. The window systems include windows with aluminum or metal frames and windows with other frames that have a lower conductivity (e.g., thermally broken aluminum, wood, vinyl, and fiberglass). As can be seen in Table 13, the total window solar heat gain coefficient varies with the type of operator, size of the fenestration product, and type of frame.

The glazing  $T_v$ ,  $T_{sol}$ ,  $R^f$ ,  $R^b$ , and SHGC values have been calculated using manufacturers' spectral data following methods described in the section on Solar-Optical Properties of Glazing (Finlayson et al. 1994, Wright 1995a). The glazing values are given for 3 mm and 6 mm glass and will vary with glass thickness and glass manufacturer. The values shown are average values and may vary by  $\pm 0.05$ . It is recommended that actual values be determined using the methods described in this chapter with detailed spectral data from NFRC (1994). The front reflectance is the reflectance of the unit to the outside, and the back reflectance is the reflectance to the room side.

The visible transmittances are center-glazing values at normal incidence. A rule of thumb is to select a glazing unit whose visible transmittance is greater than its solar heat gain coefficient, especially if daylighting strategies will be used in the building. For maximum light with minimum solar gain, there are fenestration products available having visible transmittance that is 1.4 times their SHGC.

The solar heat gain coefficients are center-glazing values and total window values. The center-glazing solar heat gain coefficients are given at normal incidence ( $0^\circ$ ) and at  $40^\circ$ ,  $50^\circ$ ,  $60^\circ$ ,  $70^\circ$ , and  $80^\circ$  incidence angles. For angles other than those listed, straight-line interpolation can be used between the two closest angles for which values are shown.

The solar transmittances and front and back reflectances are also center-glazing values and are given at normal incidence ( $0^\circ$ ) and at  $40^\circ$ ,  $50^\circ$ ,  $60^\circ$ ,  $70^\circ$ , and  $80^\circ$  incidence angles. The solar absorptances can be calculated from these values using Equation (26). The effective inward-flowing fraction of absorbed radiation for the entire system (not layer-specific values) can be determined from Equation (74) by inserting the solar transmittance and corresponding SHGC.

The total window solar heat gain coefficients in Table 13 assume normal incidence. The operable and fixed window sizes in Table 4 were used. To calculate the frame area, the frame heights shown in

Figure 4 for aluminum and aluminum-clad wood/wood/vinyl were used. The frame area for the aluminum windows is 15% for the operable size and 11% for the fixed size. The frame area for other frames is 27% for the operable size and 13% for the fixed size. The ratio of projected frame area to frame surface area is assumed to be 1.0, based on Wright (1995a).

The frame solar heat gain coefficients used to determine the total window solar heat gain coefficients are calculated according to the section on solar heat gain coefficients for frames and other nonglazing elements in this chapter. The frame U-factors are taken from Table 1. The frame absorptance is assumed to be 0.5. The outside film coefficient is  $22.2 \text{ W}/(\text{m}^2 \cdot \text{K})$ , corresponding to a wind speed of 3.4 m/s. For the aluminum window, the frame solar heat gain coefficient is 0.14 for the operable window and 0.11 for the fixed window. For the other frames, the frame solar heat gain coefficient was found to vary between 0.02 and 0.07 for the various lower conductivity frame types. A frame solar heat gain coefficient of 0.04 is used for the operable window, and 0.03 is used for the fixed window. These values correspond directly to the aluminum-clad wood/reinforced vinyl frames.

For energy calculations on a daylit building, the visible transmittance for the entire window should be used. The visible transmittance of a window can be calculated by multiplying the fraction of glazing area by the center-glazing visible transmittance (see Example 13).

The U-factor of a window listed in Table 13 can be found in Table 4. The ID number for each entry in Table 13 refers to an ID number in Table 4. For a particular glazing system in Table 13, the corresponding glazing system should be the glazing system with that ID number or following that ID number in Table 4. Remember that while the gap width and gas fill have a negligible impact on the solar heat gain coefficient and other optical properties, they are important factors when determining U-factors.

**Example 13.** Estimate the overall visible light transmittance for an operable wood casement window with clear, uncoated 6 mm double glazing.

**Solution:** From Table 13, ID 5b, the center-glazing visible light transmittance is 0.78. The operable window has 27% frame area with a wood frame. The overall visible light transmittance is

$$T_v = 0.27(0) + 0.73(0.78) = 0.57$$

### Passive Solar Gain

Energy analysis of a fenestration product should include the value of passive solar gain through the product in winter. As described in Chapter 32 of the 1999 *ASHRAE Handbook—Applications*, the magnitude of this energy gain depends on such variables as latitude and orientation. In some cases, properly designed and operated fenestration allows more energy into the building over a heating season than it loses, thus making it energy-contributing rather than energy-consuming. Excessive solar gain during the cooling season must be controlled, however.

Direct beam admission to occupied spaces can often produce severe localized glare and overheating conditions. Judicious use of shades and other fenestration control strategies, as well as placement and orientation of workstations and furniture, can alleviate these problems in most cases.

### Solar Gain Rejection and Internal Load Dominated Buildings

For some buildings in certain climates, preventing solar gain is more important from an energy perspective than improving thermal insulation using multiple panes of glazing. For example, internal load dominated buildings in cool, clear climates can have substantial daytime solar and internal heat gains. These gains can be rejected by conduction through the building envelope and/or forced ventilation through the HVAC system. Preventing excessive solar gain through the fenestration systems of such buildings is very important.

**Airflow Windows**

If properly managed, airflow between panes of a double-glazed window can improve fenestration performance. In normal use, a venetian blind is located between the glazing layers. Ventilation air from the room enters the double-glazed cavity, flows over the blind, and is, in some designs, exhausted from the building or returned through the ducts to the central HVAC system. In cold weather, the window acts as a heat exchanger when sunlit so that the inner glass temperature nearly equals the room air temperature and improves thermal comfort.

The apparent conductance across the inner glazing is very low, but this is misleading since additional heat is lost to the outdoors from the moving airstream in the window cavity. During sunny winter days, the blind acts as a solar air collector; heat removed by the moving air can be used elsewhere in the building. In the summer, the window can have a very low shading coefficient if the blinds are appropriately placed since the majority of solar gains are removed from the window. These systems can control window heat transfer under many different operating conditions. Sodergren and Bostrom (1971) and Brandle and Boehm (1982) give details on airflow or exhaust windows.

**Skylights**

Skylight solar heat gain strongly depends on the configuration of the space below or adjacent to (i.e., in sloped applications) the skylight formed by the skylight curb and any associated light well.

Five aspects must be considered (1) the transmittance and absorptance of the skylight unit, (2) the transmitted solar flux that reaches the aperture of the light well, (3) whether that aperture is covered by a diffuser, (4) the transmitted solar flux that strikes the walls of the light well, and (5) the reflectance of the walls of the light well. Data for flat skylights, which may be considered as sloped glazings, are found in Tables 4 and 13.

**Domed Skylights.** Solar and total heat gains for domed skylights can be determined by the same procedure used for windows. Table 15 gives SHGCs for plastic domed skylights at normal incidence. Manufacturers' literature has further details. Given the poorly defined incident angle conditions for domed skylights, it is best to use these values without correction for incident angle, together with the correct (angle-dependent) value of incident solar irradiance.

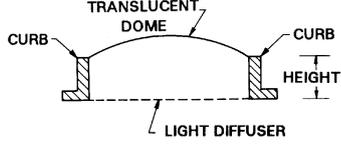

Results should be considered approximate. In the absence of other data, these values may also be used to make estimates for skylights on slanted roofs.

**Glass Block Walls**

Glass block can be used for light transmission through exterior walls when optical clarity for view is not needed or wanted. Table 16 describes a variety of glass block patterns and gives solar heat gain coefficients to be applied to the solar irradiances so that approximate instantaneous solar heat gains can be calculated.

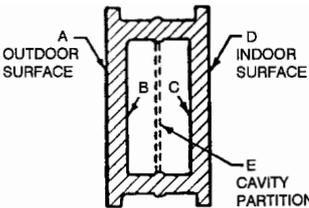

Convection and low-temperature radiative heat gain for all hollow glass block panels fall within a narrow range. Differences in SHGCs are largely the result of differences in the transmittance of the glass blocks for solar radiation. Solar heat gain coefficients for any particular glass block pattern vary depending on orientation and time of day. The SHGC for western exposures in the morning (in the

**Table 15 Solar Heat Gain Coefficients for Domed Horizontal Skylights**

**Table 16 Shading Coefficients and U-Factors for Standard Hollow Glass Block Wall Panels**

Type of Glass Block <sup>a</sup>	Description of Glass Block	Solar Heat Gain Coefficient		U-Factor, <sup>c</sup> W/(m <sup>2</sup> ·K)
		in Sun	in Shade <sup>b</sup>	
Type I	Glass colorless or aqua A, D: Smooth B, C: Smooth or wide ribs, or flutes horizontal or vertical, or shallow configuration E: None	0.65	0.40	2.9
Type IA	Same as Type I except ceramic enamel on A	0.27	0.20	2.9
Type II	Same as Type I except glass fiber screen partition E	0.44	0.34	2.7
Type III	Glass colorless or aqua A, D: Narrow vertical ribs or flutes. B, C: Horizontal light-diffusing prisms, or horizontal light-directing prisms E: Glass fiber screen	0.33	0.27	2.7
Type IIIA	Same as Type III except E: Glass fiber screen with green ceramic spray coating or glass fiber screen and gray glass or glass fiber screen with light-selecting prisms	0.25	0.18	2.7
Type IV	Same as Type I except reflective oxide coating on A	0.16	0.12	2.9

<sup>a</sup>All values are for 200 by 200 by 100 mm block, set in light-colored mortar. For 300 by 300 by 100 mm block, increase coefficients by 15%, and for 150 by 150 by 100 mm block reduce coefficients by 15%.

<sup>b</sup>For NE, E, and SE panels in shade, add 50% to the values listed for panels in the shade.

<sup>c</sup>Values shown are the same for all size block.

shade) is depressed because of the heat storage within the block, whereas the SHGC for eastern exposures in the afternoon (in the shade) is elevated as the stored heat is dissipated. Time lag effects from heat storage are estimated by using solar gains and air-to-air temperature differences for one hour earlier than the time for which the load calculation is made.

Calorimeter tests of Type 1A glass block showed little difference in solar heat gains between glass block with either black or white ceramic enamel on the exterior of the block. Because white and black ceramic enamel surfaces represent the two extremes for reflecting or absorbing solar energy, glass block with enamel surfaces of other colors should have solar heat gain coefficients between these values. Since glass blocks are good examples of strongly angularly selective fenestrations, all cautions in the section on Angular Dependence of Glazing Optical Properties apply here.

### Plastic Materials for Glazing

Generally, the factors outlined for glass apply also to glazing materials such as acrylic, polycarbonate, polystyrene, or other plastic panels. If the solar transmittance, absorptance, and reflectance are known, an SHGC and a shading coefficient can be calculated in the same way as for glass. These properties can be obtained from the manufacturer or be determined by simple laboratory tests. The National Fenestration Rating Council has developed standards for testing the optical properties of glazing (NFRC 301, NFRC 300).

In selecting plastic panels for glazing, possible deterioration from the sun, expansion and contraction because of temperature extremes, and possible damage from abrasion are concerns.

### CALCULATION OF SOLAR HEAT GAIN

As indicated in the section on Determining Fenestration Energy Flow, the solar energy flow through a fenestration may be divided into two parts, opaque and glazing portions,  $q_{op}$  and  $q_s$ , respectively, as given in Equation (5).

The glazing solar energy flux can be split into that due to incident beam radiation ( $b$ ) and that due to incident diffuse radiation ( $d$ ), which includes both diffuse sky radiation and radiation scattered (reflected) from the ground:

$$q_s = q_b + q_d \quad (92)$$

The net heat balance that would occur for a sunlit glazing if there were no diffuse radiation is shown in Figure 26. This net heat balance does not include any of the heat flows contained in  $Q_{th}$  in Equation (1) (i.e., those resulting from inside-outside temperature differences). The heat balance due to sunlight is pictured as an effect superimposed on the thermal effect, with, for example, glazing temperatures somewhat elevated over their value without the sunlight. This superposition picture cannot be carried too far, however, because the heat flows indicated in Figure 26 as resulting from convection and radiation depend in part on processes that are nonlinear with respect to temperature [e.g., Equation (25)], so that in reality the two effects cannot be separated. To calculate them, one would need the actual glazing (and other) temperatures, not simply the incremental temperature rise due to the sunlight.

One can see from Figure 26 that the glazing solar energy flow consists of two parts:

$$q_b = q_{bt} + q_{ba} \quad (93)$$

where

- $q_{bt}$  = glazing solar energy flux due to transmitted incident beam radiation
- $q_{ba}$  = glazing solar energy flux due to inward heat flow of absorbed beam radiation by convection and radiation

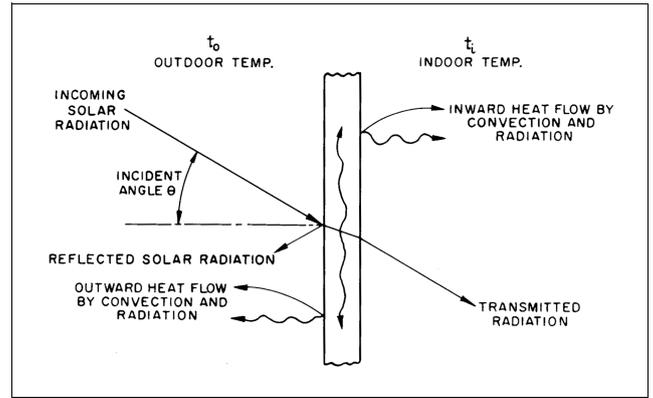

Fig. 26 Instantaneous Heat Balance for Sunlit Glazing Material

However, there is always also diffuse incident radiation, so that the glazing heat flux is in reality given by

$$q_s = q_t + q_a \quad (94)$$

where

- $q_t$  = glazing solar energy flux due to all transmitted incident solar radiation
- $q_a$  = glazing solar energy flux due to inward flow of absorbed incident solar radiation (by heat transfer processes)

It is convenient to separate the solar energy fluxes due to the two types of incident radiation for purposes of calculation. We can do this by making a definition analogous to Equation (93) for the diffuse solar heat flux:

$$q_d = q_{dt} + q_{da} \quad (95)$$

In order to calculate solar energy fluxes, one must first calculate the incident angle  $\theta$  from the local standard time and the longitude using Equations (10) and (13) through (17). The direct normal solar irradiance  $E_{DN}$  is then calculated from Equation (20), the diffuse sky irradiance  $E_d$  from Equation (22) or (23), and the ground-reflected radiation  $E_r$  from Equation (24). Note that the latter two are assumed to be ideally diffuse radiation. The total incident irradiance  $E_t$  may be calculated from Equation (12).

Because of the distinctions between beam and diffuse incident radiation, one must determine the overall solar heat gain coefficient  $SHGC_{op}$ , if desired, by first calculating  $Q_{sol}$  and then solving Equations (2) and (1).

### Opaque Fenestration Elements

The opaque portion solar energy flux is calculated from

$$q_{op} = (E_{DN}\cos\theta + E_d + E_r)SHGC_{op} \quad (96)$$

where  $SHGC_{op}$  is obtained from Equation (86).

### Glazing Systems

The following discussion of glazing system solar energy fluxes applies to unshaded glazings. For shaded glazings, see the section on Shading Devices and Fenestration Attachments.

The glazing solar energy flux due to incident beam radiation is calculated from

$$q_b = E_{DN}\cos\theta SHGC(\theta) \quad (97)$$

where the beam solar heat gain coefficient is given by Equation (79). If instead one desires the solar radiant and heat fluxes separately, one can calculate the glazing transmitted solar flux (which is solar radiation traveling in the incident direction) from

$$q_{bt} = E_{DN} \cos \theta T_{1,L}^f(\theta) \quad (98)$$

and the inward-flowing absorbed solar flux (which is heat) from

$$q_{ba} = E_{DN} \cos \theta \sum_{k=1}^L N_k \mathcal{A}_{k:(1,L)}^f(\theta) \quad (99)$$

Calculation of  $T_{1,L}^f(\theta)$  and  $\mathcal{A}_{k:(1,L)}^f(\theta)$  in these equations is described in the section on Optical Properties of Multiple-Layer Glazing Systems, and determination of  $N_k$  is discussed in the section on Calculation of Solar Heat Gain Coefficient.

The glazing solar energy flux due to diffuse incident radiation is calculated from

$$q_d = (E_d + E_r) \langle \text{SHGC} \rangle_D \quad (100)$$

where the hemispherically averaged solar heat gain coefficient is calculated from Equation (83). The solar radiant and heat fluxes can be separately calculated from

$$q_{dt} = (E_d + E_r) \langle T_{1,L}(\theta) \rangle_D \quad (101)$$

which is diffusely distributed solar radiation (note that effects of finite glazing size and thickness are neglected), and

$$q_{da} = (E_d + E_r) \sum_{n=1}^L N_n \langle \mathcal{A}_{n:1,L}^f \rangle_D \quad (102)$$

The hemispherically averaged optical properties are calculated using Equations (70) and (72).

**Example 14.** Calculate the solar energy flux through the glazing system of Example 10 under the conditions of Example 5 using (a) Table 13 and (b) the equations for optical properties.

**Solution:**

(a) The exact glazing system used in this example is not listed in Table 13 (as will frequently be the case in practice), so we must locate the glazing system that is closest in properties. The emissivity of the selective coating on surface 2 of the outer glazing is 0.05, and the transmission and reflectances for the insulating glass unit at normal incidence are  $T(0^\circ) = 0.331$ ,  $R^f(0^\circ) = 0.388$ , and  $R^b(0^\circ) = 0.396$ . The most similar unit is ID 25a, which has  $T(0^\circ) = 0.37$ ,  $R^f(0^\circ) = 0.35$ , and  $R^b(0^\circ) = 0.39$  (i.e., slightly lower front reflectance and therefore higher transmittance). Near the required angle of incidence, the table values listed for the solar heat gain coefficient are  $[\text{SHGC}(60^\circ)]_{25a} = 0.34$  and  $[\text{SHGC}(70^\circ)]_{25a} = 0.27$ , and from the diffuse column of the table we obtain  $[\langle \text{SHGC} \rangle_D]_{25a} = 0.36$ . Linear interpolation in angle yields the value  $[\text{SHGC}(63.2^\circ)]_{25a} = 0.34 + (0.27 - 0.34)/(70^\circ - 60^\circ) \times (63.2^\circ - 60^\circ) = 0.32$ . This value can then be approximately corrected for the (small) difference between the glazing of interest and ID 25a in Table 13 as follows. We first note that entry 25a has a transmittance that is 0.04 higher than the glazing in question and a front reflectance that is 0.04 lower. This means that the absorptance of the two glazings is the same to within the accuracy of Table 13. Referring to Equation (79), we see that with the absorptance held constant, a change in the transmittance of the glazing produces an additive correction to the SHGC that is equal to the difference in transmittance. Referring to Examples 11 and 12 where the transmittances for this case are calculated, we make the correction:

$$\begin{aligned} \text{SHGC}(63.2^\circ) &= [\text{SHGC}(63.2^\circ)]_{25a} \\ &+ \{T_{1,2}(0^\circ) - [T_{1,2}(0^\circ)]_{25a}\} \times \frac{T_{1,2}(63.2^\circ)}{T_{1,2}(0^\circ)} \\ &= 0.32 + (0.33 - 0.37) \times \frac{0.24}{0.33} = 0.32 - 0.3 = 0.29 \end{aligned}$$

and

$$\begin{aligned} \langle \text{SHGC} \rangle_D &= [\langle \text{SHGC} \rangle_D]_{25a} \\ &+ \{T_{1,2}(0^\circ) - [T_{1,2}(0^\circ)]_{25a}\} \times \frac{\langle T_{1,2} \rangle_D}{T_{1,2}(0^\circ)} \\ &= 0.36 + (0.33 - 0.37) \times \frac{0.25}{0.33} = 0.36 - 0.3 = 0.33 \end{aligned}$$

Note that these values are very close to those calculated below in part (b) of the solution. The solar energy flux is then calculated from Equations (92), (97), and (100), using the incident solar fluxes calculated in Example 7:

$$\begin{aligned} q_s &= q_t + q_a = E_{DN} \cos(63.2^\circ) \text{SHGC}(63.2^\circ) + (E_d + E_r) \langle \text{SHGC} \rangle_D \\ &= (388.0)(0.29) + (93.5 + 86.6)(0.33) = 172 \text{ W/(m}^2 \cdot \text{K)} \end{aligned}$$

(b) We use the previously calculated optical properties of the glazing to determine the SHGC. To do this we need the inward-flowing fractions  $N_1$  and  $N_2$  for the two glazing layers. The simplest way to obtain these is to do a heat transfer analysis of the glazing and determine the glazing temperatures under the appropriate conditions. We assume an exterior temperature  $t_o$  of 31.7°C, a wind speed of 3.4 m/s, and an indoor temperature  $t_i$  of 23.9°C. Using methods presented in the section on Determining Fenestration U-Factors, the heat transfer analysis yields a central glazing  $U$  of 1.22 W/(m<sup>2</sup>·K) and glazing layer temperatures of  $t_1 = 31.2^\circ\text{C}$  and  $t_2 = 25.3^\circ\text{C}$ . Since the temperature differences will be proportional to the thermal resistances (which are inversely proportional to the effective heat transfer coefficients),  $N_1 = (t_1 - t_o)/(t_i - t_o) = 0.064$  and  $N_2 = (t_2 - t_o)/(t_i - t_o) = 0.821$ . We can then calculate the solar heat gain coefficient for beam radiation incident at 63.2° (from Examples 5 and 6), using the results from Example 11, from Equation (79):

$$\begin{aligned} \text{SHGC}(63.2^\circ) &= T_{1,2}(63.2^\circ) + N_1 \mathcal{A}_{1:(1,2)}^f(63.2^\circ) + N_2 \mathcal{A}_{2:(1,2)}^f(63.2^\circ) \\ &= 0.244 + (0.064)(0.289) + (0.821)(0.022) = 0.281 \end{aligned}$$

and for diffuse radiation, using the results from Example 12, from Equation (84):

$$\begin{aligned} \langle \text{SHGC} \rangle_D &= \langle T_{1,2} \rangle_D + N_1 \langle \mathcal{A}_{1:(1,2)}^f \rangle_D + N_2 \langle \mathcal{A}_{2:(1,2)}^f \rangle_D \\ &= 0.277 + (0.064)(0.271) + (0.821)(0.036) = 0.324 \end{aligned}$$

The solar energy flux is then calculated from Equations (92), (97), and (100), using the incident solar fluxes calculated in Example 7:

$$\begin{aligned} q_s &= q_t + q_a = E_{DN} \cos(63.2^\circ) \text{SHGC}(63.2^\circ) + (E_d + E_r) \langle \text{SHGC} \rangle_D \\ &= (388.0)(0.281) + (93.5 + 86.6)(0.324) = 167.4 \text{ W/(m}^2 \cdot \text{K)} \end{aligned}$$

## SHADING DEVICES AND FENESTRATION ATTACHMENTS

Fenestrations with shading devices and attachments have a degree of optical and geometric complexity far greater than that of fenestrations with unshaded glazings. ASHRAE has sponsored the development of a method for determining the SHGC of glazing systems of arbitrary complexity. However, there are as yet insufficient data to make this method easy to use as a design tool. For the large number of shading systems for which there are no adequate data, it is still necessary to use the simplified solar heat gain coefficient data to estimate solar gain. In the following section, a detailed calculation method is described, and it should be used for those cases where the necessary data are available.

**Table 17 Measured Layer Inward-Flowing Fractions  $N_k$  for Typical Fenestration**

System	Bind Angle Below Horizontal	Inner Shading Layer	Inner Glass	Between-Pane Shading	Outer Glass	Exterior Shading Layer
Single glazing with interior shade		0.80 ± 0.08			0.08 ± 0.06	
Single glazing with interior venetian blind	-45°	0.69 ± 0.05			0.24 ± 0.09	
	30°	0.83 ± 0.08			0.21 ± 0.07	
	Closed	0.72 ± 0.07			0.14 ± 0.05	
Single glazing with exterior venetian blind	45°				0.46 ± 0.12	0.04 ± 0.01
Double glazing with interior shade		0.85 ± 0.10	0.52 ± 0.12		0.28 ± 0.06	
Double glazing with interior venetian blind	45°	0.86 ± 0.06	0.69 ± 0.14		0.21 ± 0.09	
Double glazing with between-pane blind	45°		0.69 ± 0.14	0.45 ± 0.06	0.34 ± 0.10	
	-45°		0.76 ± 0.10	0.40 ± 0.07	0.27 ± 0.14	
Low-e double glazing with between-pane blind	35°		0.46 ± 0.12	0.38 ± 0.05	0.32 ± 0.11	
Double glazing with exterior venetian blind	45°		0.73 ± 0.13		0.28 ± 0.12	0.03 ± 0.02

### Generalized Calculation Procedure for Shading Devices and Fenestration Attachments

A complex fenestration system is one that contains one or more nonspecular optical elements in the glazed area of the window. A **nonspecular optical element** is one for which light (or short-wave infrared radiation) incident on the element from a single spatial direction does not emerge traveling in a single transmitted direction and/or a single reflected direction. Examples of nonspecular elements are shades, drapes, blinds, honeycombs, figured glass, ground glass, and other diffusers, lenses, prisms, and holographic glazings.

These systems may have a more complicated angle dependence than do the specular glazings discussed previously. The optical properties and solar heat gain coefficient may now depend on both angles defining the incident direction rather than simply on the angle  $\theta$  between the incident direction and the surface normal. In addition, radiation incident from a given direction is not necessarily reflected or transmitted in a unique direction but may be distributed over a variety of directions. One must therefore introduce the concept of the **directional-hemispherical** transmittance (reflectance) [i.e., the fraction of radiation incident from a given direction that is transmitted (reflected) into the complete outgoing hemisphere].

With these extensions, the equation for the solar heat gain coefficient of a system with  $L$  layers becomes

$$\text{SHGC}(\theta, \phi) = T_{1,L}^{fH}(\theta, \phi) + \sum_{k=1}^L N_k \mathcal{A}_{k:(1,L)}^f(\theta, \phi) \quad (103)$$

where

- $\theta$  = incident angle relative to normal layer
- $\phi$  = azimuthal angle (in plane of layer, about normal)
- $T_{1,L}^{fH}(\theta, \phi)$  = directional-hemispherical front transmittance of system
- $\mathcal{A}_{i:(1,L)}^f(\theta, \phi)$  = directional absorptance of  $i$ th layer in system
- $N_k$  = inward-flowing fraction of absorbed energy for  $i$ th layer in system

The usual approach to complex fenestration solar heat gain has been either direct measurement or calculation of  $\text{SHGC}(\theta, \phi)$  at some specified incident direction, usually either normal incidence or  $\theta = 30^\circ$ ,  $\phi = 0^\circ$ . Such values, with SHGC re-expressed as shading coefficient, are given for a variety of systems in Tables 18 through 20 and 22. Although in the past it has been assumed that the result would be the same for all incident directions, this is not generally a true assumption, and users of these tables should be aware that they apply only to incident directions of  $30^\circ$  or less and may not include important azimuthal angle dependence. While the values in these tables may give an approximate "first guess" in the absence of better information, for accurate and reliable data, one should rely on a measurement or calculation for the incident directions of interest

unless there is independent reason for believing that incident angle or azimuthal dependencies are unimportant.

### Solar-Thermal Separation

It is possible to use Equation (103) to calculate the solar heat gain coefficient for a system from separate determinations of the system transmittance  $T_{1,L}^{fH}(\theta, \phi)$ , the layer absorptances  $\mathcal{A}_{k:(1,L)}^f(\theta, \phi)$ , and the inward-flowing fractions  $N_k$ . This has been termed **solar-thermal separation**, since the processes determining the  $N_k$  are thermal in nature, while those determining  $T_{1,L}^{fH}(\theta, \phi)$  and  $\mathcal{A}_{k:(1,L)}^f(\theta, \phi)$  are solar-optical. Table 17 gives calorimetrically determined values of  $N_k$  for a number of generic glazing/shading systems (Klems and Kelley 1996). These are independent of the solar-optical properties of the particular system.

The transmittances and layer absorptances in Equation (103) may be determined by a variety of different methods, ranging from calculation to overall system measurement. The computation procedure has advantages, for example, when one wishes to compare the performance of differing glazings or shading system colors in the same general configuration. Optical data are sometimes more readily available or more economically obtained than overall calorimetric measurements of SHGC. For example,  $T_{1,L}^{fH}(\theta, \phi)$  is rather simply measurable by an optical technique using an integrating sphere. The layer absorptances  $\mathcal{A}_{k:(1,L)}^f(\theta, \phi)$  present a more difficult problem of determination, since the data easily available are likely to be the directional absorptance of an **isolated** layer,  $a_k^f(\theta, \phi)$ , whereas  $\mathcal{A}_{k:(1,L)}^f(\theta, \phi)$  is the **in-system** layer absorptance (i.e., it includes the contributions of absorbed radiation multiply reflected back to the  $i$ th layer from all the other layers in the system). Isolated layer absorptances  $a_k^f(\theta, \phi)$  must be corrected for this effect.

### Calculating System Transmittance and Absorptances from Layer Properties

The key feature of nonspecular elements is that they produce distributions of outgoing radiation (in the solar-optical spectral region) in the transmitted and/or reflected hemisphere, even for incident radiation from a single direction. This means that they are characterized by bidirectional transmittance (BTDF) and reflectance (BRDF) distribution functions that give the outgoing radiance (energy flux per unit area per unit solid angle) as a fraction of the incident irradiance (energy flux per unit area):

$$\begin{aligned} I(\theta_o, \phi_o; \theta_i, \phi_i) &= \tau(\theta_o, \phi_o; \theta_i, \phi_i)E \\ J(\theta_o, \phi_o; \theta_i, \phi_i) &= \rho(\theta_o, \phi_o; \theta_i, \phi_i)E \end{aligned} \quad (104)$$

where

- $\theta_o, \phi_o$  = angles specifying outgoing direction
- $\theta_i, \phi_i$  = angles specifying incident direction

$E$  = incident irradiance  
 $I, J$  = transmitted, reflected radiance

In a real nonspecular element, these quantities are also functions of the location in space at which the radiation is incident on the fenestration, as can be seen by visualizing a venetian blind. However, this level of detail is only useful if one wishes to find the detailed spatial images of the outgoing radiation patterns. For determining the solar heat gain, it is sufficient to consider the process as spatially averaged over the nonspecular device so that it can be considered as a thin uniform layer with only angular dependence (Klems 1994a). By dividing the (transmission or reflection) hemisphere into a grid of solid angle sections, the bidirectional property functions can be approximated as matrices (Klems 1994b).

There are many standard commercial computer programs executable on personal computers that can perform the matrix calculations, including many popular spreadsheet programs. Use of this bi-angular grid to characterize a nonspecular layer with azimuthal dependence requires handling matrices that are  $145 \times 145$  elements, and for this level of complexity a special-purpose computer program for handling the large amount of data involved is probably desirable.

Figure 27 shows the results of such a calculation for an interior buff-colored blind (slat reflectance 62%) in combination with sealed double glazing (3 mm glass panes). The calculation used bidirectional transmittance and reflectance measurements averaged over a 200 mm square section of the blind, with 25 mm slats. These measurements were used to construct layer property matrices with the clear glazing properties taken from published literature (Rubin 1985). The SHGC was calculated using Equation (103), solar-optical transmittances and absorptances calculated by the matrix method of Klems (1994b), and inward-flowing fractions from Table 17 (Klems and Kelley 1996, Klems and Warner 1995).

### Simplified Calculation Procedure

The detailed methodology has been shown to agree with measurement (Klems et al. 1996) and should be used whenever accurate calculations are necessary and the data needed are available. Once the necessary data are available for a shading layer, Klems and Warner (1997) have shown how to calculate the performance for

any combination of that shading layer and unshaded glazings. However, the data necessary to use this exact calculation method are not readily available for many shading systems and are difficult to obtain by measurement for some (e.g., venetian blinds). It will therefore be necessary to use a simpler and less accurate method for most design purposes.

Two simplified approaches are described below. For some simple glazing systems (single glazing and clear double glazing) at solar incident angles below  $30^\circ$ , measurements of the solar heat gain coefficient exist for a number of shading configurations. These are presented in tables, and the first approach, described in the sections on Exterior Shading and Indoor and Between Glass Shading Devices on Simple Fenestrations, may be used. For situations not covered by these tables, the second approach, consisting of the following simplifying approximation together with the section on Completely Shaded Glazings, should be used.

First, one must determine the fraction (if any) of the incident radiation that passes through the fenestration essentially without encountering the shading element. This is termed the **unshaded fraction**  $F_u$ . For example, an overhang might shadow only part of a fenestration, a venetian blind or louver might under some conditions permit radiation to pass through it without encountering any of the slats, and for a drapery of open weave, some radiation passes through the gaps between threads and is effectively specularly transmitted (as opposed to radiation that is diffusely scattered by the threads). For this fraction of the incident radiation, the fenestration is essentially an unshaded one. The unshaded fraction is determined from geometric considerations, either those described below for exterior shading or those described for draperies. Once the unshaded fraction has been determined, the glazed area  $A_G$  is divided into two equivalent glazings, an unshaded one of area  $F_u A_G$  and a completely shaded one of area  $(1 - F_u)A_G$ . Heat gain through the unshaded equivalent glazing is calculated using the methods given in the section on Calculation of Solar Heat Gain, in the subsection on Glazing Systems, for unshaded glazings. Heat gain through the completely shaded equivalent glazing is calculated by the methods given in the section on Completely Shaded Glazings, which assume that the shading layer is a uniform diffuse reflector or transmitter. A **uniform diffuse reflector** or **transmitter** is one for which a given incident irradiance produces an outgoing reflected or transmitted radiance that is the same in all directions and is independent of the incident direction.

### EXTERIOR SHADING

The most effective way to reduce the solar load on fenestration is to intercept direct radiation from the sun before it reaches the glass. Fenestration products fully shaded from the outside reduce solar heat gain as much as 80%. In one way or another, fenestration can be shaded by roof overhangs, vertical and horizontal architectural projections, awnings, heavily proportioned exterior louvers, insect or shading screens, patterned screens having a weave designed for sunlight interception, sun screens of narrow fixed louvers, or a variety of vegetative shades including trees, hedges, and trellis vines. In all exterior shading structures, the air must move freely to carry away heat absorbed by the shading and glazing materials. See manufacturers' instructions regarding proper installation for achieving the expected performance by providing suitable free convection ventilation between the shading and glazing. Also, consider the geometry of the structures relative to changing sun position to determine the times and quantities of direct sunlight penetration. Detailed discussions of the effectiveness of various outside shading devices are given in Pennington (1968), Yellott (1972), and Ewing and Yellott (1976).

The general effect of exterior shading is to attenuate the solar radiation. Some of the beam radiation may pass through or around the shading, and this is accounted for by the unshaded fraction  $F_u$

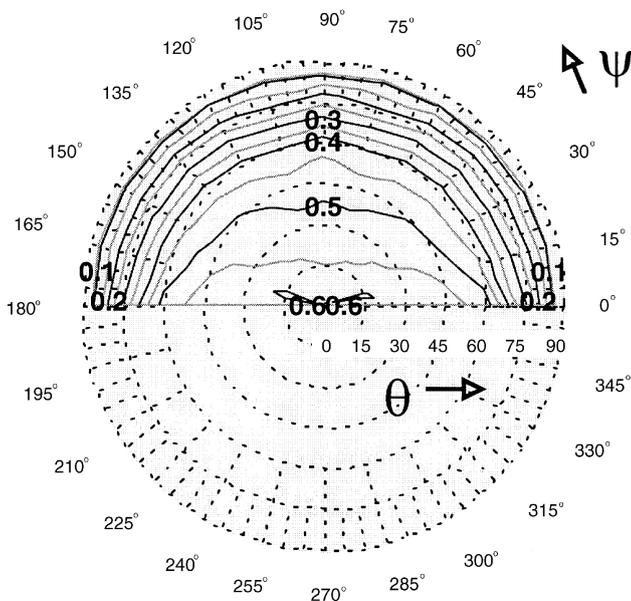

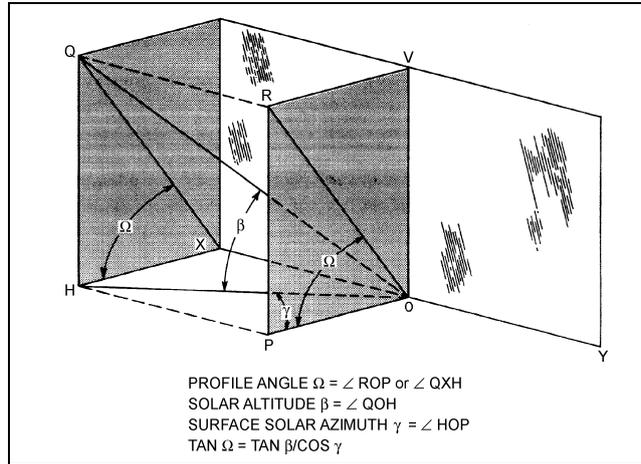

Fig. 27 Contour Plot of Beam SHGC for Double Glazed Window with Interior Venetian Blind with Slats Tilted at  $45^\circ$

**Table 18 Unshaded Fractions ( $F_u$ ) and Exterior Solar Attenuation Coefficients (EAC) for Louvered Sun Screens**

Profile Angle	Group 1			Group 2			Group 3			Group 4		
	Transmittance	$F_u$	EAC	Transmittance	$F_u$	EAC	Transmittance	$F_u$	EAC	Transmittance	$F_u$	EAC
10°	0.23	0.20	0.15	0.25	0.13	0.02	0.4	0.33	0.18	0.48	0.29	0.3
20°	0.06	0.02	0.15	0.14	0.03	0.02	0.32	0.24	0.18	0.39	0.2	0.3
30°	0.04	0.00	0.15	0.12	0.01	0.02	0.21	0.13	0.18	0.28	0.08	0.3
≥ 40°	0.04	0.00	0.15	0.11	0.00	0.02	0.07	0.00	0.18	0.2	0.00	0.3

Group 1: Black, width over spacing ratio 1.15/1; 1.1 mm between louvers. Group 2: Light color; high reflectance, otherwise same as Group 1. Group 3: Black or dark color; w/s ratio 0.85/1; 1.5 mm between louvers. Group 4: Light color or unpainted aluminum; high reflectance; otherwise same as Group 3. U-factor = 4.83 W/(m<sup>2</sup>·K) for all groups when used with single glazing.

**Fig. 28 Profile Angle for South-Facing Slat-Type Sunshades**

defined above. Some fraction of the remainder of the solar radiation will be transmitted by the shading system and will be incident on the glazing, but in the form of diffuse radiation. The actual angular distribution of this radiation may be quite complex, but for simplicity it is treated here as uniformly diffuse radiation, and it is considered to compose a fraction EAC, the exterior solar attenuation coefficient, of the total incident radiation interacting with the exterior shading system. The solar energy flux through the glazing with exterior shading is then given by

$$q = F_u E_{DN} \cos \theta \text{SHGC}(\theta) + [(1 - F_u) E_{DN} \cos \theta + E_d + E_r] \text{EAC} \langle \text{SHGC} \rangle_D \quad (105)$$

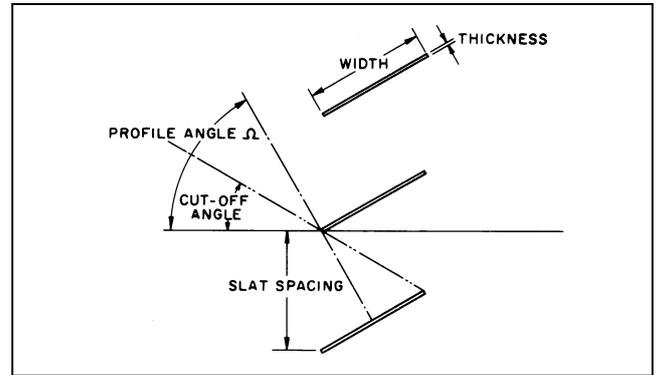

The quantities SHGC( $\theta$ ) and  $\langle \text{SHGC} \rangle_D$  in Equation (105) are the beam and diffuse solar heat gain coefficients of the unshaded glazing system. The second of the two terms on the right-hand side of the equation is the flux through the *completely shaded* glazing and is discussed in more detail in Equation (114) and the associated text, which makes clear the physical basis of the EAC.

**Louvers and Sunshades**

The ability of horizontal panels or louvers to intercept the direct component of solar radiation depends on their geometry and the profile or shadow-line angle  $\Omega$  (Figure 28), defined as the angular difference between a horizontal plane and a plane tilted about a horizontal axis in the plane of the fenestration until it includes the sun. The profile angle can be calculated by

$$\tan \Omega = \tan \beta / \cos \gamma \quad (106)$$

For slat-type sunshades, the transmitted solar radiation consists of straight-through and transmitted-through components. When the profile angle  $\Omega$  is above the cutoff angle (see Figure 29), straight-through transmission of direct radiation is completely eliminated,

**Fig. 29 Geometry of Slat-Type Sunshades**

but the transmitted diffuse and the reflected-through components remain. Their magnitude depends largely on the reflectance of the sunshade surfaces and of exterior objects.

Narrow horizontal louvers, fabricated in conventional width-to-spacing ratios and framed as window screens, retain their shading characteristics, while gaining in effective transparency (view) by eliminating the coarse striation pattern of wide louvers. Table 18 gives values of  $F_u$  and EAC for several types of louvered sun screens. Commercially available sun screens completely exclude direct solar radiation when the profile angle exceeds approximately 26° (Groups 1 and 2) or 40° (Groups 3 and 4). Group designations are defined in the footnote to Table 18.

**Roof Overhangs: Horizontal and Vertical Projections**

In the northern hemisphere, horizontal projections can considerably reduce solar heat gain on south, southeast, and southwest exposures during late spring, summer, and early fall. On east and west exposures during the entire year, and on south exposures in winter, the solar altitude is generally so low that to be effective, horizontal projections must be excessively long.

The shadow width  $S_W$  and shadow height  $S_H$  (Figure 30) produced by the vertical and horizontal projections ( $P_V$  and  $P_H$ ), respectively, can be calculated using the surface solar azimuth  $\gamma$  and the horizontal profile angle  $\Omega$  determined by Equation (106).

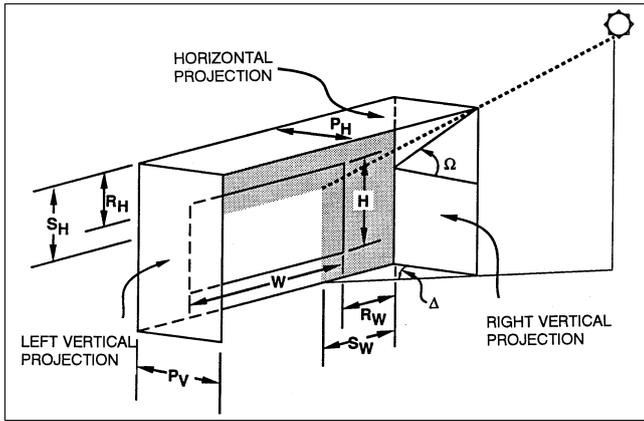

$$S_W = P_V | \tan \gamma | \quad (107)$$

$$S_H = P_H \tan \Omega \quad (108)$$

*Note:* When the surface solar azimuth  $\gamma$  is greater than 90° and less than 270°, the fenestration product is completely in the shade; thus,  $S_w = W + R_w$  and  $A_{SL} = 0$ .

The sunlit  $A_{SL}$  and shaded  $A_{SH}$  areas of the fenestration product are variable during the day and can be calculated for each moment using the following relations (see Figure 30):

$$A_{SL} = [W - (S_W - R_W)][H - (S_H - R_H)] \quad (109)$$

**Fig. 30 Vertical and Horizontal Projections and Related Profile Angles for Vertical Surface Containing Fenestration**

$$A_{SH} = A - A_{SL} \quad (110)$$

where  $A$  is total fenestration product area. McCluney (1990) described an algorithm for computer use to calculate the unshaded fraction of a window equipped with overhangs, awnings, or side fins.

**Example 15.** A window in the southwest wall of a building at 40°N latitude is 870 mm wide and 1480 mm high. The depth of the horizontal and vertical projections is 150 mm, and they are located 75 mm beyond the edges of the window.

(a) Find the sunlit and shaded area of the window at 3:00 P.M. on July 21.

(b) Find the depth of the projections necessary to fully shade the window just described.

**Solution:**

(a) The wall azimuth  $\psi$  for a southwest wall is +45° (Table 9). The solar azimuth  $\phi$  can be calculated using Equation (15). At 3:00 P.M.,  $H = 0.25 \times 180 = 45^\circ$ ; from Table 7, for July 21,  $\delta = 20.6^\circ$ .

Find the solar altitude  $\beta$  using Equation (14):

$$\sin \beta = \cos(40)\cos(20.6)\cos(45) + \sin(40)\sin(20.6)$$

$$\beta = 47.2^\circ$$

Find the solar azimuth  $\phi$  using Equation (15):

$$\cos \phi = [\sin(47.2)\sin(40) - \sin(20.6)]/[\cos(47.2)\cos(40)]$$

$$\phi = 76.7^\circ$$

Thus, from Equation (16),  $\gamma = 76.7 - 45 = 31.7^\circ$ .

Using Equation (107), the width of the vertical projection shadow is

$$S_W = 150 |\tan(31.7)| = 93 \text{ mm}$$

Using Equation (106), the profile angle for the horizontal projection is

$$\tan \Omega = \tan(47.2)/\cos(31.7)$$

$$\Omega = 51.8^\circ$$

Using Equation (108), the height of the horizontal projection shadow is

$$S_H = 150 \tan(51.8) = 191 \text{ mm}$$

Using Equations (109) and (110), the sunlit and shaded area of the window are now

$$A_{SL} = [870 - (93 - 75)] [1480 - (191 - 75)]/10^6 = 1.162 \text{ m}^2$$

$$A_{SH} = (870 \times 1480)/10^6 - 1.162 = 0.128 \text{ m}^2$$

(b) The shadow length necessary to fully shade the given window  $S_{H(fs)}$  and  $S_{W(fs)}$  from the horizontal and vertical projection are given by (see Figure 30)

$$S_{H(fs)} = 1480 + 75 = 1555 \text{ mm}$$

$$S_{W(fs)} = 850 + 75 = 945 \text{ mm}$$

Thus, using Equations (107) and (108),

$$P_{V(fs)} = 1555 \phi \cot(31.7) = 1224 \text{ mm}$$

$$P_{H(fs)} = 945 |\cot(51.8)| = 1530 \text{ mm}$$

For this example, because both horizontal and vertical projections do not need to fully shade the window, a horizontal projection of 1224 mm is satisfactory. Also, to accurately analyze the influence of external projections, an hour-by-hour calculation must be performed over the periods of the year for which shadowing is desired.

**Example 16.** Suppose that the glazing of Examples 10 and 14 has a black exterior louver shade with a width-to-spacing ratio of 1.15/1. Find the solar energy flux through the system if it is on a west-facing orientation under the conditions of Example 5.

**Solution:** In Example 5, the solar altitude was found to be  $\beta = 60.76^\circ$  and the solar azimuth was found to be  $\phi = 67.4^\circ$ . The incident angle was found in Example 6 to be  $\theta = 63.2^\circ$ . Referring to Table 9, we see that  $\psi = 90^\circ$  for a west-facing window, and so  $\gamma = \phi - \psi = 67.4^\circ - 90^\circ = -22.6^\circ$ . We can discard the sign of  $\gamma$  as irrelevant to the calculation of profile angle, since it merely determines whether the sun lies to the south or the north of the normal to the glazing. From Equation (106), we find that the profile angle is  $\Omega = \arctan(\tan\beta/\tan\gamma) = \arctan[\tan(60.76^\circ)/\tan(22.6^\circ)] = 76.9^\circ$ .

From the footnote to Table 18, we see that the louver system corresponds to Group 1, and from the table, we see that for profile angles greater than or equal to 40° we should use  $F_u = 0$  and  $EAC = 0.15$ . In Example 14, the (unshaded) glazing system was determined to have  $SHGC(63.2^\circ) = 0.29$  and  $\langle SHGC \rangle_D = 0.33$ , respectively, using Table 13. In Example 7, the incident solar fluxes for these conditions were calculated to be  $E_{DN}\cos(\theta) = 388 \text{ W/m}^2$ ,  $E_d = 93.5 \text{ W/m}^2$ , and  $E_r = 86.6 \text{ W/m}^2$ . Using Equation (105), we calculate

$$q = (0)(388)(0.29) + [(1 - 0)(388) + 93.5 + 86.6](0.15)(0.33) = 28 \text{ W/m}^2$$

**Equations for Computer Calculations of External Shadowing of Inclined Surfaces**

Incident angle:  $\theta = \cos^{-1}(\cos \beta \cos \gamma \sin \Sigma + \sin \beta \cos \Sigma)$

Vertical surface:  $\theta_V = \cos^{-1}(\cos \beta \cos \gamma)$

Horizontal surface:  $\theta_H = \cos^{-1}(\sin \beta)$

Vertical projection profile angle:

$$\Delta = \tan^{-1}\left(\frac{\sin \gamma \cos \beta}{\cos \theta}\right); |\theta| < 90^\circ$$

For  $\theta > 90^\circ$   $A_{SL} = 0$  and  $A_{SH} = A$

Vertical surface:  $\Delta_V = \tan^{-1}(\gamma)$  for  $90^\circ > |\gamma| > 270^\circ$

Horizontal surface:  $\Delta_H = \tan^{-1}\left(\frac{\sin \gamma}{\tan \beta}\right)$  for all  $\gamma$

Horizontal projection profile:

$$\text{Angle: } \Omega = \tan^{-1} \left( \frac{\sin \beta \sin \Sigma - \cos \beta \cos \gamma \cos \Sigma}{\cos \theta} \right) \text{ for } |\theta| < 90^\circ$$

$$\text{Vertical surface: } \Omega_V = \tan^{-1} \left( \frac{\tan \beta}{\cos \gamma} \right) \text{ for } 90^\circ > |\gamma| > 270^\circ$$

$$\text{Horizontal surface: } \Omega_H = \tan^{-1} \left( \frac{\cos \gamma}{\tan \beta} \right) \text{ for } 90^\circ < |\gamma| < 270^\circ$$

$$\text{Length of shadow from vertical projection: } S_W = P_V | \tan \Delta |$$

$$\text{Length of shadow from horizontal projection: } S_H = P_H | \tan \Omega |$$

Sunlit and shaded areas of the fenestration product are determined using Equations (109) and (110).

where

$\phi$  = solar azimuth

$\beta$  = solar altitude

$\gamma$  = surface solar azimuth

$\Sigma$  = surface tilt angle

$P_V$  = vertical projection depth

$P_H$  = horizontal projection depth

$W$  = fenestration product width

$H$  = fenestration product height

$R_W$  = width of opaque surface between fenestration product and vertical projection

$R_H$  = height of opaque surface between fenestration product and horizontal projection

$A$  = total projected area of the fenestration product

$\theta$  = angle of incidence

$\Omega$  = horizontal projection profile angle

$\Delta$  = vertical projection profile angle

## INDOOR AND BETWEEN-GLASS SHADING DEVICES ON SIMPLE FENESTRATIONS

### Venetian Blinds and Roller Shades

Most fenestration has some type of internal shading to provide privacy and aesthetic effects, as well as to give varying degrees of sunshine control (Ozisk and Schutrum 1960). This section provides a method of calculating the approximate SHGC for such fenestrations for a selection of simple and somewhat common shading elements and glazing systems. The information presented here is based on measurements that predate many modern developments in fenestration systems. For this reason, desired systems may not be represented in the tables, or it may be difficult to determine whether the desired conditions match those of the table. If information is not available in this section or greater accuracy or detail is desired, the reader should refer to the subsequent section on Completely Shaded Glazings, where calculation formulas are presented. However, the present state of data availability on shading devices does not permit great accuracy in the calculation of heat flow through shaded fenestrations. The user should proceed with caution.

As discussed in the text and equations associated with Equation (129), the details of solar transmission through a glazing with interior shading are quite complex. However, if one is interested only in the approximate total heat flux through the fenestration, rather than in the detailed separation into transmitted and absorbed (and thermally retransmitted) fluxes and the distribution of the absorbed energy among the fenestration layers, it will frequently be the case that measurements made on a fenestration under one set of conditions can be extrapolated to other fenestrations and conditions to give an adequate answer. In this case, the heat flux is represented by

$$q = [E_{DN} \cos \theta \text{SHGC}(\theta) + (E_d + E_r) \langle \text{SHGC} \rangle_D] \text{IAC} \quad (111)$$

where the quantity in the brackets represents the heat flow through the unshaded glazing system [compare Equations (97) and (100)] and the constant interior solar attenuation coefficient IAC represents the fraction of that heat flow that enters the room, some energy having been excluded by the shading. The solar heat gain coefficients in Equation (111) may be obtained from Table 13 or calculated by Equations (79) and (84) for unshaded glazing. Table 19 gives values of IAC (derived from measurements) for a variety of glazing and shading combinations.

It will be noticed that the IAC bears a certain similarity to the shading coefficient. There is, however, an important difference: we must calculate the solar heat flux through the unshaded glazing at the appropriate angle before applying the IAC. With the shading coefficient, only the angular dependence of single glazing was included (through the now-discarded SHGF). The effectiveness of any internal shading device depends on its ability to reflect incoming solar radiation back through the fenestration before it can be absorbed and converted into heat within the building. Table 21 lists approximate values of solar-optical properties for the typical indoor shading devices described in Tables 19 and 20.

For shading between the panes of a double-glazing system, an equation similar to Equation (111) can be used, but in this case one defines the unshaded glazing system to be the portion of the glazing that is exterior to the shading and defines a new coefficient, the between-pane solar attenuation coefficient (BAC), to describe the effect of the shading system together with the portion of the glazing that is interior to it:

$$q = [E_{DN} \cos \theta \text{SHGC}(\theta) + (E_d + E_r) \langle \text{SHGC} \rangle_D]_{ext} \text{BAC} \quad (112)$$

Values of BAC for those systems for which measurements are available are given in Table 20. For other systems, one should use the detailed equations of the section on Completely Shaded Glazings.

**Example 17.** Find the approximate SHGC and solar heat flux for a heat-absorbing double glazing with a light-colored interior venetian blind under the conditions of Example 5. The heat-absorbing double glazing has a visible transmittance of 0.41.

**Solution:** Referring to Table 19, we see that an interior, light venetian blind, heat-absorbing double glazing has an IAC value of 0.66. For the conditions of Example 5, the incident angle was found in Example 6 to be  $\theta = 63.2^\circ$ , and in Example 7 the incident solar fluxes for these conditions were calculated to be  $E_{DN} \cos \theta = 388 \text{ W/m}^2$ ,  $E_d = 93.5 \text{ W/m}^2$ , and  $E_r = 86.6 \text{ W/m}^2$ . Referring to Table 13, we see that the closest glazing system corresponds to ID 5h, 6 mm gray glass exterior, clear interior, which has  $\text{SHGC}(60^\circ) = 0.37$ ,  $\text{SHGC}(70^\circ) = 0.29$ , and  $\langle \text{SHGC} \rangle_D = 0.39$ . Interpolating in incident angle between the two table values gives  $\text{SHGC}(63.2^\circ) = 0.34$ . Using Equation (111), we find the solar heat flux  $q = [388 \times 0.34 + (93.5 + 86.6) \times 0.39] 0.66 = 133 \text{ W/m}^2$ .

There is some ambiguity about the meaning of the SHGC in this case. One could pick out the terms in Equation (111) corresponding to either the effective beam or diffuse SHGC for the overall system, but, given the fact that the IAC values in Table 19 were measured in outdoor calorimeters so that the incident radiation consisted of both beam and diffuse radiation, it is most reasonable to calculate an effective SHGC for these conditions by dividing the estimated solar heat flux by the total incident intensity:

$$\text{SHGC}_{eff} = \frac{133}{388 + 93.5 + 86.6} = 0.23$$

**Example 18.** Estimate the solar heat flux for the glazing and conditions of Example 17, but assume that the venetian blind is between the glazing panes.

**Solution:** Referring to Table 20, we see that a light venetian blind between the panes of a heat-absorbing double-glazing system has a BAC value of 0.28. We use this value in Equation (112), but in contrast to Example 17, we need the SHGC values of the exterior glazing layer rather than the full glazing system. In Example 17, we used ID 5h,

**Table 19 Interior Solar Attenuation Coefficients (IAC) for Single or Double Glazings Shaded by Interior Venetian Blinds or Roller Shades**

Glazing System <sup>a</sup>	Nominal Thickness <sup>b</sup> Each Pane, mm	Glazing Solar Transmittance <sup>b</sup>		Glazing SHGC	IAC				
		Outer Pane	Single or Inner Pane		Venetian Blinds		Roller Shades

<sup>a</sup> Systems listed in the same table block have the same IAC.

<sup>b</sup> Values or ranges given for identification of appropriate IAC value; where paired, solar transmittances and thicknesses correspond. SHGC is for unshaded glazing at normal incidence.

<sup>c</sup> Typical thickness for residential glass.

<sup>d</sup> From measurements by Van Dyke and Konen (1982) for 45° open venetian blinds, 35° solar incidence, and 35° profile angle.

<sup>e</sup> Use these values only when operation is automated for exclusion of beam solar (as opposed to day-light maximization). Also applies to tightly closed horizontal blinds.

<sup>f</sup> Refers to gray, bronze and green tinted heat-absorbing glass (on exterior pane in double glazing)

<sup>g</sup> Applies either to factory-fabricated insulating glazing units or to prime windows plus storm windows.

<sup>h</sup> The listed approximate IAC value may be higher or lower by this amount, due to glazing/shading interactions and variations in the shading properties (e.g., manufacturing tolerances).

**Table 20 Between-Glass Solar Attenuation Coefficients (BAC) for Double Glazing with Between-Glass Shading**

Type of Glass	Nominal Thickness, Each Pane	Solar Transmittance <sup>a</sup>		Description of Air Space	Type of Shading		
		Outer Pane	Inner Pane		Venetian Blinds		Louvered Sun Screen
					Light	Medium	
Clear out, Clear in	2.4, 3 mm	0.87	0.87	Shade in contact with glass or shade separated from glass by air space.	0.33	0.36	0.43
Clear out, Clear in	6 mm	0.80	0.80	Shade in contact with glass-voids filled with plastic.	—	—	0.49
Heat-absorbing <sup>b</sup> out, Clear in				Shade in contact with glass or shade separated from glass by air space.	0.28	0.30	0.37
	6 mm	0.46	0.80	Shade in contact with glass-voids filled with plastic.	—	—	0.41

<sup>a</sup> Refer to manufacturers' literature for exact values.

<sup>b</sup> Refers to gray, bronze and green tinted heat-absorbing glass.

**Table 21 Properties of Representative Indoor Shading Devices Shown in Tables 19 and 20**

Indoor Shade	Solar-Optical Properties (Normal Incidence)		
	Transmittance	Reflectance	Absorptance
Venetian blinds <sup>a</sup> (ratio of slat width to slat spacing 1.2, slat angle 45°)			
Light colored slat	0.05	0.55	0.40
Medium colored slat	0.05	0.35	0.60
Vertical blinds			
White louvers	0.00	0.77	0.23
Roller shades			
Light shades (translucent)	0.25	0.60	0.15
White shade (opaque)	0.00	0.65	0.35
Dark colored shade (opaque)	0.00	0.20	0.80

<sup>a</sup> Values in this table and Tables 19 and 20 are based on horizontal venetian blinds. However, tests show that these values can be used for vertical blinds with good accuracy.

which Table 13 shows had an exterior glazing that is 6 mm gray glass. We find that ID 1h is the entry for clear 6 mm gray glass, for which  $SHGC(60^\circ) = 0.51$ ,  $SHGC(70^\circ) = 0.44$ , and  $\langle SHGC \rangle_D = 0.52$ . Interpolating the beam SHGC values in incident angle gives  $SHGC(63.2^\circ) = 0.49$ . We then use Equation (112) to calculate

$$q = [388 \times 0.49 + (93.5 + 86.6) \times 0.52]0.41 = 116 \text{ W/m}^2$$

This indicates that having the blind between the glazings yields slightly better solar heat gain rejection than an interior placement.

**Draperies**

Draperies reduce heating and cooling loads, depending on the type and the use by the occupant. Rudoy and Duran (1975) found annual reductions between 5 and 20%. An approximate model for determining the SHGC of free-standing vertical interior shades was developed by McCluney and Mills (1993). Solar heat gain may be estimated by using Equation (111) and the IAC values listed in Table 22.

The solar optical properties of drapery fabrics can be determined accurately by laboratory tests (Yellott 1963), and manufacturers can usually supply solar transmittance and reflectance values for their products. In addition to these properties, the **open-ness factor** (ratio of the open area between the fibers to the total area of the fabric) is a useful property that can be measured exactly (Keyes 1967, Pennington and Moore 1967). It can also be estimated by inspection, since the human eye can readily distinguish between tightly woven fabrics that permit little direct radiation to pass between the fibers and loosely woven fabrics that allow the sun's rays to pass freely.

Drapery fabrics can be classified in terms of their solar-optical properties as having specific values of fabric transmittance and reflectance. Fabric reflectance is the major factor in determining the ability of a fabric to reduce solar heat gain. Based on their appearance, draperies can also be classified by yarn color as dark, medium, and light and by weave as closed, semiopen, and open.

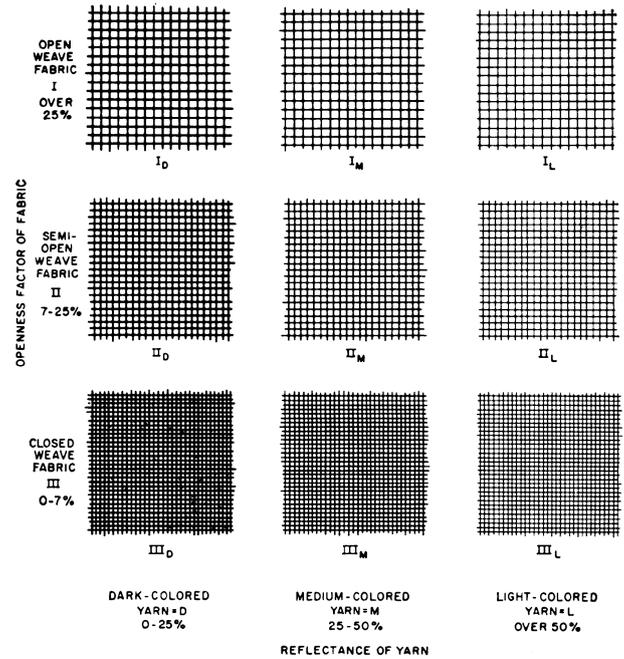

The apparent color of a fabric is determined by the reflectance of the yarn itself. The figure in Table 22 shows yarn reflectance. Figure 31 classifies drapery fabrics into nine types, rated by openness and yarn reflectances.

Figure 31 guides in the use of Table 22 for a fabric-glass combination when the solar-optical properties are unknown. Whenever possible, fabric reflectance and transmittance values should be obtained from the manufacturer, which permits more accurate solar heat flux estimates to be made. Visual estimations of openness and yarn reflectance, interpreted through Table 22, are valuable in judging the effectiveness of drapes for (1) protection from excessive radiant energy from either sunlight or sun-heated glass, (2) brightness control, (3) providing either outward view or privacy, and (4) sound control.

Table 22 applies to glass and a single drape hung with 100% fullness (drapery width is twice the width of the draped area). If the drapery is hung flat, like a fenestration product shade, a different IAC applies; with a low transmittance and high reflectance, the IAC is appreciably lower. As an extreme example, a flat opaque drapery having an aluminized or similar coating with reflectance of 0.80, in combination with 6 mm clear glass, has an SHGC of 0.18, compared with 0.32 for this material in draped form. Pennington and Moore (1967) explain the effect of folding drapery materials to provide 100% fullness and describe a method for calculating SHGC when materials are used flat.

**Example 19.** A drape with 100% fullness, having a fabric transmittance of 0.20 and a fabric reflectance of 0.40, is used with 6 mm glass. What IAC should be used?

**Solution:** Locating the point on the ideogram in Table 22 corresponding to fabric reflectance 0.40 and transmittance 0.20, we find that it is close to the diagonal line labeled "F". In column F of the table, we find

*Note:* Classes may be approximated by eye. With closed fabrics, no objects are visible through the material, but large light or dark areas may show. Semiopen fabrics do not permit details to be seen, and large objects are clearly defined. Open fabrics allow details to be seen, and the general view is relatively clear with no confusion of vision. The yarn color or shade of light or dark may be observed to determine whether the fabric is light, medium, or dark.

**Fig. 31** Designation of Drapery Fabrics

a value of 0.58 on the line corresponding to 6 mm clear glass. This is the desired IAC value.

**Example 20.** Determine the fabric designator for a fabric having an openness factor of 0.10 and a yarn reflectance of 0.60.

**Solution:** On the figure in Table 22, these lines intersect in the area of Designator II<sub>L</sub>. Refer also to Figure 30. Fabric is semiopen and light in color. Additional information: probable fabric reflectance is 0.50, and fabric transmittance is 0.35.

**COMPLETELY SHADED GLAZINGS**

This section presents approximate models (Klems 2001) for calculating the heat flow through glazing systems with shading for all cases not covered by the sections on Exterior Shading and Indoor and Between-Glass Shading Devices on Simple Fenestrations (i.e., glazing or shading systems not covered by the tables or with incident angles above 30°). With the exception of exterior fins and overhangs, all shading is modeled as a **planar, ideally diffuse layer** parallel to the glass layers, and the models do not apply if there is more than one shading layer. The effects of specular transmission or partial shading are assumed to have been separated out using the method described above under Simplified Calculation Procedure.

The shading layer is denoted by the subscript *S*. To apply these models, one or more of the following quantities must be known for the shading (the number depends on the position of the shading in the glazing system):

- $T_S^{fH}$  = front directional-hemispherical transmittance of the shading layer
- $T_S^{bH}$  = back directional-hemispherical transmittance of the shading layer
- $R_S^{fH}$  = front directional-hemispherical reflectance of the shading layer
- $R_S^{bH}$  = back directional-hemispherical reflectance of the shading layer

**Table 22 Interior Solar Attenuation Coefficients for Single and Insulating Glass with Draperies**

Glazing	Glass Transmission	Glazing SHGC (No Drapes)	IAC

**Interior Solar Attenuation (IAC)**

*Notes:*

- Interior attenuation coefficients are for draped fabrics.
- Other properties are for fabrics in flat orientation.
- Use fabric reflectance and transmittance to obtain accurate IAC values.
- Use openness and yarn reflectance or openness and fabric reflectance to obtain the various environmental characteristics, or to obtain approximate IAC values.

**Classification of Fabrics**

- I = Open weave
- II = Semiopen weave
- III = Closed weave
  
- D = Dark color
- M = Medium color
- L = Light color

**To obtain fabric designator (III<sub>L</sub>, I<sub>M</sub>, etc.).** Using either (1) fabric transmittance and fabric reflectance coordinates, or (2) openness and yarn reflectance coordinates, find a point on the chart and note the designator for that area. If properties are not known, the classification may be approximated by eye as described in the note in Figure 31.

**To obtain interior attenuation (IAC).** (1) Locate drapery fabric as a point using its known properties, or approximate using its fabric classification designator. For accuracy, use fabric transmittance and fabric reflectance; (2) follow diagonal IAC lines to lettered columns in the table. Find IAC value in selected column on line corresponding to glazing used. For example, IAC is 0.4 for 6 mm clear single glass with III<sub>L</sub> drapery (Column H).

*Note:* Unlike specular transmittance, front and back directional-hemispherical transmittances are not necessarily equal.

To match the assumptions of the model, the specular component should be *excluded* from the transmittance but *included* in the reflectances. Since the shading layer is assumed to be an ideal diffuser, the above quantities are the same for all incident directions. In addition, the notation  $\langle \rangle_D$  will be applied to various optical properties of specular glazings. This notation means the hemispherical average of the quantity over all incident directions and is the quantity labeled “diffuse” in Table 13. For example, for a particular glass layer  $j$ ,  $\langle T_j \rangle_D$  would be the hemispherical average transmittance of the glass layer, which is also the transmittance for ideally diffuse incident radiation.

Another addition to the notation is needed for discussing absorption in this section. In the treatment of unshaded multiple glazings, the notation  $\mathcal{A}_n^f(\theta)$  was used to denote the actual front absorption of the  $n$ th layer of an  $L$ -layer system. Since only one system was under consideration, no ambiguity could arise from the fact that the notation does not specifically reference the number of layers in the system. Here it will be necessary to discuss multi-layer systems that are subdivided into one or more subsystems. Since the actual absorption depends on the other layers in the system because of reflections from those layers and because it is referenced to the incident intensity on the front (or back) surface of the system, rather than on the specific layer, it is necessary to include the particular subsystem in the notation. The following notation will be used. We assume that the overall system has  $L$  layers that are numbered sequentially from outside to inside, as before. Now  $\mathcal{A}_{n:(M,N)}^f(\theta)$  is the actual front absorption of layer  $n$  in subsystem of layers  $M$  through  $N$ , and similarly for back absorption. In this notation, the front absorptance of layer  $n$  in the overall system, which previously was called  $\mathcal{A}_n^f(\theta)$ , would now be denoted  $\mathcal{A}_{n:(1,L)}^f(\theta)$ . Note that for the subsystem  $(M,N)$  the front absorptance  $\mathcal{A}_{n:(M,N)}^f$  is the fraction of the radiation incident on the front of layer  $M$  that is absorbed in layer  $n$ , while the back absorptance  $\mathcal{A}_{n:(M,N)}^b$  is the fraction of the radiation incident on the back side of layer  $N$  that is absorbed in layer  $n$ .

In all cases, we assume that there is a specular glazing of  $L$  layers, labeled as described in the section on Optical Properties of Multiple-Layer Glazing Systems in the discussion of unshaded glazing optical properties. The shading layer, denoted  $S$ , is not counted in this labeling. Differing locations of the shading layer are discussed in the following sections.

### Exterior Shading by Overhangs, Fins, etc.

In this case, we neglect (1) reduction of the sky view by the shading and (2) reflection of diffuse radiation by the face of the shading seen by the glazing. It will usually be the case that this results in an overestimate of the heat flow, but exceptions are possible (e.g., highly reflective ground and light-colored overhang). Here the effect of the shading is simply to eliminate the direct beam radiation, and one is left with an unshaded glazing with diffuse radiation incident; the relevant optical properties are the hemispherical averages of those of the unshaded glazing system.

$$q = (E_d + E_r) \langle \text{SHGC} \rangle_D \quad (113)$$

The designer should be aware that because the diffuse solar radiation is small compared to that of the direct beam, reflection of direct beam radiation from other surfaces visible to the glazing can result in significant additional heat flow (e.g., beam radiation falling on the “wrong” side of a fin or overhang intended to shade an adjacent window).

### Exterior Shading Layer

Examples of planar exterior shading layers include exterior louvers or venetian blinds. It is assumed that air has free flow between

the exterior shading system and the glazing system. Under these conditions, as Table 17 shows, the fraction of the energy absorbed in the shading that flows inward is small. If this energy flow is neglected, then the whole effect of the shading layer is to modify the intensity of the (diffuse) radiation incident on the unshaded glazing, and the heat flow is

$$q = [(1 - F_u)E_{DN} \cos \theta + E_d + E_r] \frac{T_S^{fH}}{1 - R_S^{bH} \langle R_{1,L}^f \rangle_D} \langle \text{SHGC} \rangle_D \quad (114)$$

where  $\langle \text{SHGC} \rangle_D$  is for the unshaded glazing system. To compute the amount of energy absorbed in the shading layer, one must estimate the isolated-layer absorptances of the shading layer from

$$\begin{aligned} a_S^f &= 1 - T_S^{fH} - R_S^{fH} \\ a_S^b &= 1 - T_S^{bH} - R_S^{bH} \end{aligned} \quad (115)$$

When attached to the glazing, and using  $S = 0$  to fit into the labeling scheme, the shading layer front absorptance is then

$$\mathcal{A}_{S:(S,L)}^f = a_S^f + \frac{a_S^b T_S^{fH} \langle R_{1,L}^f \rangle_D}{1 - R_S^{bH} \langle R_{1,L}^f \rangle_D} \quad (116)$$

where  $R_{1,L}^f$  refers to the unshaded glazing system.  $R_{1,L}^f$  may either be obtained from Table 13 or calculated as described previously in the section on Solar-Optical Properties of Glazings. The addition to the heat flow in Equation (114) is then

$$\Delta q = [(1 - F_u)E_{DN} \cos \theta + E_d + E_r] \mathcal{A}_S^f N_S \quad (117)$$

where the inward-flowing fraction  $N_S$  for the shading layer is taken from the appropriate line of Table 17.

### Between-Glass Shading Layer

One must first identify the position of the shading layer within the  $L$ -layer glazing system, remembering that the labeling of glazing layers did not count the shading layer  $S$ . We count the layers, beginning with the one in contact with the exterior air, until we reach the layer next to the shading layer. Let the number of that layer be  $K$ . We now relabel the shading layer by setting  $S = K + 1$  and relabel all subsequent glazing layers, making the one to the interior of  $S$  layer  $K + 2$  (or  $S + 1$ ), and continuing until we reach glazing layer  $L$ , which becomes  $L + 1$  in the new labeling scheme. We now have an  $L + 1$  layer system that consists of three parts: (1) an exterior glazing subsystem of  $S - 1$  layers, (2) the shading layer  $S$ , and (3) an interior glazing subsystem, consisting of layers  $S + 1$  to  $L + 1$ , a total of  $(L + 1) - S$  or  $L - K$  layers in all. Both the exterior glazing and interior glazing subsystems are assemblies of unshaded, specular glazing layers, and their optical properties are calculated by the methods described in the section on Optical Properties of Multiple-Layer Glazing Systems for unshaded glazings. The exterior and interior glazing subsystems will often be either a single or double glazing, and, if they are sufficiently common, their properties may then be found in Table 13.

For calculational purposes, it is convenient to consider two other subsystems, one consisting of the shading layer together with the exterior glazing, an  $S$ -layer subsystem consisting of layers 1 through  $S$ , and the other consisting of the shading layer together with the interior glazing, consisting of layers  $S$  through  $L + 1$ , a total of  $L - S + 2$  or  $L - K + 1$  layers. For the former subsystem, we will need the directional-hemispherical transmittance:

$$T_{1,S}^{fH}(\theta) = \frac{T_{1,S-1}(\theta)T_S^{fH}}{1 - R_S^{fH}\langle R_{1,S-1}^b \rangle_D} \quad (118)$$

and the hemispherical back reflectance (which is the same for all incident directions):

$$R_{1,S}^{bH} = R_S^{bH} + \frac{\langle R_{1,S-1}^b \rangle_D T_S^{bH} T_S^{fH}}{1 - R_S^{fH}\langle R_{1,S-1}^b \rangle_D} \quad (119)$$

For the latter subsystem, we need the hemispherical front reflectance:

$$R_{S,L+1}^{fH} = R_S^{fH} + \frac{\langle R_{S+1,L+1}^f \rangle_D T_S^{bH} T_S^{fH}}{1 - R_S^{bH}\langle R_{S+1,L+1}^f \rangle_D} \quad (120)$$

The directional-hemispherical transmittance of the total system is then

$$\begin{aligned} T_{1,L+1}^{fH}(\theta) &= \frac{T_{1,S}^{fH}(\theta)T_{S+1,L+1}^{fH}}{1 - R_{1,S}^{bH}\langle R_{S+1,L+1}^f \rangle_D} \\ &= \frac{T_{1,S-1}(\theta)T_S^{fH}T_{S+1,L+1}^{fH}}{[1 - R_S^{fH}\langle R_{1,S-1}^b \rangle_D][1 - R_{S+1,L+1}^{fH}\langle R_{S+1,L+1}^f \rangle_D]} \end{aligned} \quad (121)$$

The absorptances for the  $k$ th layer are for  $k < S$

$$\begin{aligned} \mathcal{A}_{k:(1,L+1)}^f(\theta) &= \mathcal{A}_{k:(1,S-1)}^f(\theta) \\ &+ \langle \mathcal{A}_{k:(1,S-1)}^b \rangle_D \frac{T_{1,S}^{fH}(\theta)}{1 - R_{S,L+1}^{fH}\langle R_{1,S-1}^b \rangle_D} \end{aligned} \quad (122)$$

for  $k = S$

$$\begin{aligned} \mathcal{A}_{k:(1,L+1)}^f(\theta) &= \frac{a_S^f T_{1,S-1}(\theta)}{1 - R_{S,L+1}^{fH}\langle R_{1,S-1}^b \rangle_D} \\ &+ \frac{a_S^b T_{1,S}^{fH}(\theta)\langle R_{S+1,L+1}^f \rangle_D}{1 - R_{1,S}^{bH}\langle R_{S+1,L+1}^f \rangle_D} \end{aligned} \quad (123)$$

for  $k > S$

$$\mathcal{A}_{k:(1,L+1)}^f(\theta) = \langle \mathcal{A}_{k:(S+1,L+1)}^f \rangle_D \frac{T_{1,S}^{fH}(\theta)}{1 - R_{1,S}^{bH}\langle R_{S+1,L+1}^f \rangle_D} \quad (124)$$

The hemispherical average of the appropriate above equation then gives  $\langle \mathcal{A}_{k:(1,L+1)}^f \rangle_D$ .

For convenience, we split the heat flow up into three parts: that due to transmitted direct beam radiation (subscript  $B$ ), that due to transmitted diffuse beam and ground-reflected radiation (subscript  $d$ ), and that due to energy absorbed in the various layers and flowing inward by the normal mechanisms of heat transfer (subscript  $a$ ):

$$q = q_B + q_d + q_a \quad (125)$$

We note that  $q_B$  and  $q_d$  consist of diffusely distributed radiation in the solar wavelength range, while  $q_a$  is a heat flux. The quantities in Equation (125) are given by

$$q_B = E_{DN} \cos(\theta) T_{1,L+1}^{fH}(\theta) \quad (126)$$

$$q_d = (E_d + E_r) \langle T_{1,L+1}^{fH} \rangle_D \quad (127)$$

$$\begin{aligned} q_a &= E_{DN} \cos(\theta) \sum_{k=1}^{L+1} \mathcal{A}_{k:(1,L+1)D}^f(\theta) N_k \\ &+ (E_d + E_r) \sum_{k=1}^{L+1} \langle \mathcal{A}_{k:(1,L+1)}^f \rangle_D N_k \end{aligned} \quad (128)$$

The values of the layer-specific inward-flowing fractions  $N_k$  are chosen from the appropriate lines of Table 17. All types of shading should be considered equivalent when using Table 17 with this simplified method; accordingly, corresponding entries in the lines for differing blind tilts should be averaged in the case of double glazing.

For systems with more than two glazing layers, for which no information exists in Table 17, the following estimate should be used. If the glazing system contains no low-e coating, then information for double glazing with between-pane shading should be averaged; if the system contains one or more low-e coatings, then the line corresponding to low-e double glazing should be chosen. For  $k < S$ , use for  $N_k$  the value in Table 17 corresponding to the outer glass; for  $k = S$ , use the value for the shading layer; and for  $k > S$ , use the value corresponding to the inner glass.

### Interior Shading Layer

For interior shading, we can consider the shading layer  $S$  to form the  $(L+1)$ th layer of an  $(L+1)$  layer system. The total directional-hemispherical transmittance of this system is given by

$$T_{1,L+1}^{fH}(\theta) = \frac{T_{1,L}(\theta)T_S^{fH}}{1 - R_S^{fH}\langle R_{1,L}^b \rangle_D} \quad (129)$$

and the total diffuse transmittance of the system is the hemispherical average of this quantity is given by

$$\langle T_{1,L+1}^{fH} \rangle_D = \frac{\langle T_{1,L}(\theta) \rangle_D T_S^{fH}}{1 - R_S^{fH}\langle R_{1,L}^b \rangle_D} \quad (130)$$

In discussing layer absorptance, we need to consider a layer both in its role in the  $L$ -layer unshaded system and in the  $(L+1)$ -layer system formed by adding the shading layer. The  $L$ -layer system is an unshaded one, so all quantities pertaining to that system can be calculated from Equations (60) through (65), (79), and (84) for the optical properties of multilayer, unshaded glazings above. If it is a sufficiently common system, its properties may be found in Table 13, and the table values may be linearly interpolated to the desired incident angle; see also the previous section on Spectral Averaging of Glazing Properties and Examples 11, 12, and 13. The addition of the shading layer causes an additional contribution to the absorptance in each layer of the  $L$ -layer system due to the backward incidence of diffuse radiation reflected by the shade:

$$\mathcal{A}_{k:(1,L+1)}^f(\theta) = \mathcal{A}_{k:(1,L)}^f(\theta) + \langle \mathcal{A}_{k:(1,L)}^b \rangle_D \frac{T_{1,L}(\theta) R_S^{fH}}{1 - R_S^{fH} \langle R_{1,L}^b \rangle_D} \quad (131)$$

and the hemispherical average of this quantity over incident direction is given by

$$\langle \mathcal{A}_{k:(1,L+1)}^f \rangle_D = \langle \mathcal{A}_{k:(1,L)}^f \rangle_D + \langle \mathcal{A}_{k:(1,L)}^b \rangle_D \frac{\langle T_{1,L} \rangle_D R_S^{fH}}{1 - R_S^{fH} \langle R_{1,L}^b \rangle_D} \quad (132)$$

The absorptance in the shade layer is

$$\mathcal{A}_{S:(1,L+1)}^f(\theta) \equiv \mathcal{A}_{L+1:(1,L+1)}^f(\theta) = \frac{T_{1,L}(\theta) a_S^f}{1 - R_S^{fH} \langle R_{1,L}^b \rangle_D} \quad (133)$$

with, again, a hemispherical average given by

$$\langle \mathcal{A}_{L+1:(1,L+1)}^f \rangle_D = \frac{\langle T_{1,L} \rangle_D a_S^f}{1 - R_S^{fH} \langle R_{1,L}^b \rangle_D} \quad (134)$$

The heat flow is calculated from Equations (125) through (128).

The inward-flowing fractions  $N_k$  in Equation (128) are chosen from Table 17 when possible. The most thermally resistive glazing system with interior shading in this table is double glazing. For higher resistance systems (low-e double glazing, triple glazing, or higher, etc.), there are three possible procedures:

1. Calculate the  $N_k$  ( $k < S$ ) for the unshaded glazing, and for the shading layer ( $k = S$ ), take the value from the Inner Shading Layer column of Table 17 for the system that is closest to the desired one.
2. Treat the shading layer as an additional (uncoated, unless the shading layer has low emissivity on the exterior side) glazing and calculate the  $N_k$  for the resulting  $(L+1)$ -layer glazing.
3. Take  $N_1, N_2$ , and the value for the interior shading layer from the table entries for double glazing with interior shade, and take  $N_k = N_2$  for all subsequent glazing layers. Using as an alternative assumption  $N_L = N_2$  and  $N_k = N_1$  for all  $k < L$  will give an estimate of the range of error to be expected.

Method (1) will produce values of  $N_k$  for  $k \leq L$  that tend to be too high, and a value of  $N_S$  ( $S = L + 1$ ) that may be too low. Method (2) will produce values of  $N_k$  for  $k \leq L$  that tend to be too low and a value of  $N_S$  that also tends to be too low (since some heat that transfers outward by convection from layer  $S$  would be carried to the interior with an unsealed air space). By comparing the resulting solar energy fluxes using each of the three methods, one can obtain an estimate of the sensitivity of the results to uncertainty in calculating  $N_k$ .

**Example 21.** Calculate the solar energy flux through the glazing system of Example 10 with a closed interior translucent light shade, under the conditions of Example 5.

**Solution:** From Table 21, we take the properties of a translucent light shade to be  $T_S^{fH} = 0.25$ ,  $R_S^{fH} = 0.60$ , and  $a_S^f = 0.15$ . We assume that the reflectance is diffuse and that the transmittance is independent of incident angle. By using method (1) above for determining the inward-flowing fractions, we can take the values of  $N_1 = 0.064$  and  $N_2 = 0.821$  calculated in Example 14, and we take  $N_S = 0.85$  from the entry in Table 17 for double glazing with interior shade. We use the property values for an incident angle  $\theta$  of  $63.2^\circ$  (from Example 6) that were calculated for the unshaded glazing in Example 11:  $T_{1,2}(63.2^\circ) = 0.244$ ,

$R_{1,2}^b(63.2^\circ) = 0.446$ ,  $R_{1,2}^b(63.2^\circ) = 0.444$ ,  $\mathcal{A}_{1:(1,2)}^f(63.2^\circ) = 0.289$ ,  $\mathcal{A}_{1:(1,2)}^b(63.2^\circ) = 0.144$ ,  $\mathcal{A}_{2:(1,2)}^f(63.2^\circ) = 0.022$ ,  $\mathcal{A}_{2:(1,2)}^b(63.2^\circ) = 0.167$ . We use the hemispherical average properties calculated in Example 12:  $\langle T_{1,2} \rangle_D = 0.277$ ,  $\langle R_{1,2}^b \rangle_D = 0.405$ ,  $\langle R_{1,2}^b \rangle_D = 0.442$ ,  $\langle \mathcal{A}_{1:(1,2)}^f \rangle_D = 0.271$ ,  $\langle \mathcal{A}_{1:(1,2)}^b \rangle_D = 0.138$ ,  $\langle \mathcal{A}_{2:(1,2)}^f \rangle_D = 0.036$ , and  $\langle \mathcal{A}_{2:(1,2)}^b \rangle_D = 0.141$ . In the shaded fenestration, the shade comprises layer 3 (i.e.,  $S = 3$ ); the total transmittance at an incident angle of  $63.2^\circ$  is calculated from Equation (129).

$$T_{1,S}^{fH}(63.2^\circ) = \frac{T_{1,2}(63.2^\circ) T_S^{fH}}{1 - R_S^{fH} \langle R_{1,2}^b \rangle_D} = \frac{(0.244)(0.25)}{1 - (0.60)(0.442)} = 0.083$$

The layer absorptances are calculated from Equation (131):

$$\begin{aligned} \mathcal{A}_{1:(1,S)}^f(63.2^\circ) &= \mathcal{A}_{1:(1,2)}^f(63.2^\circ) + \langle \mathcal{A}_{1:(1,2)}^b \rangle_D \frac{T_{1,2}(63.2^\circ) R_S^{fH}}{1 - R_S^{fH} \langle R_{1,2}^b \rangle_D} \\ &= 0.289 + (0.138) \frac{(0.244)(0.60)}{1 - (0.60)(0.442)} = 0.316 \end{aligned}$$

$$\begin{aligned} \mathcal{A}_{2:(1,S)}^f(63.2^\circ) &= \mathcal{A}_{2:(1,2)}^f(63.2^\circ) + \langle \mathcal{A}_{2:(1,2)}^b \rangle_D \frac{T_{1,2}(63.2^\circ) R_S^{fH}}{1 - R_S^{fH} \langle R_{1,2}^b \rangle_D} \\ &= 0.022 + (0.141) \frac{(0.244)(0.60)}{1 - (0.60)(0.442)} = 0.050 \end{aligned}$$

and Equation (133):

$$\mathcal{A}_{S:(1,S)}^f(63.2^\circ) = \frac{T_{1,2}(63.2^\circ) a_S^f}{1 - R_S^{fH} \langle R_{1,2}^b \rangle_D} = \frac{(0.244)(0.15)}{1 - (0.60)(0.442)} = 0.050$$

From this we calculate the solar heat gain coefficient, using Equation (79),

$$\begin{aligned} \text{SHGC}(63.2^\circ) &= T_{1,S}^{fH}(63.2^\circ) + \sum_{k=1}^{S(=3)} N_k \mathcal{A}_{k:(1,2)}^f(63.2^\circ) \\ &= T_{1,S}^{fH}(63.2^\circ) + N_1 \mathcal{A}_{1:(1,S)}^f(63.2^\circ) \\ &\quad + N_2 \mathcal{A}_{2:(1,S)}^f(63.2^\circ) + N_S \mathcal{A}_{S:(1,S)}^f(63.2^\circ) = (0.083) \\ &\quad + (0.064)(0.316) + (0.821)(0.050) + (0.85)(0.050) = 0.187 \end{aligned}$$

The corresponding hemispherical average properties are calculated from Equations (130), (131), and (134):

$$\langle T_{1,S}^{fH} \rangle_D = \frac{\langle T_{1,2} \rangle_D T_{1,S}^{fH}}{1 - R_S^{fH} \langle R_{1,2}^b \rangle_D} = \frac{(0.277)(0.25)}{1 - (0.60)(0.442)} = 0.094$$

$$\begin{aligned} \langle \mathcal{A}_{1:(1,S)}^f \rangle_D &= \langle \mathcal{A}_{1:(1,2)}^f \rangle_D + \langle \mathcal{A}_{1:(1,2)}^b \rangle_D \frac{\langle T_{1,2} \rangle_D R_S^{fH}}{1 - R_S^{fH} \langle R_{1,2}^b \rangle_D} \\ &= 0.271 + (0.138) \frac{(0.277)(0.25)}{1 - (0.60)(0.442)} = 0.302 \end{aligned}$$

$$\begin{aligned} \langle \mathcal{A}_{2:(1,S)}^f \rangle_D &= \langle \mathcal{A}_{2:(1,2)}^f \rangle_D + \langle \mathcal{A}_{2:(1,2)}^b \rangle_D \frac{\langle T_{1,2} \rangle_D R_S^{fH}}{1 - R_S^{fH} \langle R_{1,2}^b \rangle_D} \\ &= 0.036 + (0.141) \frac{(0.277)(0.60)}{1 - (0.60)(0.442)} = 0.068 \end{aligned}$$

$$\langle \mathcal{A}_{S:(1,S)}^f \rangle_D = \frac{\langle T_{1,2} \rangle_D a_S^f}{1 - R_S^{fH} \langle R_{1,2}^b \rangle_D} = \frac{(0.277)(0.15)}{1 - (0.60)(0.442)} = 0.057$$

Using these values, one calculates the diffuse solar heat gain coefficient from Equation (84):

$$\begin{aligned} \langle \text{SHGC} \rangle_D &= \langle T_{1,S}^f \rangle_D + \sum_{k=1}^{S(=3)} N_k \langle \mathcal{A}_{k:(1,2)}^f \rangle_D \\ &= \langle T_{1,S}^f \rangle_D + N_1 \langle \mathcal{A}_{1:(1,S)}^f \rangle_D + N_2 \langle \mathcal{A}_{2:(1,S)}^f \rangle_D + N_S \langle \mathcal{A}_{S:(1,S)}^f \rangle_D \\ &= 0.094 + (0.064)(0.302) + (0.821)(0.068) + (0.85)(0.057) \\ &= 0.218 \end{aligned}$$

In Example 7, the incident solar irradiances are calculated:  $E_{DN} \cos(63.2^\circ) = 388 \text{ W/m}^2$ ,  $E_d \cos(63.2^\circ) = 93.5 \text{ W/m}^2$ , and  $E_r \cos(63.2^\circ) = 86.6 \text{ W/m}^2$ . From these values, the solar energy flux is calculated from Equations (92), (97), and (100):

$$\begin{aligned} q_s &= q_b + q_d = [E_{DN} \cos(63.2^\circ)] \text{SHGC}(63.2^\circ) + (E_d + E_r) \langle \text{SHGC} \rangle_D \\ &= [388](0.243) + (93.5 + 86.6)(0.218) = 133 \text{ W/m}^2 \end{aligned}$$

## VISUAL AND THERMAL CONTROLS

The ideal fenestration system permits optimum light, heat, ventilation, and visibility; minimizes moisture and sound transfer between the exterior and the interior; and produces a satisfactory physiological and psychological environment. The controls of an optimum system will react to varying climatological and occupant demands. Fixed controls may have operations or cost advantages or both but do not react to physical and psychological variations. Variable controls are, therefore, more effective in energy conservation and environmental satisfaction.

### Operational Effectiveness of Shading Devices

Shading devices vary in their operational effectiveness. Some devices such as overhangs, light shelves, and tinted glazings do not require operation, have long life expectancies, and do not degrade significantly over their effective life. Other types of shading devices, especially operable interior shades, may have reduced effectiveness due to less than optimal operation and degradation of effectiveness over time. It is important to evaluate operational effectiveness when considering the actual heat rejection potential of shading devices.

The performance of shading devices for the reduction of peak cooling loads and annual energy use should account for operational effectiveness or reliability in actual operation. Passive devices, such as architectural elements and glazing tinting, are considered 100% effective in operation. Glazing coatings and adherent films may degrade over time. Shade screens are removable and may be assumed to be operated seasonally, but in any given population of users, some will remain in place all year long and some will not be installed or removed at optimum times. Automated shading devices controlled for optimum thermal operation are considered more effective than manual devices, but controls require ongoing maintenance,

and some occupants may object to the lack of personal control with totally automated devices. Automated shading devices may also be operated for nonthermal purposes such as glare and daylighting optimization, and this may reduce thermal effectiveness. Manually operated devices will be subject to wide variation in use effectiveness, and this diversity in effective use should be considered when evaluating performance.

### Indoor Shading Devices

While the thermal comfort of occupants within the glazed space may be paramount to the HVAC designer, other factors (see Table 22 and Figure 31) that should be considered, some of which may be more important to the user, include the following:

**Radiant Energy Protection.** Unshaded fenestration products become sources of radiant heat by transmitting short-wave solar radiation and by emitting long-wave radiation to dissipate some of the absorbed solar energy. In winter, glass temperatures usually fall below room air temperature, which may produce thermal discomfort to occupants near the fenestration. In summer, individuals seated near the unshaded fenestration product may experience discomfort from both direct solar rays and long-wave radiation emitted by sun-heated glass. In winter, loss of heat by radiation to cold glass can also cause discomfort. Tightly woven, highly reflective drapes minimize such discomfort; drapes with high openness factors are less effective because they permit short-wave and long-wave radiation to pass more freely. Light-colored shading devices with maximum total surface usually provide the best protection since they absorb less heat and tend to lose heat readily by convection to the conditioned air.

**Outward Vision.** Outward vision is normally desirable in both business and living spaces. Open-weave, dark-colored fabrics of uniform pattern permit maximum outward vision, while uneven pattern weaves reduce the ability to see out. A semiopen weave modifies the view without completely obscuring the outdoors. Tightly woven fabrics block off outward vision completely.

**Privacy.** Venetian blinds, either vertical or horizontal, can be adjusted and, when completely closed, afford full privacy. When draperies are closed, the degree of privacy is determined by their color and tightness of weave and the source of the principal illumination. To obscure the view so completely that not even shadows or silhouettes can be detected, fully opaque materials are used. Generally, the more brightly lit side of a partially shaded glazing is the most visible from the opposite side, making the interior fairly private in daytime, but not at night.

**Brightness Control.** Visual comfort is essential in many occupied areas, and freedom from glare is an important factor in performing tasks. *Discomfort glare* is produced by uneven brightnesses in occupied spaces, with areas or spots that are much brighter than

5. Effectiveness in modifying unattractive or distracting view out of window	Little	Little	Some	Some	Good	Good	Blocks	Blocks	Blocks

<sup>a</sup>Good when bright illumination is on the viewing side.

<sup>b</sup>To obscure view completely, material must be completely opaque.

<sup>c</sup>Poor rating applies to white fabric in direct sunlight. Use off-white color to avoid excessive transmitted light.

surrounding surfaces. Windows themselves, when they look out onto bright skies or brightly reflecting surfaces, can be glare sources if care is not taken to keep surround brightnesses comparable. A maximum brightness ratio of about 3 to 1 is sometimes quoted. Moderation of this ratio can be achieved through the use of interior furnishings and wall coverings, which on average have moderately high diffuse reflectances and access to admitted daylight. Conversely, dark interior surfaces, and those shaded from daylight illumination, will accentuate the brightness difference between the window and its surroundings. Interior surface brightness can also be elevated by ample use of interior electric lighting, but this can have adverse consequences for the building's energy use. In general, larger window apertures admit more sunlight, increasing interior brightnesses without affecting the perceived brightness of the window, all other things being equal.

An important guideline is the dictum that direct sunlight must not strike the eye, and reflected sunlight from bright or shiny surfaces is equally disturbing and even disabling. A tightly woven white fabric with high solar transmittance attains such brilliance when illuminated by direct sunshine that, by contrast with its surroundings, it creates excessive glare. Off-white colors should be used so their surface brightness is not too great. Venetian blinds permit considerable light to enter by interreflection between slats. When two shading devices are used, the one on the inside (away from the fenestration product) should be darker and more open. With this arrangement, the inside device can be used to control brightness for the other shading devices and, when used alone, to reduce brightness while still permitting some view of the outside.

**View Modification.** When the view is unattractive or distracting, draperies modify the view to some degree, depending on the fabric weave and color (summarized in Table 23), but the fenestration product remains as an effective connection to the outside.

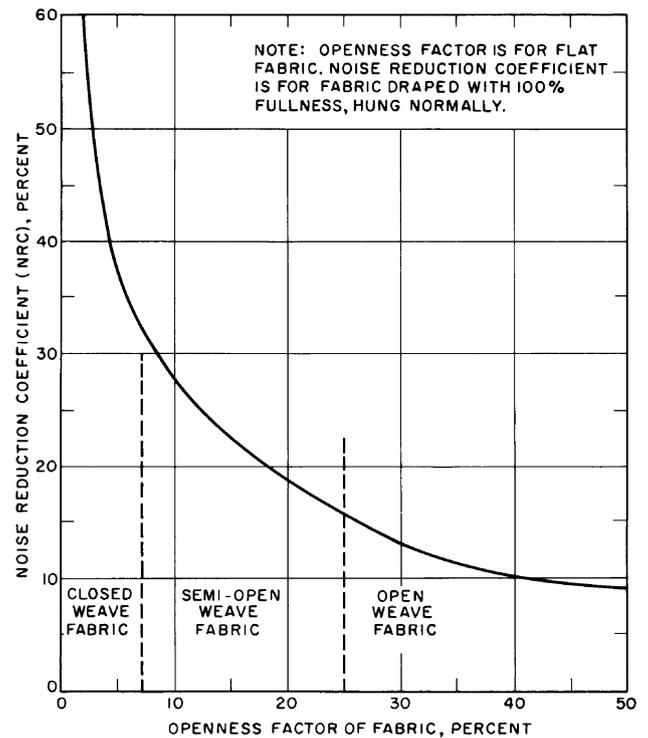

**Sound Control.** Indoor shading devices, particularly draperies, can absorb some of the sounds originating within the room but have little or no effect in preventing outdoor sounds from entering. For excessive internally generated sound, the usual remedy is to apply acoustical treatment to the ceiling and other room surfaces. While these materials can be effective in controlling sound, they are often located on the two horizontal surfaces (ceiling and floor) and leave the opposing vertical surfaces of glass and bare wall to reflect sound. The noise reduction coefficient (NRC = average absorptance coefficient at four frequencies) for venetian blinds is about 0.10, compared to 0.02 for glass and 0.03 for plaster. For drapery fabrics at 100% fullness, NRC ranges from 0.10 to 0.65, depending on the tightness of weave. Class III (tightly woven) fabrics have NRC values of 0.35 to 0.65. Figure 32 shows the relationship between NRC and openness factor for fabrics of normal weight.

**Example 22.** To select a drapery fabric, consider the five environmental factors listed in Table 23. Choose a fabric designator that has suitable performance for all the factors important to the case being considered. If this is not possible, make compromises resulting in an acceptable designator. Determine from Table 23 if the IAC for the chosen designator is satisfactory. Specific cases follow:

1. Where modification of a distracting view is necessary but a degree of outward vision is needed and an IAC of 0.50 with 6 mm gray glass is satisfactory (see Table 23, Item 5), select  $II_M$  or  $II_L$ ; from Item 2, select  $II_M$ . The IAC for  $II_M$  on Table 23 is approximately 0.46, therefore satisfactory.
2. Where protection from radiation is paramount and minimum IAC is necessary (see Table 23, Item 1), select a closed weave,  $III_M$  or  $III_L$ . Since the IAC for  $III_L$  is lowest (see Table 23), choose  $III_L$ .
3. When good outward vision is desired, together with some reduction in brightness, choose  $I_M$  or  $I_D$  (Table 23).

### Double Drapery

Double draperies (two sets of drapery covering the same area) have a light, open weave on the fenestration product side for out-

**Fig. 32 Noise Reduction Coefficient Versus Openness Factor for Draperies**

ward vision and daylight when desired and a heavy, closed weave or opaque drapery on the room side to block out sunlight and provide privacy when desired. When properly selected and used, double draperies can provide a reduced U-factor and a lowered IAC.

The reduced U-factor results principally from adding a semi-closed air space to the barrier. A U-factor of about  $1.80 \text{ W}/(\text{m}^2 \cdot \text{K})$  is achieved using double draperies with single glass, and about  $1.17 \text{ W}/(\text{m}^2 \cdot \text{K})$  with insulating glass.

To most effectively reduce solar heat gain, the drapery exposed to sunlight should have high reflectance and low transmittance. The light, open-weave drapery should be opened when the heavy drapery is closed to prevent entry of sunlight.

Properly used double draperies give (1) extreme flexibility of vision and light intensity, (2) a lowered U-factor and IAC, and (3) an improved comfort condition, since the room-side drapery is more nearly at room temperature. Table 23 gives characteristics of individual draperies. For large areas, the IAC should be calculated in detail to determine the cooling load.

## AIR LEAKAGE

### Infiltration Through Fenestration

Air infiltration through fenestration products affects occupant comfort and energy consumption. Infiltration should not be confused with ventilation. Infiltration is the uncontrolled inward leakage of air caused by pressure effects of wind or differences in air density, such as the stack effect. While fenestration products can be operated to intentionally provide natural ventilation and increase comfort, infiltration should be reasonably minimized to avoid unpleasant accompanying problems. If additional air is required, controlled ventilation is preferable to infiltration. Mechanical ventilation provides air in a comfortable manner and when desired. For infiltration, however, the peak supply is more likely to occur as an

uncomfortable draft and when least desired, such as during a storm or the coldest weather.

ASHRAE/IESNA *Standard* 90.1, ASHRAE's energy standard for all buildings other than low-rise residential buildings, establishes an air leakage maximum of XX per square metre of gross fenestration product area (XX/m<sup>2</sup> for swinging entrance doors and revolving doors). This air leakage is as determined in accordance with NFRC 400 and ASTM *Standard* E 283 and allows direct comparison of all fenestration products: operable and fixed, windows and doors.

Most manufactured fenestration products achieve these reasonable standards of maximum air infiltration. However, products that do not completely seal, such as *jalousie* windows or doors, are not likely to do so and are most appropriate for installation in unconditioned spaces.

For products achieving this infiltration standard, the energy consumption due to infiltration is likely to be significantly less than the energy associated with U-factor and solar heat gain coefficient. Also, while overall air infiltration is a significant component in determining a building's heating and cooling loads, the infiltration through fenestration products meeting the above standard is generally likely to be a small portion of that total. Chapter 26 presents calculation procedures for air infiltration.

### Indoor Air Movement

Because supply air grilles are frequently located directly below fenestration products, air sweeps the interior glass surface. Heated supply air should be directed away from the glass to prevent large temperature differences between the center and edges of the glass. These thermal effects must be considered, particularly when annealed glass is used and air is forced over the glass surface during the heating season. Direct flow of heated air over the glass surface can increase the heat transfer coefficient and the temperature difference, causing a substantial increase in heat loss; it may also lead to thermally induced stress and risk of glass breakage.

Systems designed predominantly for cooling lower the glass temperature and rapidly pick up the cooling load. Both tend to improve the comfort condition of the space. However, the air-conditioned space has an increased net heat gain caused by (1) increase in the solar heat gain coefficient (SHGC) due to delivery of a larger portion of the absorbed heat to the indoor space, (2) increase in the fenestration U-factor because of the greater convection effect at the indoor surface, and (3) increase in the air-to-air temperature difference since supply air rather than room air is in contact with the indoor glass surface. The principal increase in heat gain with clear glass is the result of the higher U-factor and the greater air-to-air temperature difference.

## DAYLIGHTING

### DAYLIGHT PREDICTION

Daylighting is the illumination of building interiors with sunlight and sky light and is known to affect visual performance, lighting quality, health, human performance, and energy efficiency. In many European countries with predominantly cloudy skies, there are codes regulating minimum window size, minimum daylight factor, and window position in order to provide views to all occupants and to create a minimum interior brightness level. For practical reasons, daylighting provides backup interior illumination in the event of power outages. Daylighting may have some positive or negative health effects on the skin, eyes, hormone secretion, and mood. Its temporal variation, intensity, spectral content, and diurnal and temporal variation may be used to combat jet lag, sick building syndrome, and other health problems.

In terms of energy efficiency, daylighting can provide substantial whole-building energy reductions in nonresidential buildings

through the use of electric lighting controls. Daylight admission can displace the need for electric lighting at the perimeter zone with vertical windows and at the core zone with skylights. Lighting and its associated cooling energy use constitute 30 to 40% of a nonresidential building's energy use. Energy use reductions can be achieved, perhaps less reliably, in residential buildings with manual or automated switching of electric lights on and off to match space occupancy. For internal load-dominated buildings, daylight admission must be balanced against solar heat admission to achieve optimum energy efficiency. Since the heat gains from solar radiation typically define peak load conditions, daylighting is also a very effective method of decreasing peak demand. The use of daylighting can not only decrease annual operating costs through energy efficiency but may also reduce capital cost due to mechanical downsizing.

For conventional sidelit nonresidential buildings, three fundamental relationships for daylight optimization are given as a function of (1) glazing properties and (2) window area or the **window-to-wall area ratio** (WWR), which is defined as the ratio of the transparent glazing area to the exterior floor-to-floor wall area:

1. Annual cooling energy use (including fan energy use) increases linearly with solar radiation admission, as indicated by the product of SHGC and WWR, but is affected by decreases in electric lighting heat gains.
2. Annual lighting energy use decreases exponentially/asymptotically with daylight admission, as indicated by the product of  $T_v$  and WWR.
3. Annual heating energy use (including fan energy use) increases linearly with decreased lighting heat gains.

Figure 33 illustrates the first two relationships for a prototypical nonresidential building. A similar relationship can be demonstrated with skylights.

To determine the fenestration design that achieves an optimum balance between daylight admission and solar rejection requires iterative calculations where the glazing area and/or glazing solar-optical properties are varied parametrically. For each case, the following general steps should be taken for each hour over a year:

1. **Interior Daylight Illuminance.** Determine the building characteristics, configuration, outdoor design conditions, and operating schedules as described in the section on Initial Design Considerations in Chapter 29. These include building orientation, exterior obstructions, ground reflectance, etc. Determine the depth from the window wall for each electric lighting zone. Typical sidelighting windows can effectively daylight the perimeter zone to a depth of 1.5 times the head height of the window. In private offices, one dimming zone is typically cost-effective, while in open plan offices, two zones are cost-effective.

Select a typical task location within each of the lighting zones. Determine interior daylight illuminance due to all window and skylight sources at these locations. Interior illuminance may be determined using computer simulation tools or physical scale models. Comprehensive explanations of simple and computer-based tools are available (IEA 1999). The majority of these tools can model simple box geometry with noncomplex fenestration systems. Some advanced simulation tools, such as Radiance (Ward 1990) and Adeline (Erhorn and Dirksmüller 2000), are capable of modeling complex geometry and fenestration systems with adequate bidirectional solar-optical data, but this capability is not routine.

2. **Lighting Energy Use.** Determine the type of lamps, ballasts, and control system to be used in the perimeter zones. Determine whether the lamp is capable of being dimmed or switched. For example, fluorescent lamps can be dimmed, while metal halides cannot be switched or dimmed. Cold, outdoor applications of some lamps may prevent switching. For electronic dimming bal-

lasts, obtain dimming power and light output characteristics. Obtain control specifications to determine how the system will respond to available light; dead-band ranges, response times, and commissioning will affect the sensitivity and accuracy of the system. The type of switching (on-off, bilevel, multilevel, and continuous dimming controls) will be dictated by both the type of lamp and space use.

Determine the task illuminance design set point for each zone. Determine the percentage electric lighting power reduction  $F_{daylight}$  [see Equation (135)] that will result with automatic daylight controls, and apply to the installed wattage. Simplified methods for calculating lighting power reductions based on task illuminance levels are given in Robbins (1986). More sophisticated programs (Choi and Mistrick 1999) model commercially available photosensor dimming control systems (typically located in the ceiling above the work plane task) more rigorously; the spectral and bidirectional response of the photosensor to incident flux is used to determine voltage output, which is then used by the ballast controller algorithm to determine the lighting power reduction. Response delays and commissioning set points will further affect this predicted output. Lights may also be switched manually, but there are no modeling prediction tools for manual switching. Field tests (Jennings et al. 1999) indicate that with bilevel switching, 45% of the lighting zone-hours were at less than full power lighting, with 28% at only one-third of full lighting output levels. Manual switching occurred less in public spaces. Occupancy and other types of switching may occur as well and should be accounted for as a confounding effect with any daylighting controls.

3. **Mechanical Energy Use.** Determine mechanical energy use due to the fenestration loads and reduced electric lighting heat gains.

Fenestration heat gains and losses may be computed using the section on Determining Fenestration Energy Flow. Instantaneous lighting heat gains  $q_{el}$ , described by Equation (1) in Chapter 29, must be multiplied by the power reduction factor  $F_{daylight}$ .

Mechanical loads and energy use may then be determined as described in Chapter 29. There have been many studies investigating the magnitude of change in heating and cooling energy use associated with reductions of lighting energy use in nonresidential buildings, as will be realized with daylighting controls. In a DOE-2.1E simulation study (Sezgen and Koomey 2000), the greatest savings were generated in hospitals, large offices, and large hotels; for every \$1.00 saved through lighting energy efficiency, additional savings as a result of reduced HVAC were \$0.26, \$0.16, and \$0.14, respectively. These results emphasize the need to include HVAC effects when assessing the impact of daylighting. Simplified design tools are available that enable one to conduct such parametric runs for preliminary analysis. For vertical windows, the BEEM program can be used to determine the relative impacts of daylighting on energy use, peak demand, and costs for a given window and lighting control system (Rundquist 1991). Skylighting tools based on regressions using DOE-2 data or simplified DOE-2 procedures are also available (AAMA 1988, Heschong et al. 1998). More comprehensive building energy prediction tools combined with daylighting algorithms, such as DOE-2.1E (Winkelmann 1983), implement hour-by-hour calculations using existing weather data and enable one to evaluate glare, visual comfort, and quality of light as well.

In the United States, a general rule has been that the fenestration area should be at least 20% of the floor area. In Europe, a similar rule was based on a minimum illumination value on the normal work plane from a standard overcast sky condition. In general, it is more energy-efficient to use larger window areas to elevate interior surface brightnesses as a glare reduction strategy than to increase interior electric lighting levels. As window area increases, interior brightness increases while window brightness remains the same. Of course there are mitigating considerations, such as the higher cost of larger windows and increased heat transfers through larger windows. The latter problem can be mitigated through the use of insulating multiple-pane windows and special coatings to reduce solar gain without serious loss of light transmission, as discussed in the section on Selecting Fenestration.

The secondary visual benefit of fenestration is the amount and quality of light it produces in the work environment. One general rule determined the need for auxiliary electric light by assuming that daylight was adequate for a depth of two-and-one-half times the height of the fenestration product into the room based on a normal sill height. To prevent excessive glare, all fenestration should have sun controls. Variable and removable controls are often more effective in daylight than fixed controls.

For more accurate evaluation of daylight distribution within a space, several prediction tools, such as the *Recommended Practice of Daylighting* (IESNA 1999), are available. This practice shows a simple way of calculating the daylight distribution on the work plane from windows and skylights with and without controls. Many other daylight prediction tools calculate illuminance from radiant flux transfer or ray tracing.

Any or all of the various daylight prediction tools can be used to compare the relative value of daylight distribution from alternative fenestration systems, but ultimately the designer must evaluate costs and benefits to choose between alternative designs. This may be based on energy use or, more properly, on overall costs and benefits to the client. Also, the negative possibility of total loss of productivity from an electric brown-out in a space with no natural ventilation or daylight may be as important as the benefits of many energy-saving schemes.

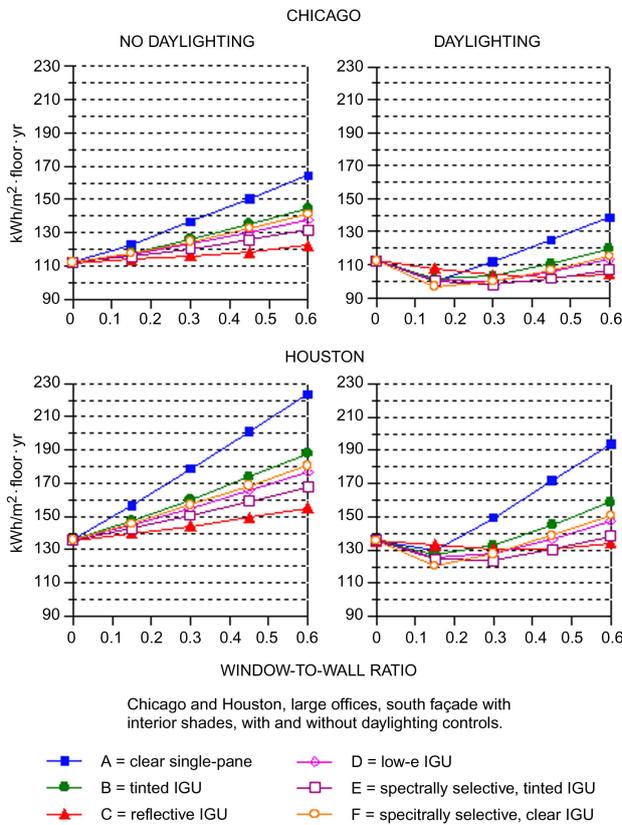

Fig. 33 Window-to-Wall Ratio Versus Annual Electricity Use (kWh/m²·floor·year)

**LIGHT TRANSMITTANCE AND DAYLIGHT USE**

When daylight is to be the primary lighting system, the minimum expected daylight in the building must be calculated for the building performance cycle and integrated into the lighting calculations. IESNA (1999) gives daylight design and calculation procedures. In some glazing applications, such as artists' studios and showrooms, maximum transmittance may be required for adequate daylighting of the interior. Regular clear glass, produced by float, plate, or sheet process, may be the logical choice.

When daylight is a supplementary light source, the electric lighting can be designed independently of the daylight system. However, adequate switching must be included in the electric distribution to substitute available daylight for electric lighting by automatic or prescribed manual control whenever possible and practical. Photosensitive controls automatically adjust shading devices to provide uniform illumination and reduce energy consumption. Manual control is less effective.

Buildings with large areas of glass usually have insulating glass units with clear, tinted, or reflective coatings. The tinted and reflecting units reduce the brightness contrast between fenestration products and other room surfaces and provide a relatively glare-free environment for most daylight conditions.

Tables 13 and 24 list typical solar energy transmittances and daylight transmittances for various glass types. Manufacturers' literature has more appropriate values.

The color of glass chosen for a building depends largely on where and how it is used. For commercial building lobbies, showroom fenestration products, and other areas where maximum visibility from exterior to interior is required, regular clear glass is generally best. Clear glass with a low-e coating is also suitable for these locations, including for retail storefronts, as it only decreases the light transmittance by 10% or so. For other glass areas, a tinted glass may best complement the interior colors. Bronze, gray, and reflective-film glasses also give some privacy to building occupants during daylight hours. Patterned, etched, or sandblasted glass that diffuses lighting is available. In warm climates, a tinted outer glass in an insulated double-pane system can have solar heat gain rejection benefits, while providing good color rendering illumination of the interior without apparent color.

The primary purpose of a fenestration product is not just to save energy but to provide a view of the exterior. One sees out of a fenestration product by virtue of the light from the outside that comes through that fenestration product into the occupant's eyes. The light from outside is valuable not only for views of the outdoors but for providing daylight illumination of the interior.

Some buildings are designed especially to use the daylight coming through fenestration systems in displacing electric lighting and

its attendant energy costs. Using daylighting to displace electric lighting benefits the energy bill directly through reduced direct consumption by the lighting systems involved and indirectly through reduced electrically produced heat gain that may have to be removed by the air-conditioning system.

The light-transmitting properties of fenestration systems are therefore of great importance, not only for permitting views of the outdoors but also for admitting daylight to reduce electric lighting. It is conceivable that one could design a fenestration product with excellent solar heat gain performance for hot climates (meaning a very low solar heat gain coefficient) but very poor view and daylight illumination performance. If this problem is bad enough, it can cause occupants to turn on electric lights indoors during the daytime, which adds to the electric bill and possibly causes problems of thermal discomfort as well.

The light-transmitting property of a fenestration product is called the visible **transmittance**  $T_v$ . It is similar to the solar-weighted solar transmittance, except that an additional weighting function is needed, in this case to account for the spectral response of the human eye.

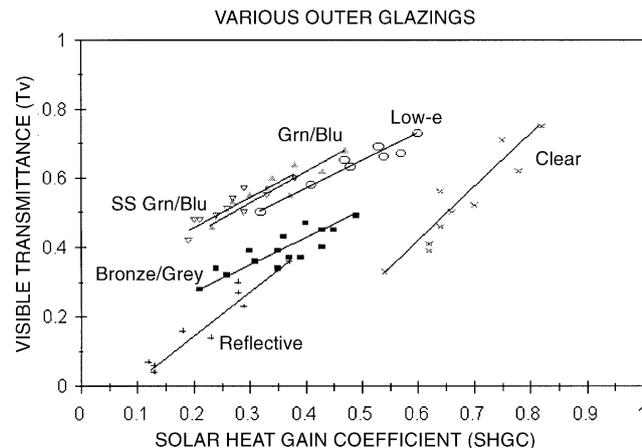

In most applications, it is important to have a high visible transmittance. In northern climates, a good solar heat gain is also important for offsetting wintertime heating costs. In southern climates, a low solar heat gain is good for offsetting summertime cooling costs. In the latter situation, it is difficult to have both a high visible transmittance and a low solar heat gain coefficient. Figures 34 and 35 show a plot of visible transmittance versus SHGC for a number of glazing systems covering a range of spectral selectivities. The data are for normal incidence and a single, ASTM standard solar spectral distribution.

A rule of thumb is to select a glazing unit having a visible transmittance greater than its shading solar heat gain coefficient, especially if daylighting strategies will be used in the building. For maximum light with minimum solar gain, there are fenestration products available having a visible transmittance 1.4 times the SHGC.

Three different zones are delineated on Figure 35. In the **neutral zone**, it is possible to have colorless glazing systems, meaning glazings with approximately uniform transmittance over the visible spectrum. Of course, one can have glazings in this zone with color, but this is not necessary. In the **color zone**, the only way to achieve higher visible transmittance for a given level of solar heat gain coefficient is by stripping off some of the red and blue wavelengths at the edges of the  $V-\lambda$  function with a spectrally selective glazing transmittance, imparting color to the transmitted radiation (or by

**Table 24 Daylight Transmittance for Various Types of Glass**

Type of Glass	Visible Transmittance $T_v$
3 mm regular sheet or float glass	0.86 to 0.91
3 mm gray sheet	0.31 to 0.71
5 mm gray sheet	0.61
5.5 mm gray sheet	0.14 to 0.56
6 mm gray sheet	0.52
6 mm green/float glass	0.75
6 mm gray plate glass	0.44
6 mm bronze plate glass	0.49
13 mm gray plate glass	0.21
13 mm bronze plate glass	0.25
Coated glasses (single, laminated, insulating)	0.07 to 0.50

**Fig. 34 Visible Transmittance Versus SHGC for Several Glazings with Different Spectral Selectivities**

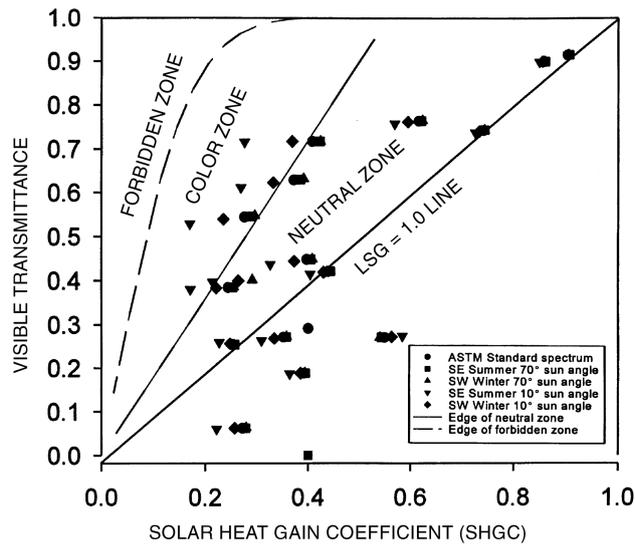

Fig. 35 Visible Transmittance Versus SHGC at Various Spectral Selectivities (McCluney 1996)

otherwise altering the spectral transmittance and hence the color over the visible portion of the spectrum). In the **forbidden zone**, no combination of visible transmittance and solar heat gain coefficient is possible for normal incidence and for the solar spectral distribution used. (Changing the solar spectral distribution used to calculate  $T_v$  and SHGC will shift the transition curves somewhat. A low solar altitude angle, direct-beam spectrum will move the curves to the left on the plot in Figure 35.) It can be seen that the glazings that transmit more solar radiant heat than light cluster on the lower portion of the plot.

The  $T_v$  versus SHGC chart can be a useful tool for illustrating the degree of spectral selectivity attained by a glazing system. These concepts lead to an index of spectral selectivity that can be useful. It is called the **light-to-solar-gain ratio**, or LSG, defined as

$$LSG = \frac{T_v}{SHGC} \quad (135)$$

Some characteristic values for  $T_v$ , SHGC, and LSG are given in Table 25 for several different glazings, using the ASTM standard spectral distribution at normal incidence to calculate the values.

The LSG can be useful in spotting errors in the calculation of the SHGC. Values of SHGC that lie outside reasonable ranges can be spotted fairly quickly and used to identify possible problems in calculations or measurements. In general, it is very difficult and therefore unlikely to have a useful glazing system for buildings with an LSG value greater than 2.0. Values near 0 should be particularly suspect, since they indicate a glazing that transmits considerably more heat than light and would be unlikely candidates for general use. Generally, a high value of LSG is desired for residential buildings in hot climates, to maximize daylight admission with minimal solar heat gain. This is also true for internal load-dominated nonresidential buildings in many climates, since solar gain rejection is often desired for such buildings, even in cool or cold climates. An LSG value somewhat below 1.0 would be appropriate in cold climates for residential buildings and nonresidential buildings without strong internal cooling loads.

Table 25 Spectral Selectivity of Several Glazings

Glazing	$T_v$	SHGC	LSG
Reflective blue-green	0.33	0.38	0.87
Film on clear glass	0.19	0.22	0.86
Green tinted, medium	0.75	0.69	1.09
Green low-e	0.71	0.49	1.45
Sun-control low-e + green	0.36	0.23	1.56
Super low-e + clear	0.71	0.40	1.77
Super low-e + green	0.60	0.30	2.00

## SELECTING FENESTRATION

Since fenestration systems provide so many functions and because environmental conditions and user needs vary widely, it is difficult to make a completely optimal selection of a fenestration system. Aesthetic and cost considerations are perhaps the most important to residential users, with visual and comfort performance also being of interest. Considering annual energy costs, peak load consequences, and acoustic characteristics, the choice is seldom optimal. The HVAC system designer, fortunately, has a more restricted range of interests, mainly dealing with the energy consequences of a particular fenestration selection. This section therefore focuses on fenestration energy performance determination.

### ANNUAL ENERGY PERFORMANCE

Instantaneous energy performance indices (U-factor, solar heat gain coefficient, air leakage, etc.) are typically used to compare fenestration systems under a fixed set of conditions. However, the absolute and relative effect of these indices on a building's heating and cooling load can fluctuate as environmental conditions change. As a result, these indices alone are not good indicators of the annual energy performance (energy savings/costs) attributable to the fenestration. Furthermore, fenestration annual energy performance is difficult to quantify in and of itself because of the many dynamic responses that occur between the fenestration system and the total environment in which it is installed. The four basic mechanisms of fenestration energy performance that were each addressed previously in the chapter—thermal heat transfer, solar heat gains, air leakage, and daylighting—should all be taken into account but are not independent of many other parameters that influence fenestration annual energy performance. As a result, the annual energy performance of fenestration systems can be accurately determined only when a large number of variables are considered. Building type and orientation, climate (weather, temperature, wind speed), microclimate (shading from adjacent buildings, trees, terrain), occupant usage patterns, and certain HVAC parameters can significantly affect the annual energy impacts of fenestration systems.

For these reasons, the most effective means of establishing fenestration annual energy performance is through detailed, dynamic, hourly computer simulations for the specific building and climate of interest. Since the instantaneous performance of the fenestration will often vary by differing magnitudes as climatic conditions change, the most accurate simulation results are obtained when these variances are accounted for in a building energy simulation computer program. After constructing the building energy simulation model following the procedures defined in Chapters 28 and 29 (for residential and commercial construction, respectively), specific changes to the fenestration system can be modeled, and the annual energy performance changes attributable to fenestration can be quantified. These analytical techniques do not consider issues of performance durability for the various instantaneous indices and should only be used as an initial annual energy performance indicator (Mathis and Garries 1995).

### Simplified Techniques for Rough Estimates of Fenestration Annual Energy Performance

While dynamic hourly modeling is certainly the most accurate technique for determining fenestration annual energy performance, it is not readily available to many decision makers and end users of fenestration products simply because it may not be practical or cost-effective. Under these circumstances, it may be useful to assess the relative importance of, or balance the trade-off between, the known instantaneous performance indices of U-factor, SHGC, air leakage, and  $T_v$  for any given fenestration system when considering heating, cooling, and lighting loads for many different building types and climates. Mitchell et al. (1999) and Huang et al. (1999) describe personal computer programs that are being developed to run this simplified analysis for residential windows.

Broad generalizations can be made for some classifications of building types and climates. For instance, with large commercial buildings, which require substantial cooling energy use because of high internal loads, significant thermal mass, or high orientation dependency, the primary objective may be to place the most emphasis on low SHGC to reduce the cooling load. Also, an evaluation of commercial fenestration annual energy use can take into account the trade-off between artificial lighting and the natural daylighting benefits associated with a particular fenestration system. Contrary to this, electric lighting loads in low-rise detached residential buildings are typically very small in comparison to the heating and cooling loads because of high envelope-dependent energy use, egress requirements, and occupant usage patterns, and therefore the energy influence of daylighting may be neglected altogether. Yet, despite these generalizations, the problem still exists of balancing and assessing the impact of each of the remaining parameters to establish the seasonal or annual energy performance for cases in which detailed computer modeling is not performed.

Realizing the need for characterization of fenestration annual energy performance, scientists in many different countries have been working over the last several years to develop simplified annual energy performance indices for fenestration. These simplified techniques typically involve using the instantaneous fenestration performance indices to quantify building- and climate-independent scalars of annual or seasonal energy performance for rating purposes. Many of these performance indices have value in that they can be relatively independent of building type, climate, distribution of products, orientation, and other items needed for hourly dynamic building energy analyses. These normalized, scalar-based approaches are also limited in accuracy for the same reasons. A further limitation with the simplified techniques is that they do not have broad applicability to varied building types (commercial versus residential buildings, for example). The usefulness of these scalar-based approaches can be increased when limiting the comparison to a single building type. Currently, the simplified techniques for characterizing fenestration annual energy performance are applicable only to fenestration systems for detached residential buildings and are not appropriate for use with multifamily residential or commercial building fenestration systems.

### Simplified Residential Annual Energy Performance Ratings

Annual energy performance ratings can provide a simple means of product comparisons for consumers. Such ratings have been derived with many assumptions, usually to suit local climatic conditions.

The Canadian Standards Association (CSA Standard A440.2) developed a simplified energy rating applicable to residential heating in the Canadian climate, which has been adopted in the 1995 *National Energy Code for Houses*. The standard also provides for specific energy ratings to compare products by orientation and climate.

In the United States, where heating and cooling are both significant, the NFRC is developing a rating system that includes both effects (Crooks et al. 1995, Arasteh et al. 2000).

### CONDENSATION RESISTANCE

Water vapor condenses in a film on fenestration surfaces that are at temperatures below the dew-point temperature of the inside air. If the surface temperature is below freezing, frost forms. Sometimes, condensation occurs first, and ice from the condensed water forms when temperatures drop below freezing. Condensation frequently occurs on single glazing and on aluminum frames without a thermal break. The edge-seal creates a thermal bridge at the perimeter of the IGU.

The circulation of fill gas due to temperature differences in the IGU cavity contributes to the condensation problem at the bottom of the indoor glazing (Wright and Sullivan 1995a, 1995b; Curcija and Goss 1994, 1995a). In winter, fill gas near the indoor glazing is warmed and flows up, while gas near the outdoor glazing is cooled and flows down. The descending gas becomes progressively colder until it reaches the bottom of the cavity. There, the gas turns and flows to the indoor glazing, resulting in higher heat transfer rates at the bottom. Thus, the bottom edge of the indoor glazing is cooled both by edge-seal conduction and by fill-gas convection. The combined effect of these two heat transfer mechanisms is shown in Figure 36. The surface isotherms show a wider band of cold glass at the bottom of the window. Typical condensation patterns match these isotherms. The vertical indoor surface temperature profile also shows the effect of edge-seal conduction and that the minimum indoor surface temperature is near the bottom edge of the glass.

Condensation to the fenestration and surrounding structures can cause extensive structural, aesthetic, and health problems. Specific examples include peeling of paint, rotting of wood, saturation of insulation, and mold growth. Ice can render doors and windows inoperable and prevent egress during an emergency.

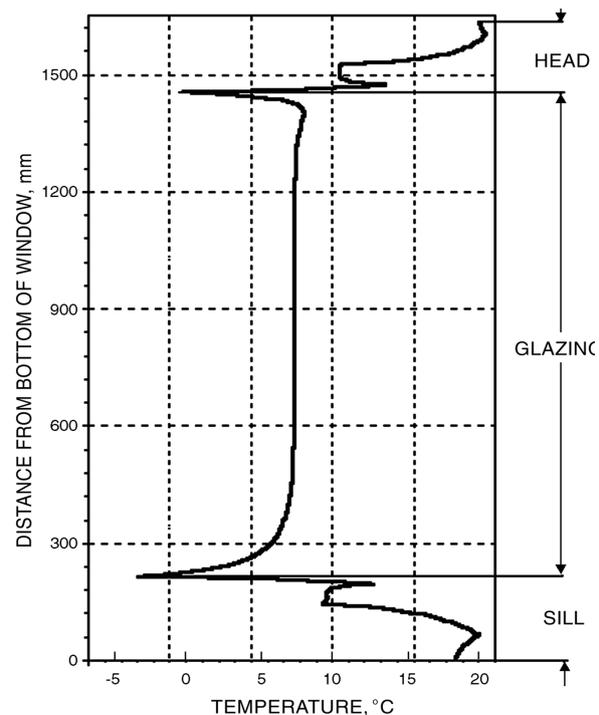

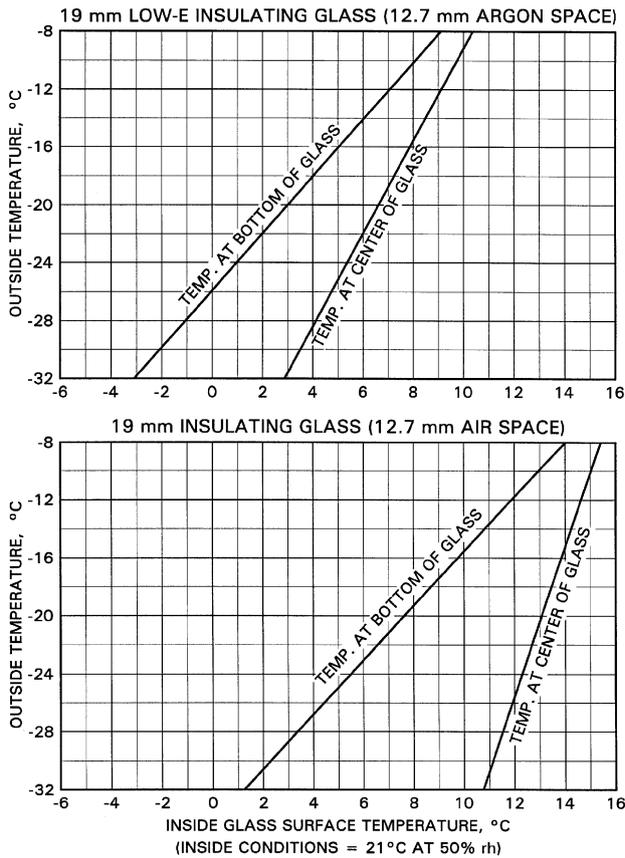

Fig. 36 Temperature Distribution on Indoor Surfaces of Insulating Glazing Unit

**Fig. 37 Minimum Indoor Surface Temperatures Before Condensation Occurs**

Energy-efficient housing has been accompanied by reduced ventilation. The resulting increase in indoor humidity has contributed to the condensation problem. However, the solution does not lie in the reduction of humidity levels to a minimum. Relative humidity below 20% and above 70% can increase health risks and reduce comfort. Generally, a minimum of 30% rh should be maintained, and 40% to 50% is more desirable (Sterling et al. 1985).

Minimum indoor surface temperatures can be quantified in a variety of ways. Sullivan et al. (1996), Griffith et al. (1996), Elmahdy (1996), Zhao et al. (1996), and de Abreu et al. (1996) demonstrated good agreement between detailed two-dimensional numerical simulation and surface temperature measurements using thermographs. Wright and Sullivan (1995c), and Curcija et al. (1996) developed simplified simulation models to predict condensation resistance. Estimates of center-glass and bottom-edge surface temperatures that can be expected for two different glazing systems exposed to a range of outdoor temperature are shown in Figure 36. Both glazing systems include insulating foam edge seals. High-performance glazing systems (e.g., low-e/argon and insulated spacers) permit significantly higher indoor humidity levels.

Current measures of condensation resistance of a fenestration system are the **condensation index** (CI) as defined by NFRC (2000a), the **condensation resistance factor** (CRF) as defined by AAMA (1988), or the **temperature index** (I), as defined in CSA Standards A440 and A440.1.

The condensation index is a measure of condensation potential that is based on both area and temperature weighting and is expressed as a minimum of center-of-glazing, edge-of-glazing, and frame CIs. The novelty of this index lies in the fact that it is determined using computer simulation tools unless the overall thermal performance cannot be validated with testing. In the case

that thermal performance cannot be validated, a testing option for determining CI is used.

Computer simulation is done for characteristic two-dimensional cross sections in much the same way that U-factors are determined. The basic difference between U-factor and CI simulations is that more advanced models are used for CI calculations. This is necessary because temperatures are intrinsically local quantities, as opposed to U-factors, which are average quantities, and it is necessary to provide better models for convective heat transfer in glazing cavities and convective and radiative heat transfer on indoor fenestration boundaries. The most general expression of the formula for calculating frame, center-of-glazing, and edge-of-glazing CI is given by the following equation:

$$CI = \left\{ 1 - \left\{ \frac{1}{3} \sum_{j=1}^3 \left[ \frac{\sum_i (t_{dpp,j} - t_i)^+ A_i}{(t_{dpp,j} - t_o) A} \right] \right\}^{1/3} \right\} \times 100 \quad (136)$$

where

- $i$  = frame, center-of-glazing, or edge-of-glazing section
- $j$  = 30%, 50%, and 70% relative humidity
- $t_{dpp} = t_{dp} + 0.3 \text{ K}$
- $t_{dp}$  = dew-point temperature, °C
- $+$  = positive values only

The other two standards define the values by a single dimensionless number as

$$CRF \text{ or } I = \frac{t_h - t_c}{t_h - t_c} \quad (137)$$

where  $t_h$  and  $t_c$  are the warm and cold side temperatures, respectively. Figure 38 can be used to determine the acceptable range of CRF/I for a specific climatic zone.

The two standards differ in the methods used to determine temperature. The CSA test procedure is based on thermocouple measurements at the coldest location on the frame plus three locations on the glass, each X mm above the bottom sightline. The AAMA procedure specifies two separate factors: one for the frame (CRF<sub>F</sub>), which uses weighted frame temperature obtained from surface temperature measurements at predetermined and roving locations on the frame, and one for the IGU (CRF<sub>G</sub>), which uses the average of six temperatures measured at predetermined locations near the top, middle, and bottom of the glazed area.

Inside details can significantly alter the potential for condensation on window surfaces. Items such as venetian blinds, roll blinds, insect screens, and drapes increase the thermal resistance between the indoor space and the window and lower the temperature of the window surfaces. These window treatments do not prevent migration of moisture, so they can cause increased condensation. Figure 39 shows different situations that affect the potential for condensation. Note that window reveal plays an important role. If the window is placed near the outside of the wall, the increase in the outdoor film coefficient and decrease in the indoor film coefficient cause colder window surfaces. This effect is more pronounced near the corners of the recess where the indoor film coefficient is locally suppressed because air movement is restricted. Also, blinds should be placed at least 100 mm from the plane of the wall to allow some natural convection between the window and the blind.

Air leakage, especially in operable sections of fenestration, is another important cause of low surface temperature. Leakage near the edge-of-glass sections can further increase the potential for condensation. However, the drier outdoor air decreases the relative humidity near the leakage sites and, in some cases, offsets the

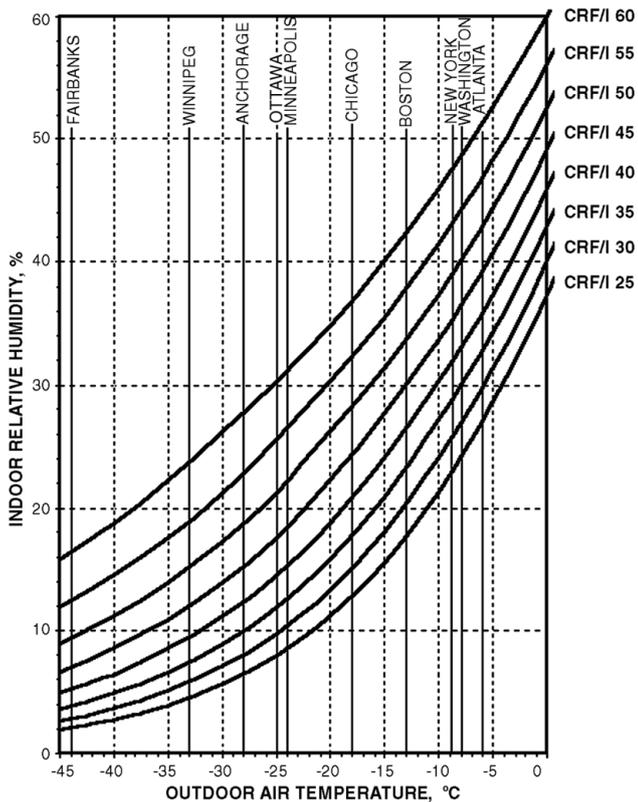

Fig. 38 Minimum Condensation Resistance Requirements ( $t_h = 20^\circ\text{C}$ )

undesirable effect of the lower surface temperatures. The net effect of air leakage cannot readily be determined experimentally or with simulation.

### OCCUPANT COMFORT AND ACCEPTANCE

Human thermal comfort is an immediate sensation that reflects building occupants' perceived response to many physical factors. Unlike much building design that is based primarily on long-term energy and economic considerations, comfort-related design focuses on, and must take heed of, short-term responses of the body's physiology to its surroundings.

Windows influence thermal comfort through a combination of three mechanisms: long-wave radiation exchange, absorption of solar radiation, and convective draft effects (Figure 40). An understanding of these phenomena is important to help designers evaluate the benefits of improved windows and create comfortable buildings. Although it is well understood that high-performance windows can reduce building energy consumption, a better understanding of their impact on comfort might lead to further savings. For example, Hawthorne and Reilly (2000) suggest that significant energy consumption is caused by the standard practice of using perimeter duct distribution in houses to mitigate potential discomfort caused by windows. They found that perimeter heating is often not necessary when high-performance windows are installed and that heating energy savings of 10 to 15% could result from installing a simpler, less expensive duct system. Better windows can allow thermostat settings to be lowered with no loss of comfort. Another simulation study (Lyons et al. 2000) examined the relative magnitudes of a residential window's physical influences under a wide variety of winter and summer climates, glazing parameters, and clothing levels. They found that

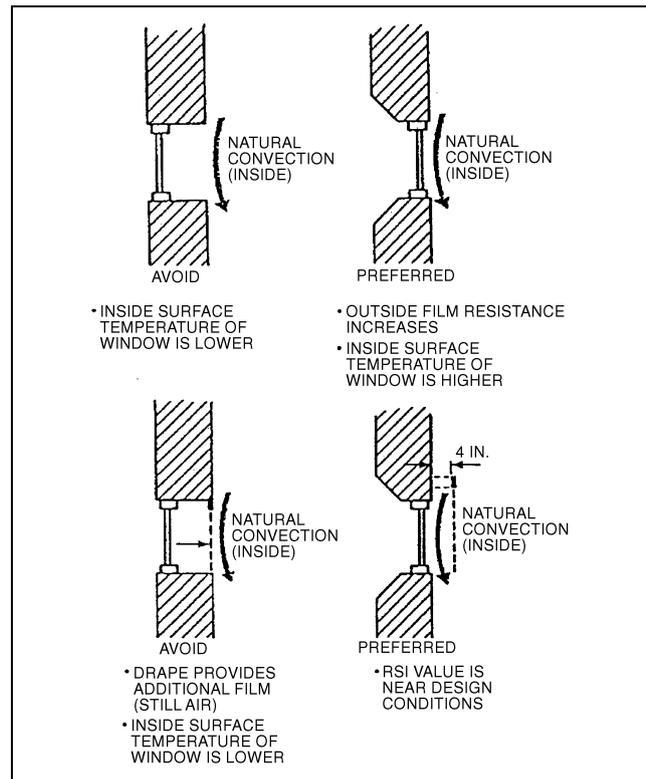

Fig. 39 Location of Fenestration Product Reveals and Blinds/Drapes and Their Effect on Condensation Resistance

- Long-wave, thermal radiation influences of the window dominate unless direct sun strikes the occupant
- Direct solar load has a major influence on perceptions of comfort
- For most residential-size windows, draft effects are generally small

With all but highly insulating windows, the inside surface temperature of the window is heavily influenced by exterior conditions, and this temperature can significantly affect the radiant heat exchange between an occupant and the environment. If this heat exchange moves outside the acceptable range, discomfort will result. Mean radiant temperature (MRT) is commonly used to simplify the characterization of the radiant environment. On a cold day, the inside surface temperature can easily drop below  $-9^\circ\text{C}$  for a clear single-pane window and below  $4^\circ\text{C}$  for a clear, double-pane window. If the occupant is sitting sufficiently near the window, MRT could drop to  $13^\circ\text{C}$  for the single-pane case and  $17^\circ\text{C}$  for the double-pane case. Based on ASHRAE *Standard 55*, even the use of the clear double-pane window could result in discomfort. [This example assumes an outdoor air temperature of  $-18^\circ\text{C}$ , indoor air temperature of  $22^\circ\text{C}$ , nonwindow surface temperatures of  $22^\circ\text{C}$ , occupant-window view factor of 0.3, 0.9 clo (standard winter indoor clothing), and activity level of 1 met.] In addition to the MRT effect, a cold inside glass surface can induce a downward draft that increases air movement, contributing to further discomfort. If direct solar radiation strikes the glazing or occupant, the situation is much more complex.

In winter, the warming effect of sunlight on skin and clothing is often welcome, depending on the compounding effect of other factors such as air temperature. Windows also absorb and transmit a significant amount of solar radiation. Because of such absorption, a solar-heated window may improve MRT for a nearby person. The premise of passive solar design is that occupants will welcome, or at least tolerate, solar gain in exchange for savings on heating energy. However, it is desirable that the onset of discomfort be able to be

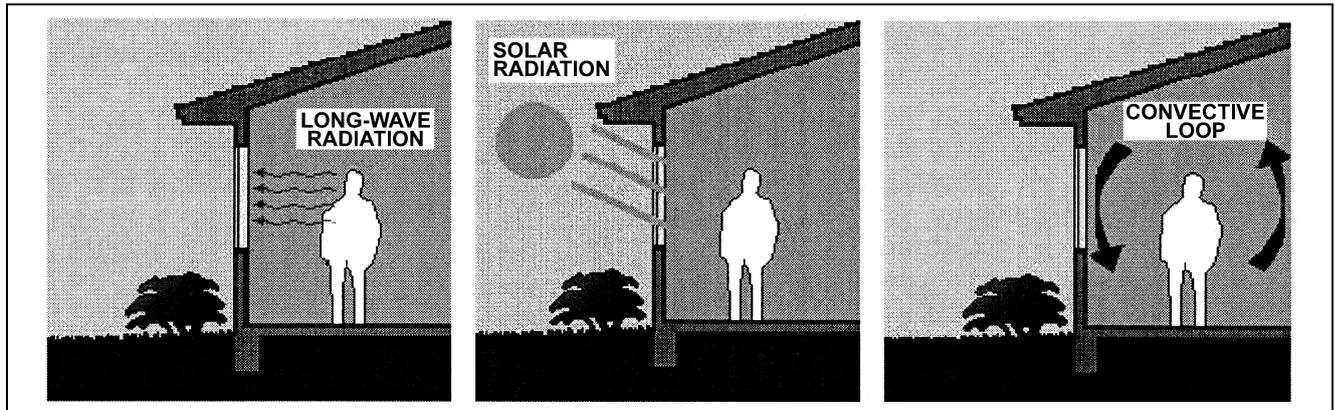

Fig. 40 Fenestration Impacts on Thermal Comfort: Long-Wave Radiation, Solar Radiation, Convective Draft

predicted; otherwise, the energy-saving design may be defeated if occupants draw shades to prevent overheating.

In summer, solar-heated glass may become uncomfortably hot and, in commercial premises, actually devalue rented space near windows. The inside surface of body-tinted, heat-absorbing glass can routinely reach temperatures above 50°C in summer conditions, raising MRT by as much as 8 K. This can be ameliorated with the addition of a second pane of glass on the inside. Transmitted radiation often causes discomfort if it falls directly on the occupant. A person sitting near a window in direct solar radiation can experience heat gain equivalent to a 11 K rise in MRT [Arens et al. (1986)]. Similarly, in residential applications, the perceived need for solar control is affected both by the contribution of window surfaces to MRT and by overheating due to direct solar load.

Advances in window technology, especially high-performance glazings, mean that the designer has a choice of potential glazing systems. On the basis of annual energy performance for heating, cooling, and lighting, these alternatives may give similar outcomes. However, because they represent different combinations of U-factor, SHGC, and inside glass surface temperature, their comfort outcomes may differ considerably. Research continues to develop tools that will help designers evaluate such difficult trade-offs. In the meantime, several general rules of thumb may be followed:

- In heating-dominated climates, windows with the lowest U-factor tend to give the best comfort outcomes. However, there is likely to be a trade-off between the twin goals of maximizing instantaneous comfort and minimizing annual energy consumption.
- In cooling-dominated climates or for orientations where cooling loads are of concern, windows with the lowest rise in surface temperature for a given SHGC tend to give the best comfort outcomes.

Table 26 Sound Transmittance Loss for Various Types of Glass

Type of Glass	Sound Transmittance Loss, dB
3 mm double-strength sheet glass	24
6 mm plate or float glass	27
13 mm plate glass	32
19 mm. plate glass	35
25 mm plate glass	36
6 mm. laminated glass (11 mm plastic interlayer)	30
25 mm insulating glass	32
13 mm laminated glass (11 mm plastic interlayer)	34
Insulating glass, 150 mm air space, 6 mm plate or float glass	40

### Sound Reduction

Proper acoustical treatment of exterior walls can decrease noise levels in certain areas. The airtightness of a wall is the primary factor to consider in reducing sound transmission from the exterior. Once walls and fenestration products are tight, the choice of glass and draperies becomes important. Draperies do not prevent sound from coming through the fenestration; they act as an absorber for sound that does penetrate. Table 26 lists average sound transmission losses for various types of glass. These averages apply for the frequency range of 125 to 4000 Hz and were determined by tests based on ASTM *Standard E 90*.

### Strength and Safety

In addition to its thermal, visual, and aesthetic functions, glass for building exteriors must also perform well structurally. Wind loads are specified in most building codes, and these requirements may be adequate for many structures. However, detailed wind tunnel tests should be run for tall or unusually shaped buildings and for buildings where the surroundings create unusual wind patterns. The strength of annealed, heat-strengthened, tempered, laminated, and insulated glass is given in ASTM *Standard E 1300*.

Thermal expansion and contraction of glass can result in breakage of ordinary annealed glass. This expansion and contraction can be caused by solar radiation onto partly shaded glass, by heat traps from drop ceilings and tight-fitting drapes, or by HVAC ducts incorrectly directed toward the glazing. High-performance tinted and reflective glasses with low-e coatings are usually more vulnerable to thermal stress breakage than clear glass. Heat treating (heat strengthening or fully tempering) the glass resists thermal stress breakage. Heat-strengthened glass, although not a safety glass, is usually preferred to tempered (safety) glass because it typically has less distortion and is much less likely to have spontaneous breakage. Spontaneous breakage can occur on very rare occasions in tempered glass. The glass manufacturer or fabricator should be consulted for information on thermal stress performance.

Building codes may require glass in certain positions to perform with certain breakage characteristics, which can be satisfied by tempered, laminated, or wired glass. In this case, glass should meet *Federal Standard 16 CFR 1201* or other appropriate breakage performance requirements.

### Life-Cycle Costs

Alternative building shells should be compared to ensure satisfactory energy use and total energy budget compliance, if required. ASHRAE *Standards 90.1* and *90.2* should be used as a starting point. A life-cycle cost model should be developed for each system considered. See Chapter 35 of the 1999 *ASHRAE Handbook—Applications*.

## DURABILITY

The service life and long-term performance of fenestration systems depend on the durability of all the components that make up the system. Representative samples of IGUs are usually tested (for seal durability) according to test methods to ensure the integrity of the seal. Failure of IGUs is usually indicated by loss of adhesion of sealant to the glass; as a result, fogging occurs inside the glazing cavity.

In the case of argon-filled units, the seal failure means the loss of argon and, hence, degradation in the thermal characteristics of the unit. Extensive work was done at the National Research Council of Canada to study the durability of IGUs filled with argon gas (Elmahdy and Yusuf 1995). The results indicated that, under normal conditions, argon loss due to diffusion through the sealant is very small. However, when cracks or pinholes exist in the sealant, most of the argon gas escapes from the unit, which implies that the implementation of stringent quality control procedures is essential for the production of durable IGUs.

The degradation of organic materials and other chemical components in the IGUs, as a result of exposure to ultraviolet radiation, is also among the factors affecting the durability and service life of fenestration systems. The use of low-e coating on glass tends to enhance the appearance of chemical deposits on the glass surface. Also, the insertion of muntin bars in the glazing cavities may result in excessive rate of unit failure during the ultraviolet volatile (fogging) test unless strict quality assurance processes are implemented. The current ASTM (United States) and CGSB (Canada) durability standards are being reviewed to reflect the emergence of new technologies in the fenestration industry.

Insulating glass products have been studied in a 15-year correlation study by the Sealed Insulating Glass Manufacturers Association (SIGMA). During this study, it was found that long-term performance and durability of insulating glass correlated well with the test level to which such a unit's construction had been manufactured with regard to the ASTM *Standard E 773* test method and ASTM *Standard E 774* specification for sealed insulating glass. The units showing the highest percentage of resistance to seal failure were those that were tested in conformance with the ASTM *Standard E 774* Class CBA standard. Units that did not qualify to the A level showed a definite correlation to a higher percentage of failure. During the field correlation studies, it was found that units glazed in compliance with the SIGMA recommendations perform for longer periods than units not constructed properly, having deficiencies in the glazing system, or not meeting the ASTM requirements.

The durability of fenestration systems is also dependent on the durability of other system components such as the weatherstripping, gaskets, glazing tapes, air seals, and hardware. The wear and tear of these elements with time and use may result in excessive air and water leakage, which will affect the overall performance and the service life of the system. Excessive water leakage may result in damage to the fenestration product, especially the edge seal, as well as the wall section where the product is mounted. Excessive air leakage may lead to frost buildup and condensation on the fenestration surfaces.

Studies conducted at the National Research Council of Canada (Elmahdy 1995) and elsewhere (Patenaude 1995) showed that when windows are tested at high pressure and temperature differentials, they experience air leakage rates which exceed those determined at 75 Pa and zero temperature differential (these conditions are used in rating the window air leakage in U.S. and Canadian standards). In other studies (CANMET 1991, 1993), the effect of pressure and motion cycling on windows resulted in excessive degradation in almost all the window performance factors, particularly the condensation resistance, ease of operation, air leakage, and water leakage.

In order to predict long-term performance, the unit construction for insulating glass should be subjected to a test and certification

program such as ASTM *Standard E 774* Class CBA level and the requirements of SIGMA or CGSB *Standard 12.8* certified by the Insulating Glass Manufacturers Association of Canada (IGMAC) or equivalent.

In addition to affecting the fenestration performance factors mentioned above, durability may also affect long-term energy performance.

## CODES AND STANDARDS

### National Fenestration Rating Council (NFRC)

The National Fenestration Rating Council (NFRC) was formed in 1989 to respond to a need for fair, accurate, and credible ratings for fenestration products. NFRC has adopted rating procedures for U-factor (NFRC 100), solar heat gain coefficient and visible transmittance (NFRC 200), optical properties (NFRC 300), emissivities (NFRC 301), and air leakage (NFRC 400). To provide certified ratings, manufacturers follow the requirements in the NFRC *Product Certification Program* (PCP) which involves working with laboratories accredited to the NFRC *Laboratory Accreditation Program* (LAP) and independent certification and inspection agencies accredited through the NFRC *Certification Agency Program* (CAP).

NFRC 100 was the first of the NFRC rating procedures approved and thus the first NFRC procedure adopted into energy codes in the United States. NFRC 100 requires the use of a combination of state-of-the-art computer simulations and improved thermal testing to determine U-factors for the whole product. The next step is product certification. NFRC has a series of checks and balances to ensure that the rating system is accurately and uniformly employed. Products and their ratings are authorized for certification by an NFRC-licensed independent certification and inspection agency (IA). Finally, two labels are required: the temporary label, which contains the product ratings, and a permanent label, which allows tracking back to the IA and information in the NFRC *Product Directory*. In addition to informing the buyer, the temporary label provides the building inspector with the information necessary to verify energy code compliance. The permanent label provides access to energy rating information for a future owner, property manager, building inspector, lending agency, or building energy rating organization.

This process has a number of noteworthy features that make it superior to previous fenestration energy rating systems and correct past problems:

- The procedures provide a means for manufacturers to take credit for all the nuances and refinement in their product design and a common basis for others to compare product claims.
- The involvement of independent laboratories and the IA provides architects, engineers, designers, contractors, consumers, building officials, and utility representatives with greater confidence that the information is unbiased.
- Requiring simulation and testing provides an automatic check on accuracy. This also remedies a shortcoming of previous energy code requirements that relied on testing alone, which allowed manufacturers to perform several tests and then use the best one for code purposes.
- The certification process indicates that the manufacturer is consistently producing the product that was rated. This corrects a past concern that manufacturers were able to make an exceptionally high quality sample and obtain a good rating in a test but not consistently produce that product.
- There is now a readily visible temporary label that can be used by the building inspector to quickly verify compliance with the energy code.
- There is now a permanent label that enables future access to energy rating information.

While the NFRC program is similar for other fenestration characteristics, there are differences worth pointing out. The solar heat gain coefficient and visible transmittance ratings (NFRC 200), which have been referenced in several codes, are based on simulation alone. Optical properties (NFRC 300) and emissivity (NFRC 301) are based on measurements by the manufacturer, with independent verification. The air leakage ratings (NFRC 400) are based on testing alone. For site-assembled fenestration products (such as curtain walls and window walls), there is an NFRC label certificate that fulfills the labeling requirements and serves the certification purpose. There must be a separate NFRC label certificate for each "individual product" in a particular project.

#### United States Energy Policy Act (EPAct)

In the United States, the 1992 Energy Policy Act (EPAct) required the development of national fenestration energy rating systems and specified NFRC as the preferred developer. (The U.S. Department of Energy was to establish procedures if the NFRC did not.) While this recognition provided an impetus for NFRC to develop the desired procedures and programs, the EPAct sections on energy codes have been a key factor in their implementation.

EPAct set energy code baselines for state energy codes. The ICC 2000 *International Energy Conservation Code* (IECC) and ASHRAE/IESNA *Standard 90.1-1999, Energy Standard for Buildings Except Low-Rise Residential Buildings* are the current successors to the versions cited in the 1992 legislation. The majority of states have adopted the predecessors to the 2000 *IECC* (including the 1998 *IECC* and the CABO 1995 *Model Energy Code*) and to ASHRAE/IESNA *Standard 90.1-1999* (i.e., ASHRAE/IESNA *Standard 90.1-1989*) into their codes either directly or by reference when adopting a building code published by one of the three national code organizations in the United States. The ICC 2000 *International Building Code* (the U.S. model building code jointly developed by ICBO, BOCA, and SBCCI) references the 2000 *International Energy Conservation Code*.

#### The ICC 2000 International Energy Conservation Code

The ICC 2000 *International Energy Conservation Code* (IECC) references NFRC 100 for U-factor (as did the 1998 *IECC* and the 1995 *Model Energy Code*) and NFRC 200 for solar heat gain coefficient (SHGC) (as did the 1998 *IECC*). Section 102.3, which applies to all occupancies, requires U-factors of fenestration products (windows, doors, and skylights) to be determined in accordance with NFRC 100 by an accredited independent laboratory and labeled and certified by the manufacturer. While the language does not specify NFRC accreditation, it both requires the use of the NFRC rating procedure by an independent entity and requires labeling and certification.

#### ASHRAE/IESNA Standard 90.1-1999

In 1999, ASHRAE and IESNA published a comprehensive update to the 1989 version of *Standard 90.1*. The fenestration rating, labeling, and certification criteria are in Sections 5.2.2 and 5.2.3. U-factors are to be determined in accordance with NFRC 100, solar heat gain coefficient in accordance with NFRC 200, visible transmittance in accordance with NFRC 300, and air leakage in accordance with NFRC 400.

For further information on U.S. energy codes, the Building Codes Assistance Project (BCAP) publishes a bimonthly summary entitled "Status of State Energy Codes," which provides information on current codes and pending legislation. For additional information, contact BCAP at 1200 18th Street NW, Suite 900, Washington DC 20036; voice: 202-530-2200; fax: 202-331-9588; e-mail: bcap@ase.org; website: <http://solstice.crest.org/efficiency/bcap/update.html>.

#### Canadian Standards Association (CSA)

In Canada, the Canadian Standards Association (CSA) promulgates fenestration energy rating standards. CSA *Standard A440.2*

addresses most fenestration products, and CSA *Standard A453* addresses doors. These are companion standards to NFRC 100. NFRC and CSA have established a Thermal Harmonization Task Force to attempt to harmonize their fenestration energy rating standards.

### SYMBOLS

$a$	= absorptance in a layer, considered as an isolated layer
$A$	= apparent solar constant
$A$	= total projected area of the fenestration product
AST	= apparent solar time
$B$	= atmospheric extinction coefficient
$C$	= sky diffuse factor
$e$	= hemispherical emissivity
$E_{DN}$	= direct normal irradiance
$E_D$	= direct irradiance
$E_d$	= diffuse sky irradiance
$E_r$	= diffuse ground reflected irradiance
$E_t$	= total irradiance
ET	= equation of time
$h$	= surface heat transfer coefficient
$H$	= fenestration product height
$H$	= hour angle
$k$	= thermal conductivity
$L$	= latitude
LON	= longitude
LSM	= local standard meridian
LST	= local standard time
$n$	= refractive index
$P_V$	= vertical projection depth
$P_H$	= horizontal projection depth
$q$	= instantaneous energy flux
$Q$	= instantaneous energy flow
$R$	= reflectance of a layer or collection of layers (system or subsystem)
$R_H$	= height of opaque surface between fenestration product and horizontal projection
$R_W$	= width of opaque surface between fenestration product and vertical projection
SHGC	= solar heat gain coefficient
$t$	= relative temperature
$T$	= absolute temperature
$T$	= transmittance of a layer or collection of layers (system or subsystem)
$U$	= overall coefficient of heat transfer
$W$	= fenestration product width
$Y$	= ratio of vertical/horizontal sky diffuse
$\alpha$	= material absorptivity
$\beta$	= solar altitude
$\delta$	= declination
$\Delta$	= vertical projection profile angle
$\phi$	= solar azimuth
$\gamma$	= surface solar azimuth
$\eta$	= day of year
$\lambda$	= wavelength
$\theta$	= incident angle
$\rho_g$	= ground reflectance
$\bar{\omega}$	= solid angle
$\Omega$	= horizontal projection profile angle
$\xi$	= refractive angle
$\psi$	= surface azimuth
$\Sigma$	= surface tilt
$\bar{A}$	= absorptance in a layer or a collection of layers (system or subsystem)

## GENERAL CONSIDERATIONS

**T**HE ENERGY requirements and fuel consumption of HVAC systems have a direct impact on the cost of operating a building and an indirect impact on the environment. This chapter discusses methods for estimating energy use for two purposes: modeling for the design of buildings and HVAC systems and associated design optimization (**forward modeling**); and modeling the energy use of existing buildings for establishing baselines and calculating retrofit savings (**inverse modeling**).

### FORWARD AND INVERSE MODELS

A mathematical **model** is a description of the behavior of a system. It is made up of three components (Beck and Arnold 1977):

1. **Input variables** (statisticians call these regressor variables while physicists refer to them as forcing variables), which act on the system. Note that there are two types of such variables: controllable by the experimenter, and such uncontrollable variables as climate.
2. **System structure and parameters/properties**, which provide the necessary physical description of the system (for example, thermal mass or mechanical properties of the elements).
3. **Output** (or response or dependent) variables, which describe the reaction of the system to the input variables. Energy use is often a response variable.

The science of mathematical modeling as applied to physical systems involves determining the third component of a system when the other two components are given or specified. We can broadly differentiate between two distinct categories of modeling, the choice of which is dictated essentially by the objective or purpose behind the investigation (Rabl 1988).

**Forward or Classical Approach.** The objective is to predict the output variables of a specified model with known structure and known parameters when subject to specified input variables. In order to ensure accuracy of prediction, the models have tended to become increasingly complex, especially with the advent of cheap and powerful computing power. This approach presumes detailed knowledge not only of the various natural phenomena affecting system behavior but also of the magnitude of various interactions (e.g., effective thermal mass, heat and mass transfer coefficients, etc.). The main advantage of this approach is that the system need not be physically built in order to predict its behavior. Thus, this approach

is ideal in the preliminary design and analysis stage and is most often employed as such.

Forward modeling as applied to building energy use begins with a physical description of the building system or component of interest. For example, we define the building geometry, geographical location, physical characteristics (such as wall material and thickness), type of equipment and operating schedules, type of HVAC system, building operating schedules, plant equipment, etc. The peak and average energy use of such a building can then be predicted or simulated by the forward simulation model. The primary benefits of this method are that it is based on sound engineering principles usually taught in colleges and universities and consequently has gained widespread acceptance by the design and professional community. Major government-developed simulation codes, such as BLAST, DOE-2, and EnergyPlus, are based on forward simulation models. Figure 1 is a flow chart that illustrates the ordering of the analysis that is typically performed by a building energy simulation program.

**Inverse or Data-Driven Approach.** In this case, the input and output variables are known and measured, and the objective is to determine a mathematical description of the system and to estimate the system parameters. In contrast to the forward approach, the inverse approach is relevant to the case when the system has already been built and actual performance data are available for model development and/or identification. Two types of performance data can be used: nonintrusive and intrusive. **Intrusive data** are gathered under conditions of certain predetermined or planned experiments on the system in order to elicit system response under a wider range of system performance than would have occurred under normal system operation. Such performance data allow for more accurate model specification and identification. When constraints on system operation do not permit such tests to be performed, the model must be identified from **nonintrusive data** obtained under normal operation.

The inverse modeling approach often allows identification of system models that are not only simpler to use but that are more accurate predictors of future system performance than forward models. The inverse approach arises in many fields, such as physics, biology, engineering, and economics. Although several monographs, textbooks, and even specialized technical journals are available in this area, the approach has not been widely adopted in energy-related curricula and has yet to diffuse in a significant and pervasive manner (as has the forward approach) into the building professional community.

The preparation of this chapter is assigned to TC 4.7, Energy Calculations.

## CHARACTERISTICS OF MODELS

### Forward Models

Although the procedures for estimating energy requirements vary considerably in their degree of complexity, they all have three common elements: the calculation of (1) space load, (2) secondary equipment load, and (3) primary equipment energy requirements. Here, secondary refers to equipment that distributes the heating, cooling, or ventilating medium to conditioned spaces, while primary refers to central plant equipment that converts fuel or electric energy to heating or cooling effect. A major distinction is made between **steady-state** methods (based on degree-days or temperature bins) and **dynamic** methods (e.g., based on transfer functions).

The first step in calculating energy requirements is to determine the **space load**, which is the amount of energy that must be added to or extracted from a space to maintain thermal comfort. The simplest procedures assume that the energy required to maintain comfort is only a function of the outdoor dry-bulb temperature. More detailed methods consider solar effects, internal gains, heat storage in the walls and interiors, and the effects of wind on both building envelope heat transfer and infiltration. Chapters 28 and 29 discuss load calculation in detail.

While energy calculations are similar to the heating and cooling load calculations used to size equipment, they are not the same. Energy calculations are based on average use and typical weather conditions rather than on maximum use and worst-case weather. Currently, the most sophisticated procedures are based on hourly profiles for climatic conditions and operational characteristics for a number of typical days of the year or on 8760 h of operation per year.

The second step translates the space load to a **load on the secondary equipment**. This can be a simple estimate of duct or piping losses or gains or a complex hour-by-hour simulation of an air system, such as variable air volume with outdoor-air cooling. This step must include the calculation of all forms of energy required by the

secondary system (i.e., electrical energy to operate fans and/or pumps, as well as energy in the form of heated or chilled water).

The third step calculates the fuel and **energy required by the primary equipment** to meet these loads and the peak demand on the utility system. It considers equipment efficiencies and part-load characteristics. It is often necessary to keep track of the different forms of energy, such as electrical, natural gas, or oil. In some cases, where calculations are required to assure compliance with codes or standards, these energies must be converted to source energy or resource consumed, as opposed to energy delivered to the building boundary.

Often, energy calculations lead to an economic analysis to establish the cost-effectiveness of conservation measures (ASHRAE *Standard* 90.1). Thus, thorough energy analysis provides intermediate data, such as time of energy usage and maximum demand, so that utility charges can be accurately estimated. Although not part of the energy calculations, estimated capital equipment costs should be included in such an analysis.

Complex and often unexpected interactions can occur between the systems or between various modes of heat transfer. For example, radiant heating panels impact the space loads by raising the mean radiant temperature in the space (Howell and Suryanarayana 1990). As a result, the air temperature can be lowered while maintaining comfort. Compared to a conventional heated air system, radiant panels create a greater temperature difference from the inside surface to the outside air. Thus, conduction losses through the walls and roof increase because the inside surface temperatures are greater. At the same time, the heating load due to infiltration or ventilation decreases because of the reduced indoor air to outdoor air temperature difference. The infiltration rate may also decrease because the reduced air temperature difference reduces the stack effect.

### Inverse Models

The inverse model has to meet requirements very different from the forward model. The inverse model can only contain a relatively small number of parameters because of the limited and often repetitive information contained in the performance data. (For example, building operation from one day to the next is fairly repetitive.) The inverse model is thus a much simpler model that contains fewer terms representative of aggregated or macroscopic parameters (e.g., overall building heat loss coefficient and time constants). Since the model parameters are deduced from actual building performance, it is much more likely to accurately capture the as-built system performance, thus allowing more accurate prediction of future system behavior under certain specific circumstances. Performance data collection and model formulation need to be appropriately tailored for the specific circumstance, which often requires a higher level of skill and expertise of the user. In general, inverse models are less flexible than forward models in evaluating energy implications of different design and operational alternatives, and so they are not a substitute in this regard.

To better understand the uses of inverse models, consider some of the questions that a building professional may ask about an existing building whose energy consumption is known (Rabl 1988):

- How does the consumption compare with design predictions (and, in case of discrepancies, are they due to anomalous weather, to unintended building operation, to improper operation, or to other causes)?
- How would the consumption change if the thermostat settings, ventilation rates, or indoor lighting levels were changed?
- How much energy could be saved by retrofits to the building shell, changes to air handler operation from CV to VAV, or changes in the various control settings?
- If the retrofits are implemented, can one verify that the savings are due to the retrofit and not to other causes (e.g., the weather)?
- How can one detect faults in HVAC equipment and optimize control and operation?

All the above questions are better addressed by the inverse approach. The forward approach could also be used, for example, by going back to the blueprints of the building and of the HVAC system, and repeating the analysis performed at the design stage while using actual building schedules and operating modes. This, however, is tedious and labor-intensive, and materials and equipment often perform differently under as-built conditions than as specified. Tuning the forward simulation model is often awkward and labor intensive, although it is still an option (as adopted in the calibrated inverse approach).

### CHOOSING AN ANALYSIS METHOD

The most important step in selecting an energy analysis method is to match the method capabilities with project requirements. The method must be capable of evaluating all design options with sufficient accuracy to make correct choices. The following factors apply generally (Sonderegger 1985):

- **Accuracy.** The method should be sufficiently accurate to allow correct choices. Because of the many parameters involved in energy estimation, absolutely accurate energy prediction is not possible (Waltz 1992).
- **Sensitivity.** The method should be sensitive to the design options being considered. The difference in energy use between two choices should be accurate.
- **Versatility.** The method should allow the analysis of all options under consideration. When different methods must be used to consider different options, an accurate estimate of the differential energy use cannot be made.
- **Speed and cost.** The total time (gathering data, preparing input, calculations, and analysis of output) to make an analysis should be appropriate to the potential benefits gained. With greater speed, more options can be considered in a given time. The cost of analysis is largely determined by the total time of analysis.
- **Reproducibility.** The method should not allow so many vaguely defined choices that different analysts would get completely different results (Corson 1992).
- **Ease of use.** This impacts both on the economics of analysis (speed) and the reproducibility of results.

ASHRAE *Standard* 140, Method of Test for the Evaluation of Building Energy Analysis Computer Programs, has been developed to identify and diagnose differences in predictions that may possibly be caused by algorithmic differences, modeling limitations, or coding errors.

### Selecting Energy Analysis Computer Programs

The selection of a building energy analysis program depends on its application, the number of times it will be used, the experience of the user, and the hardware available to run it. The first criterion is the capability of the program to deal with the application. For example, if the effect of a shading device is to be analyzed on a building that will also be shaded by other buildings part of the time, the capability of analyzing detached shading is an absolute requirement, regardless of any other factors.

Because almost all manual methods are now implemented on a computer, the selection of an energy analysis method is the selection of a computer program. Today, all well-known programs run on microcomputers. However, the cost of the computer facilities and the software itself are typically a small part of running a building energy analysis. The major costs are the cost of learning to use the program and the cost of using it. Major issues that influence the cost of learning a program include (1) complexity of the input procedures, (2) quality of the user's manual, and (3) availability of a good support system to answer questions. As the user becomes more experienced, the cost of learning becomes less important, but the need to obtain and enter a complex set of input data will continue to consume the

time of even an experienced user until such data are readily available in electronic form compatible with simulation programs.

The **complexity of input** is largely influenced by the availability of default values for the input variables. Default values can be used as a simple set of input data when detail is not needed or when the building design is very conventional, but additional complexity can be supplied when needed. Secondary defaults, which can be supplied by the user, are also useful in the same way. Some programs allow the user to specify a level of detail. Then the program requests only the information appropriate to that level of detail, using default values for all others.

The **quality of the output** is another factor to consider. Reports should be easy to read and uncluttered. The titles and headings should be unambiguous. Units should be stated explicitly. The user's manual should explain the meanings of the data presented. Graphic output can be very helpful. In most cases, simple summaries of overall results are the most useful, but very detailed output is needed for certain studies and also for debugging program input during the early stages of an analysis.

Before a final decision is made, manuals for the most suitable programs should be obtained and reviewed, and, if possible, demonstration versions of the programs should be obtained and run. During this last part of the selection process, support from the software supplier should be tested. The availability of training should be considered when choosing a more complex program.

The **availability of weather data** and the availability of a weather data processing subroutine or program are major features of a program. Some programs include subroutine or supplementary programs that allow the user to create a weather file for any site for which weather data is available. Programs that do not have this capability must have weather files for various sites created by the program supplier. In that case, the available weather data and the terms on which the supplier will create new weather data files must be checked.

**Auxiliary capabilities**, such as economic analysis and design calculations, are a final concern in selecting a program. An economic analysis may include only the ability to calculate annual energy bills from utility rates, or it might extend to calculations or even to life-cycle cost optimization. An integrated program may save time because some input data will have been entered already for other purposes.

The results of computer calculations should be accepted with caution, as the software vendor does not accept responsibility for the correctness of calculations or the use of the program. A manual calculation should be run to develop a good understanding of the underlying physical processes and building behavior. In addition, the user should (1) review the computer program documentation to determine what calculation procedures are used, (2) compare the results with manual calculations and measured data, and (3) conduct sample tests to confirm that the program delivers acceptable results.

### Tools for Energy Analysis

The most accurate methods for calculating building energy consumption are the most costly because of their intense computational requirements and the needed expertise on the part of the designer or analyst. Simulation programs that assemble component models into system models and then exercise those models with weather and occupancy data are preferred by experts for determining energy use in buildings. This chapter provides descriptions of methods to model heating and cooling loads, including heat flow through building foundations, and methods to model the performance of secondary and primary HVAC equipment. The chapter continues with information about system-level modeling.

Often, energy consumption at a system or whole-building level must be estimated quickly to study trends, compare systems, or study building effects such as envelope characteristics. For these purposes, simpler methods may be used. Degree-day and bin methods are two

Table 1 Classification of Analysis Methods For Building Energy Use

Method	Inverse				Comments
	Forward	Empirical or Black-Box	Calibrated Simulation	Physical or Gray-Box	
<i>Steady-State Methods</i>					
Simple linear regression (Kissock et al. 1998, Ruch and Claridge 1991)	—	X	—	—	One dependent parameter, one independent parameter. May have slope and y-intercept.
Multiple linear regression (Dhar 1995, Dhar et al. 1998, 1999a,b, Katipamula et al. 1998, Sonderegger 1998)	—	X	—	—	One dependent parameter, multiple independent parameters.
Modified degree-day method	X	—	—	—	Based on fixed reference temperature of 18.3°C.
Variable-base degree-day method, or 3-P change point models (Fels 1986, Reddy et al. 1997, Sonderegger 1998)	X	X	—	X	Variable base reference temperatures.
Change point models: 4-P, 5-P (Fels 1986, Kissock et al. 1998)	—	X	—	X	Uses daily or monthly utility billing data and average period temperatures.
ASHRAE bin method and inverse bin method (Thamilseran and Haberl 1995)	X	X	—	—	Hours in temperature bin times load for that bin.
ASHRAE TC 4.7 modified bin method (Knebel 1983)	X	—	—	—	Modified bin method with cooling load factors.
Multistep parameter identification (Reddy et al. 1999)	—	—	—	X	Uses daily data to determine overall heat loss and ventilation of large buildings.
<i>Dynamic Methods</i>					
Thermal network (Sonderegger 1977, Rabl 1988, Reddy 1989)	X	—	—	X	Uses equivalent thermal parameters (inverse mode).
Response factors (Stephenson and Mitalas 1967, Mitalas and Stephenson 1967, Mitalas 1968, Kusuda 1969)	X	—	—	—	Tabulated or as used in simulation programs.
Fourier analysis (Shurcliff 1984, Subbarao 1988)	X	—	X	X	Frequency domain analysis convertible to time domain.
ARMA model (Subbarao 1986, Rabl 1988, Reddy 1989)	—	—	—	X	Autoregressive Moving Average model.
PSTAR (Subbarao 1988)	X	—	X	X	Combination of ARMA and Fourier series, includes loads in time domain.
Modal analysis (Bacot et al. 1984, Rabl 1988)	X	—	—	X	Building described by diagonalized differential equation using nodes.
Differential equation (Rabl 1988)	—	—	—	X	Analytical linear differential equation.
Computer simulation: DOE-2, BLAST (Norford et al. 1994, Haberl and Bou-Saada 1998, Manke et al. 1996)	X	—	X	—	Hourly simulation programs with system models.
Computer emulation (HVACSIM+, TRNSYS) (Clark 1985, Klein et al. 1994)	X	—	—	—	Subhourly simulation programs.
Artificial neural networks (Kreider and Wang 1991, Kreider and Haberl 1994)	—	X	—	—	Connectionist models.

simpler approaches described in the chapter. Finally, the chapter addresses inverse models in detail.

Table 1 classifies methods for analyzing building energy use as forward or inverse and steady-state or dynamic. The U.S. Department of Energy maintains an up-to-date listing of building energy software with links to other sites that describe energy modeling tools: [www.eren.doe.gov/buildings/tools\\_directory/](http://www.eren.doe.gov/buildings/tools_directory/)

## COMPONENT MODELING AND LOADS

### CALCULATING SPACE SENSIBLE LOADS

Calculating instantaneous space sensible load is a key step in any building energy simulation. The **heat balance method** and the **weighting factor method** are two methods used for these calculations. A third method, the **thermal network method**, while not widely used, shows promise.

The **instantaneous space sensible load** is the rate of heat flow into the space air mass. This quantity, sometimes called the cool-

ing load, differs from heat gain in that heat gain usually contains a radiative component that passes through the air and is absorbed by other bounding surfaces. Instantaneous space sensible load is entirely convective; even loads from internal equipment, lights, and occupants enter the air by convection from the surface of such objects or by convection from room surfaces that have absorbed the radiant component of energy emitted from these sources. However, some adjustment must be made when radiant cooling and heating systems are evaluated because some of the space load is offset directly by radiant transfer without convective transfer to the air mass.

For equilibrium, the instantaneous space sensible load must match the heat removal rate of the conditioning equipment. Any imbalance in these rates changes the energy stored in the air mass. Customarily, however, the thermal mass (heat capacity) of the air itself is ignored in an analysis, so that the air is always assumed to be in thermal equilibrium. Under these assumptions, the instantaneous space sensible load and the rate of heat removal are equal in magnitude and opposite in sign.

The weighting factor method and the heat balance method use conduction transfer functions (or their equivalents) to calculate transmission heat gain or loss. The principal difference is in the methods used to calculate the subsequent internal heat transfers to the room. Experience with both methods has indicated largely the same results, provided the weighting factors are determined for the specific building under analysis.

### Heat Balance Method

The heat balance method for calculating net space sensible loads is more fundamental than the weighting factor method. Its development relies on the first law of thermodynamics (conservation of energy) and the principles of matrix algebra. Because it requires fewer assumptions than the weighting factor method, it is also more flexible. However, the heat balance method requires more calculations at each point in the simulation process, using more computer time. The weighting factors used in the weighting factor method are determined with a heat balance procedure. Although not necessary, linearization is commonly used to simplify the radiative transfer formulation.

The heat balance method allows the net instantaneous sensible heating and/or cooling load to be calculated on the space air mass. Generally, a heat balance equation is written for each enclosing surface, plus one equation for room air. This set of equations can then be solved for the unknown surface and air temperatures. Once these temperatures are known, they can be used to calculate the convective heat flow to or from the space air mass. The heat balance method is developed in Chapter 29 for use in design cooling load calculations, so a fuller description is omitted here. However, one fundamental difference is that the heat balance procedure described in Chapter 29 is aimed at obtaining the design cooling load for a fixed zone air temperature. For building energy analysis purposes, it is preferable to know the actual heat extraction rate.

This may be determined by recasting Equation (36) of Chapter 29 so that the system heat transfer is determined simultaneously with the zone air temperature. The system heat transfer is the rate at which heat is transferred to the space by the system. Although this can be done by simultaneously modeling the zone and the system (Taylor et al. 1990, 1991), it is convenient to make a simple, piecewise-linear representation of the system known as a control profile. This usually takes the form

$$q_{sys_j} = a + bt_{a_j} \quad (1)$$

where

$q_{sys_j}$  = system heat transfer at time step  $j$ , W

$a, b$  = coefficients that apply over a certain range of zone air temperatures

$t_{a_j}$  = zone air temperature at time step  $j$ , °C

The system heat transfer  $q_{sys_j}$  may be considered positive when heating is provided to the space and negative when cooling is provided. It is equal in magnitude but opposite in sign to the zone cooling load, as defined in Chapter 29, when the zone air temperature is fixed.

Substituting Equation (1) into Equation (36) of Chapter 29 and solving for the zone air temperature,

$$t_{a_j} = \frac{a + \sum_{i=1}^N A_i h_{ci} t_{si,j} + \rho c V_{infil_j} t_{o_j} + \rho c V_{vent_j} t_{v_j} + q_{c,int_j}}{-b + \sum_{i=1}^N A_i h_{ci} + \rho c V_{infil_j} + \rho c V_{vent_j}} \quad (2)$$

where

$t_{a_j}$  = zone air temperature at time step  $j$ , °C

$N$  = number of zone surfaces

$A_i$  = area of  $i$ th surface, m<sup>2</sup>

$h_{ci}$  = convection coefficient for  $i$ th surface

$t_{si,j}$  = surface temperature for  $i$ th surface at time step  $j$ , °C

$\rho$  = density, kg/m<sup>3</sup>

$c$  = specific heat of air, J/kg · K

$V$  = volumetric flow rate of air, m<sup>3</sup>/s

$t_{o_j}$  = outdoor air temperature at time step  $j$ , °C

$t_{v_j}$  = ventilation air temperature at time step  $j$ , °C

$q_{c,int_j}$  = sum of the convective portions of all internal heat gains at time step  $j$ , W

The zone air heat balance equation [Equation (2)] must be solved simultaneously with the interior and exterior surface heat balance equations [Equations (35) and (34)] described in Chapter 29. Also, it is necessary to determine the correct temperature range to use the proper set of  $a$  and  $b$  coefficients. This may be done iteratively. Once the zone air temperature is found, the actual system heat transfer rate may be found directly from Equation (1).

Beyond the treatment of the system heat transfer, there are a few other considerations that may be important in building energy analysis programs. These include simulations over periods as long as a year, treatment of radiant cooling and heating systems, treatment of interzone heat transfer, modeling of convection heat transfer, and modeling of radiation heat transfer.

The heat balance method presented in Chapter 29 assumes the use of a single design day. When utilized in a building energy analysis program, it is most commonly used with a year's worth of design weather data. In this case, the first day of the year is usually simulated several times until a steady-periodic response is obtained. Then, each day is simulated sequentially, and, where needed, historical data for surface temperatures and heat fluxes from the previous day are utilized.

When radiant cooling and heating systems are evaluated, the radiant source should be identified as a room surface. The calculation procedure considers the radiant source in the heat balance analysis. Therefore, the heat balance method is preferred over the weighting factor method for evaluating radiant systems. Strand and Pedersen (1997) have described the implementation of heat-source conduction transfer functions, which may be used for modeling of radiant panels, into a heat balance-based building simulation program.

In principle, the heat balance method described above extends directly to multiple spaces, with heat transfer between zones. In this case, some surface temperatures will appear in the surface heat balance equations for two different zones. In practice, however, the size of the coefficient array required for solving the simultaneous equations becomes prohibitively large, and the solution time excessive. For this reason, many programs solve only one space at a time and assume that the adjacent space temperatures are either the same as the space in question or some assigned, constant value. Other approaches may remove this limitation (Walton 1980).

Relatively simple exterior and interior convection models may be used for design cooling load calculation procedures. However, it may be desirable to use more sophisticated exterior convection models (Cooper and Tree 1973, Fracastoro et al. 1982, Melo and Hammond 1991, Walton 1983, Yazdani and Klems 1993) that incorporate the effects of wind speed, wind direction, surface orientation, etc. Likewise, a number of more detailed interior convection correlations have been published for use in buildings (Alamdari and Hammond 1982, 1983; Altmayer et al. 1983; Bauman et al. 1983; Bohn et al. 1984; Chandra and Kerestecioglu 1984; Khalifa and Marshall 1990; Spitler et al. 1991; Walton 1983).

Also, more detailed models of exterior long-wave radiation transfer [e.g., Cole (1976) and Walton (1983)] and interior long-wave radiation transfer have been implemented in detailed building

simulation programs. See Carroll (1980), Davies (1988), Kamal and Novak (1991), Steinman et al. (1989), and Walton (1980) for further discussion of interior radiation heat transfer models.

### Weighting Factor Method

The weighting factor method of calculating instantaneous space sensible load represents a compromise between simpler methods, such as a steady-state calculation, that ignore the ability of building mass to store energy, and more complex methods, such as complete energy balance calculations. With this method, space heat gains at constant space temperature are determined from a physical description of the building, ambient weather conditions, and internal load profiles. Along with the characteristics and availability of heating and cooling systems for the building, space heat gains are used to calculate air temperatures and heat extraction rates. This discussion is in terms of heat gains, cooling loads, and heat extraction rates. Heat losses, heating loads, and heat addition rates are merely different terms for the same quantities, depending on the direction of the heat flow.

The weighting factors represent Z-transfer functions (York and Cappiello 1982, Kerrisk et al. 1981). The Z-transform is a method for solving differential equations with discrete data. Two groups of weighting factors are used: heat gain and air temperature.

**Heat gain weighting factors** represent transfer functions that relate space cooling load to instantaneous heat gains. A set of weighting factors is calculated for each group of heat sources that differ significantly in (1) the relative amounts of energy appearing as convection to the air versus radiation, and (2) in the distribution of radiant energy intensities on different surfaces.

**Air temperature weighting factors** represent a transfer function that relates room air temperature to the net energy load of the room. The weighting factors for a particular heat source are determined by introducing a unit pulse of energy from that source into the room's network. The network is a set of equations that represents a heat balance for the room. At each time step (1 h intervals), including the initial introduction, the energy flow to the room air represents the amount of the pulse that becomes a cooling load. Thus, a long sequence of cooling loads can be generated from which the weighting factors are calculated. Similarly, a unit pulse change in room air temperature can be used to produce a sequence of cooling loads.

A two-step process is used to determine the air temperature and heat extraction rate of a room or building zone for a given set of conditions. First, the room air temperature is assumed to be fixed at some reference value. This reference temperature is usually chosen as the average air temperature expected for the room over the simulation period. Instantaneous heat gains are calculated based on this constant air temperature. Various types of heat gains are considered. Some, such as solar energy entering through windows or energy from lighting, people, or equipment, are independent of the reference temperature. Others, such as conduction through walls, depend directly on the reference temperature.

A space sensible cooling load for the room, defined as the rate at which energy must be removed from the room to maintain the reference value of the air temperature, is calculated for each type of instantaneous heat gain. The cooling load generally differs from the instantaneous heat gain because some energy from the heat gain is absorbed by walls or furniture and stored for later release to the air. At an hour  $\theta$ , the calculation uses present and past values of the instantaneous heat gain ( $q_\theta, q_{\theta-1}$ ), past values of the cooling load ( $Q_{\theta-1}, Q_{\theta-2}, \dots$ ), and the **heat gain weighting factors** ( $v_0, v_1, v_2, \dots, w_1, w_2, \dots$ ) for the type of heat gain under consideration. Thus, for each type of heat gain  $q_\theta$ , the cooling load  $Q_\theta$  is calculated as

$$Q_\theta = v_0 q_\theta + v_1 q_{\theta-1} + \dots - w_1 Q_{\theta-1} - w_2 Q_{\theta-2} \dots \quad (3)$$

The heat gain weighting factors are a set of parameters that quantitatively determine how much of the energy entering a room is stored and how rapidly the stored energy is released during later hours. Mathematically, the weighting factors are parameters in a Z-transfer function relating the heat gain to the cooling load.

These weighting factors differ for different heat gain sources because the relative amounts of convective and radiative energy leaving various sources differ and because the distribution of radiative energy can differ. The heat gain weighting factors also differ for different rooms because room construction influences the amount of incoming energy stored by walls or furniture and the rate at which it is released. Sowell (1988) showed the effects of 14 zone design parameters on zone dynamic response. After the first step, the cooling loads from various heat gains are added to give a total cooling load for the room.

In the second step, the total cooling load is used—along with information on the HVAC system attached to the room and a set of **air temperature weighting factors**—to calculate the actual heat extraction rate and air temperature. The actual heat extraction rate differs from the cooling load (1) because, in practice, the air temperature can vary from the reference value used to calculate the cooling load or (2) because of HVAC system characteristics. The deviation of the air temperature  $t_\theta$  from the reference value at hour  $\theta$  is calculated as

$$t_\theta = 1/g_0 + [(Q_\theta - ER_\theta) + P_1(Q_{\theta-1} - ER_{\theta-1}) + P_2(Q_{\theta-2} - ER_{\theta-2}) + \dots - g_1 t_{\theta-1} - g_2 t_{\theta-2} - \dots] \quad (4)$$

where  $ER_\theta$  is the energy removal rate of the HVAC system at hour  $\theta$ , and  $g_0, g_1, g_2, \dots, P_1, P_2, \dots$  are the air temperature weighting factors, which incorporate information about the room, particularly the thermal coupling between the air and the storage capacity of the massive elements.

Tables of values of weighting factors for typical building rooms are presented in the table below. One of the three groups of weighting factors, for light, medium, and heavy construction rooms, can be used to approximate the behavior of any room. Some automated simulation techniques allow weighting factors to be calculated specifically for the building under consideration. This option improves the accuracy of the calculated results, particularly for a building with an unconventional design. McQuiston and Spitler (1992) provided electronic tables of weighting factors for a large number of parametrically defined zones.

#### Normalized Coefficients of Space Air Transfer Functions

Room Envelope Construction	$g_0^*$	$g_1^*$	$g_2^*$	$p_0$	$p_1$
	W/(m <sup>2</sup> ·K)			Dimensionless	
Light	+9.54	-9.82	+0.28	1.0	-0.82
Medium	+10.28	-10.73	+0.45	1.0	-0.87
Heavy	+10.50	-11.07	+0.57	1.0	-0.93

Two assumptions are made in the weighting factor method. First, the processes modeled are linear. This assumption is necessary because heat gains from various sources are calculated independently and summed to obtain the overall result (i.e., the superposition principle is used). Therefore, nonlinear processes such as radiation or natural convection must be approximated linearly. This assumption does not represent a significant limitation because these processes can be linearly approximated with sufficient accuracy for most calculations. The second assumption is that system properties influencing the weighting factors are constant (i.e., they are not functions of time). This assumption is necessary because only one set of weighting factors is used during the entire simulation period. This assumption can limit the use of weighting factors in situations where important room properties vary during the calculation. Two examples are the distribution of

solar radiation incident on the interior walls of a room, which can vary hourly, and inside surface heat transfer coefficients.

When the weighting factor method is used, a combined radiative-convective heat transfer coefficient is used as the inside surface heat transfer coefficient. This value is assumed constant even though in a real room (1) the radiant heat transferred from a surface depends on the temperature of other room surfaces (not on the room air temperature) and (2) the combined heat transfer coefficient is not constant. Under these circumstances, an average value of the property must be used to determine the weighting factors. Cumali et al. (1979) have investigated extensions to the weighting factor method to eliminate this limitation.

### Thermal Network Methods

Although implementations of the thermal network method vary, they all have in common the discretization of the building into a network of nodes, with interconnecting paths through which energy flows. In many respects, thermal network models may be considered a refinement of the heat balance method. Where the heat balance model generally uses one node for zone air, the thermal network method might use multiple nodes. For each heat transfer element (wall, roof, floor, etc.), the heat balance model generally has one interior surface node and one exterior surface node; the thermal network model may include additional nodes. Heat balance models generally use simple methods for distributing radiation from lights; thermal network models may model the lamp, ballast, and luminaire housing separately. Furthermore, thermal network models depend on a heat balance at each node to determine the node temperature and the energy flow between all connected nodes. The energy flows may include conduction, convection, short-wave radiation, and long-wave radiation.

For any mode of energy flow, a range of techniques may be used to model the energy flow between two nodes. Taking conduction heat transfer as an example, the simplest thermal network model would be a resistance-capacitance network (Sowell 1990). By refining the network discretization, the models become what are commonly thought of as finite difference or finite volume models (Clarke 1985, Lewis and Alexander 1990, Walton 1993).

Thermal network models generally use a set of algebraic and differential equations. In most implementations, the solution procedure is separated from the models so that, in theory, different solvers might be used to perform the simulation. In contrast, most heat balance programs and weighting factor programs interweave the solution technique with the models. Various solution techniques have been used in conjunction with thermal network models. Examples include graph theory combined with Newton-Raphson and predictor-corrector ordinary differential equation integration (Buhl et al. 1990) and the use of Euler explicit integration combined with sparse matrix techniques (Walton 1993).

Of the three zone models discussed, thermal network models are the most flexible and have the greatest potential for high accuracy. As a trade-off, they also require the most computation time, and, in current implementations, they require more user effort to take advantage of the flexibility.

### GROUND HEAT TRANSFER

The thermal performance of building foundations, including guidelines for placement of insulation, is described in Chapter 24 of this volume and Chapter 42 of the 1999 *ASHRAE Handbook—Applications*. Chapter 28 provides information needed to calculate transmission heat losses through slab foundations and through basement walls and floors. These calculations are appropriate for design loads but are not intended for estimating annual energy usage. This section provides simplified calculation methods suitable for energy estimates over time periods of arbitrary length.

The thermal performance of building foundations has been largely ignored. It is estimated that in the early 1970s, only 10% of the total energy use of a typical U.S. home was attributed to the heat transfer from its foundation (Labs et al. 1988). Since then, the thermal performance of above-grade building elements has improved significantly, and the contribution of ground-coupled heat transfer to total energy use in a typical U.S. home has increased. Shipp and Broderick (1983) estimated that the heat transfer from an uninsulated basement in Columbus, Ohio, can represent up to 67% of the total building envelope heating load.

Earth-contact heat transfer, rated at 1 to 3 EJ of energy annually in U.S. buildings, has an impact similar to infiltration on annual heating and cooling loads in residential buildings (Claridge 1988a). Adding insulation to building foundations is estimated to save up to 0.5 EJ of annual energy use in the U.S. (Labs et al. 1988).

### Simplified Calculation Method for Slab Foundations and for Basements

A simplified design tool for calculating heat loss for slabs and basements is presented by modifying the design tool for slab-on-grade floors developed by Krarti and Chuangchid (1999). The proposed design tool is easy to use and requires straightforward input parameters with continuously variable values, including foundation size, insulation R-values, soil thermal properties, and indoor and outdoor temperatures. The simplified method provides a set of equations that are suitable for estimating the design, seasonal, and annual total heat loss of a slab or a basement as a function of a wide range of variables.

When the indoor temperature of the building is maintained constant, the ground-coupled heat transfer  $q(\theta)$  varies with time according to the following equation:

$$q(\theta) = q_{mean} + q_{amp} \sin(\omega\theta + \phi) \quad (5)$$

where

$q_{mean}$  = annual-mean heat loss/gain, W

$q_{amp}$  = heat loss/gain amplitude, W

$\phi$  = phase lag between total slab heat loss/gain and soil surface temperature, s

$\omega$  = annual angular frequency ( $\omega = 1.992 \times 10^{-7}$  rad/s)

$\theta$  = time, s

Equation (5) is convenient and flexible because it can be used to calculate the foundation heat loss/gain not only at any time but also at design conditions and for any time period (such as a heating season or 1 year). In particular, the design heat loss/gain load  $Q_{des}$  for a slab foundation is obtained as follows:

$$Q_{des} = q_{mean} + q_{amp} \quad (6)$$

The parameters  $q_{mean}$  and  $q_{amp}$  are functions of such variables as building dimensions, soil properties, and insulation R-values. Expressions developed by nondimensional analysis allow the calculation of  $q_{mean}$  and  $q_{amp}$ .

The soil conductivity is normalized to form four parameters— $U_o$ ,  $G$ ,  $H$ , and  $D$ :

$$J_o = \frac{k_s}{(A/P)_{eff, t}} \quad (7)$$

where

$k_s$  = soil thermal conductivity, W/(m·K)

$P$  = slab perimeter, m

$A$  = slab area, m<sup>2</sup>

For mean calculations,

$$(A/P)_{eff, b, mean} = [1 + b_{eff}(-0.4 + e^{-H_b})](A/P)_b \quad (8)$$

For annual calculations,

$$(A/P)_{eff, b, amp} = (1 + b_{eff}e^{-H_b})(A/P)_b \tag{9}$$

where

$$H_b = \frac{(A/P)_b}{k_s R_{eq}} \tag{10}$$

$$b_{eff} = \frac{B}{(A/P)_b} \tag{11}$$

$B$  = basement depth, m (0 m for slab)

$$G = k_s R_{eq} \sqrt{\frac{\omega}{\alpha_s}} \tag{12}$$

where

$R_{eq}$  = equivalent thermal resistance for the entire slab,  $m^2 \cdot K/W$   
 $\alpha_s$  = soil thermal diffusivity,  $m^2/s$

For uniform insulation configurations (placed horizontally beneath the slab floor),

$$R_{eq} = R_f + R_i \tag{13}$$

where

$R_f$  = thermal resistance of the floor,  $m^2 \cdot K/W$   
 $R_i$  = thermal resistance of insulation,  $m^2 \cdot K/W$

For partial insulation configurations (both horizontal and vertical),

$$R_{eq} = \frac{R_f}{\left[1 - \left(\frac{c}{A/P} \frac{R_i}{R_i + R_f}\right)\right]} \tag{14}$$

where  $c$  = insulation length of slab, m.

$$H = \frac{(A/P)_{eff, t}}{k_s R_{eq}} \tag{15}$$

$$D = \ln \left[ \left(1 + H\right) \left(1 + \frac{1}{H}\right)^H \right] \tag{16}$$

The effective heat-transfer coefficients for mean heat flow  $U_{eff, mean}$  and heat-flow amplitude  $U_{eff, amp}$ ,  $W/m^2 \cdot K$ , are

**Table 2 Coefficients  $m$  and  $a$  for Slab-Foundation Heat Transfer Calculations**

Insulation Placement	$m$	$a$
Uniform—Horizontal	0.40	0.25
Partial—Horizontal	0.34	0.20
Vertical	0.28	0.13

$$U_{eff, mean} = m U_o D \tag{17}$$

$$U_{eff, amp} = a U_o D^{0.16} G^{-0.6} \tag{18}$$

where the dimensionless coefficients  $m$  and  $a$  depend on the insulation placement configurations and are provided in Table 2.

The annual-mean slab foundation and basement heat loss/gain can now be defined as

$$q_{mean} = U_{eff, mean} A (t_a - t_r) \tag{19}$$

where

$t_a$  = annual average ambient dry-bulb temperature,  $^{\circ}C$   
 $t_r$  = annual average indoor dry-bulb temperature,  $^{\circ}C$

The heat loss/gain amplitude for slab foundations and basements is

$$Q_a = U_{eff, a} A t_{amp} \tag{20}$$

where  $t_{amp}$  = annual amplitude ambient temperature,  $K$ .

This simplified model for slab-foundation and basement heat flows provides accurate predictions when  $A/P$  is larger than 0.5 m. To illustrate the use of the simplified models, two examples are presented: one for a slab-on-grade floor for a building insulated with uniform horizontal insulation, and one for a basement structure insulated with uniform insulation.

**Example 1. Calculation for Slab Foundations.** Determine the annual mean and annual amplitude of total slab heat loss for the slab foundation illustrated in Figure 2. The building is located in Denver, Colorado.

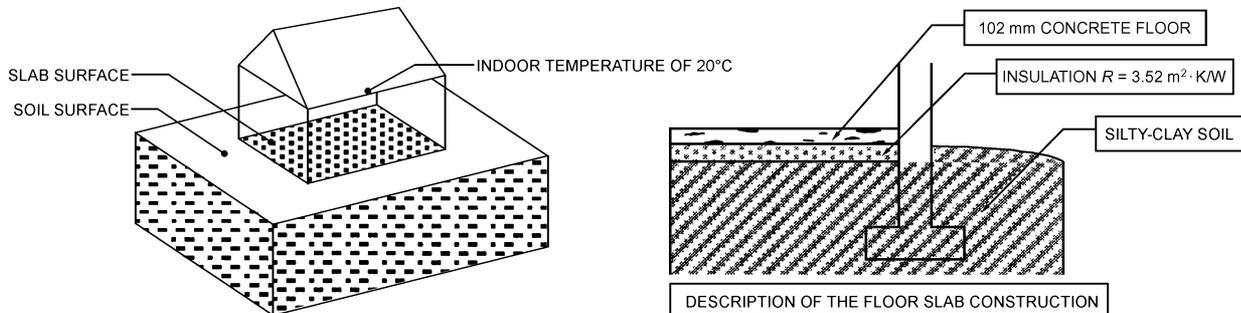

**Solution:**

**Step 1.** Provide the required input data.

**Dimensions**

Slab width = 10.0 m  
 Slab length = 15.0 m  
 Ratio of slab area to slab perimeter,  $A/P = 3.0$  m

102 mm thick reinforced concrete slab, thermal resistance  $R_f = 0.5$   $m^2 \cdot K/W$

**Fig. 2 Slab Foundation for Example 1**

**Soil Thermal Properties**

Soil thermal conductivity  $k_s = 1.21 \text{ W/m}\cdot\text{K}$   
 Soil density  $\rho = 700 \text{ kg/m}^3$   
 Soil thermal diffusivity  $\alpha_s = 5.975 \times 10^{-7} \text{ m}^2/\text{s}$

**Insulation**

Uniform insulation R-value  $R_i = 3.52 \text{ m}^2\cdot\text{K/W}$

**Temperatures**

Indoor temperature  $t_r = 20^\circ\text{C}$   
 Annual average ambient temperature  $t_a = 6.3^\circ\text{C}$   
 Annual amplitude ambient temperature  $t_{amp} = 20 \text{ K}$   
 Annual angular frequency  $\omega = 1.992 \times 10^{-7} \text{ rad/s}$

**Step 2.** Calculate  $q_{mean}$  and  $q_{amp}$  values.

The various normalized parameters are first calculated using Equations (7) through (18). Then, the annual mean and amplitude of the foundation slab heat loss/gain are determined using Equations (19) and (20).

$$U_o = \frac{k_s}{(A/P)} = \frac{1.21}{3.0} = 0.4033$$

$$H = \frac{(A/P)}{k_s R_{eq}} = \frac{3.0}{1.21(0.5 + 3.52)} = 0.6168$$

$$D = \ln \left[ (1 + H) \left( 1 + \frac{1}{H} \right)^H \right] = 1.0748$$

$$G = k_s R_{eq} \sqrt{\frac{\omega}{\alpha_s}} = 1.21(0.5 + 3.52) \sqrt{\frac{1.992 \times 10^{-7}}{5.975 \times 10^{-7}}} = 2.8086$$

Therefore,

$$I_{mean} = U_{eff, mean} A (t_r - t_a) = 0.4 \times 0.4033 \times 1.0748 \times 150 \times (20 - 6.3) = 356 \text{ W}$$

and

$$I_{amp} = U_{eff, amp} A t_{amp} = 0.25 \times 0.4033 \times 1.0748^{0.16} \times 2.8086^{-0.6} \times 150 \times 20 = 165 \text{ W}$$

**Example 2. Calculation for Basements.** Determine the annual mean and annual amplitude of total basement heat loss for a building located in Denver, Colorado.

**Solution:**

**Step 1.** Provide the required input data.

**Dimensions**

Basement width = 10.0 m  
 Basement length = 15.0 m  
 Basement wall height  $B = 1.5 \text{ m}$   
 Basement slab and wall total area = 225.0 m<sup>2</sup>  
 Ratio of slab and wall area to slab and wall perimeter,  
 $(A/P)_b = 3.629 \text{ m}$   
 102 mm thick reinforced concrete slab, thermal resistance  
 $R_f = 0.5 \text{ m}^2\cdot\text{K/W}$

**Soil Thermal Properties**

Soil thermal conductivity  $k_s = 1.21 \text{ W/m}\cdot\text{K}$   
 Soil thermal diffusivity  $\alpha_s = 4.47 \times 10^{-7} \text{ m}^2/\text{s}$

**Insulation**

Uniform insulation R-value  $R_i = 1.152 \text{ m}^2\cdot\text{K/W}$

**Temperatures**

Indoor temperature,  $t_r = 22^\circ\text{C}$   
 Annual average ambient temperature,  $t_a = 10^\circ\text{C}$   
 Annual amplitude ambient temperature,  $t_{amp} = 12.7 \text{ K}$   
 Annual angular frequency,  $\omega = 1.992 \times 10^{-7} \text{ rad/s}$

**Step 2.** Calculate  $q_{mean}$  and  $q_{amp}$  values.

The normalized parameters are first calculated using Equations (7) through (18). Then the annual mean and amplitude of the basement heat loss are determined using Equations (19) and (20).

$$H_b = \frac{(A/P)_b}{k_s R_{eq}} = \frac{3.629}{1.21(0.5 + 1.152)} = 1.8155$$

$$b_{eff} = \frac{B}{(A/P)_b} = \frac{1.5}{3.629} = 0.4133$$

$$A/P_{eff, b, mean} = [1 + 0.4133(-0.4 + e^{-1.8155})] \times 3.629 = 3.2731$$

$$A/P_{eff, b, amp} = [1 + 0.4133e^{-1.8155}] \times 3.629 = 3.8731$$

$$I_o, mean = \frac{k_s}{(A/P)_{eff, b, mean}} = \frac{1.21}{3.2731} = 0.369$$

$$J_o, amp = \frac{k_s}{(A/P)_{eff, b, amp}} = \frac{1.21}{3.8731} = 0.3124$$

$$I_{mean} = \frac{(A/P)_{eff, b, mean}}{k_s R_{eq}} = \frac{3.2731}{1.21(0.5 + 1.152)} = 1.637$$

$$I_{amp} = \frac{(A/P)_{eff, b, amp}}{k_s R_{eq}} = \frac{3.8731}{1.21(0.5 + 1.152)} = 1.937$$

$$D_{mean} = \ln \left[ (1 + H_{mean}) \left( 1 + \frac{1}{H_{mean}} \right)^{H_{mean}} \right] = 1.7503$$

$$D_{amp} = \ln \left[ (1 + H_{amp}) \left( 1 + \frac{1}{H_{amp}} \right)^{H_{amp}} \right] = 1.8839$$

$$G = k_s R_{eq} \sqrt{\frac{\omega}{\alpha_s}} = 1.21(0.5 + 1.152) \sqrt{\frac{1.992 \times 10^{-7}}{4.47 \times 10^{-7}}} = 1.3344$$

Therefore,

$$I_{mean} = U_{eff, mean} A (t_a - t_r) = 0.4 \times 0.3697 \times 1.7503 \times 225 \times (22 - 10) = 699 \text{ W}$$

and

$$I_{amp} = U_{eff, amp} A t_{amp} = 0.25 \times 0.3124 \times 1.8839^{0.16} \times 1.3344^{-0.6} \times 225 \times 12.7 = 208 \text{ W}$$

Table 3 compares results of the simplified method presented here and the more exact interzone temperature profile estimation (ITPE) (Krarti 1994a, 1994b; Krarti et al. 1988a, 1988b).

**Table 3 Example 2 Heat Loss per Unit Area for the Simplified and ITPE Methods**

Method	Mean ( $q_{mean}$ ), W	Amplitude ( $q_{amp}$ ), W
Simplified	699	208
ITPE solution	658	212

**SECONDARY SYSTEM COMPONENTS**

Secondary HVAC systems generally include all elements of the overall building energy system between a central heating and cooling plant and the building zones. The precise definition depends heavily on the building design. A secondary system typically includes air-handling equipment, air distribution systems with the

associated ductwork, dampers, fans, and heating, cooling, and humidity conditioning equipment. Secondary systems also include the liquid distribution systems between the central plant and the zone and air-handling equipment, including piping, valves, and pumps.

While the exact design of secondary systems varies dramatically among buildings, they are composed of a relatively small set of generic HVAC components. These components include distribution components (e.g., pumps/fans, pipes/ducts, valves/dampers, headers/plenums, fittings) and heat and mass transfer components (e.g., heating coils, cooling and dehumidifying coils, liquid heat exchangers, air heat exchangers, evaporative coolers, steam injectors). Most secondary systems can be described by simply connecting these components to form the complete system.

Energy estimation through computer simulation often mimics the modular construction of secondary systems by using modular simulation elements [e.g. the ASHRAE *HVAC 2 Toolkit* (Brandemuehl 1993, Brandemuehl and Gabel 1994), the simulation program TRNSYS (Klein et al. 1994), and Annex 10 activities of the International Energy Agency]. To the extent that the secondary system consumes energy and transfers energy between the building and central plant, an energy analysis can be performed by characterizing the energy consumption of the individual components and the energy transferred among system components. In fact, few of the secondary components consume energy directly, except fans, pumps, furnaces, direct expansion air-conditioning package units with gas-fired heaters, and inline heaters. In this chapter, secondary components are divided into two categories: distribution components and heat and mass transfer components.

### Fans, Pumps, and Distribution Systems

The distribution system of an HVAC system affects energy consumption in two ways. First, fans and pumps consume electrical energy directly, based on the flow and pressures under which the device operates. Ducts and dampers, or pipes and valves, and the system control strategies affect the flow and pressures at the fan or pump. Second, thermal energy is often transferred to (or from) the fluid due to heat transfer through pipes and ducts and due to the electrical input to fans and pumps. The analysis of system components should, therefore, account for both direct electrical energy consumption and thermal energy transfer.

Fan and pump performance are discussed in Chapters 18 and 39 of the 2000 *ASHRAE Handbook—Systems and Equipment*. In addition, Chapter 34 of this handbook covers pressure loss calculations for airflow in ducts and duct fittings. Chapter 35 presents a similar discussion for fluid flow in pipes. While these chapters do not specifically focus on energy estimation, energy use is governed by the same performance characteristics and engineering relationships. Strictly speaking, performance calculations of the fan and air distribution systems in a building require a detailed pressure balance on the entire network. For example, in an air distribution system, the airflow through the fan depends on its physical characteristics, the operating speed, and the pressure differential across the fan. The pressure drop through the duct system depends on the duct design, the position of all dampers, and the airflow through the fan. The interaction between the fan and duct system results in a set of coupled, nonlinear algebraic equations. Models and subroutines for performing these calculations are available in the *ASHRAE HVAC 2 Toolkit* (Brandemuehl 1993).

While a detailed analysis of a distribution system requires flow and pressure balancing among the components, nearly all commercially available energy analysis methods approximate the effect of the interactions with part-load performance curves. This procedure eliminates the need to calculate pressure drop through the distribution system at off-design conditions. The part-load curves are often expressed in terms of a **power input ratio** as a function of the part-load ratio, defined as the ratio of part-load flow to design flow:

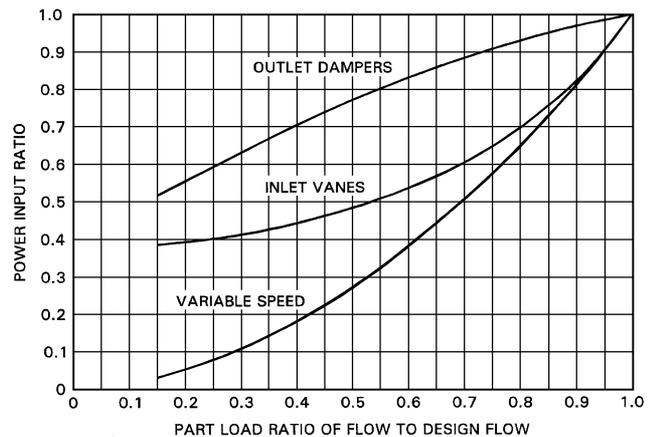

Fig. 3 Part-Load Curves for Typical Fan Operating Strategies

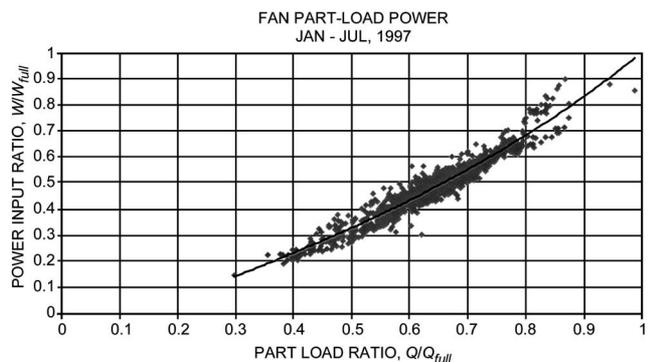

Fig. 4 Fan Part-Load Curve Obtained from Measured Field Data under ASHRAE 823-RP

$$\text{PIR} = \frac{W}{W_{full}} = f_{plr} \left( \frac{Q}{Q_{full}} \right) \quad (21)$$

where

- PIR = power input ratio
- $W$  = fan motor power at part load, W
- $W_{full}$  = fan motor power at full load or design, W
- $Q$  = fan airflow rate at part load, m<sup>3</sup>/s
- $Q_{full}$  = fan airflow rate at full load or design, m<sup>3</sup>/s
- $f_{plr}$  = regression function, typically polynomial

The exact shape of the part-load curve depends on the effect of flow control on the pressure and fan efficiency and may be calculated using a detailed analysis or measured field data. Figure 3 shows the relationship for three typical fan control strategies, as represented in a simulation program (York and Cappiello 1982). Within the simulation program, the curves are represented by polynomial regression equations. Models and subroutines for performing these calculations are also available in the *ASHRAE HVAC 2 Toolkit* (Brandemuehl 1993).

Figure 4 shows an example of a similar curve for the part-load operation of a fan system in a monitored building (Brandemuehl and Bradford 1999). In this particular case, the fan system represents ten separate air handlers, each with supply and return fans, operating with variable-speed fan control to maintain a set duct static pressure. Notice that, although the shape of the curve is similar to the variable-speed curve of Figure 3, the measured data for this particular system exhibit a more linear relationship between power and flow.

Heat transferred to the airstream due to fan operation increases the temperature of the air. While the shaft power of the fan has a direct effect on the heat transfer, motor inefficiencies also heat the air if the motor is mounted inside the airstream. For pumps, this contribution is typically assumed to be zero.

The following equation provides a convenient and general model to calculate the heat transferred to the fluid:

$$q_{fluid} = [\eta_m + (1 - \eta_m)f_{m, loss}]W \quad (22)$$

where

$q_{fluid}$  = heat transferred to the fluid, W

$f_{m, loss}$  = fraction of the motor heat loss transferred to the fluid stream, dimensionless (= 1 if fan mounted in airstream, = 0 if fan mounted outside airstream)

$W$  = fan motor power, W

$\eta_m$  = motor efficiency

### Heat and Mass Transfer Components

Secondary HVAC systems comprise such heat and mass transfer components as steam-based air-heating coils, chilled water cooling and dehumidifying coils, shell-and-tube liquid heat exchangers, air-to-air heat exchangers, evaporative coolers, and steam injectors. While these components do not consume energy directly, their thermal performance dictates the interactions between the building loads and the energy-consuming primary components (e.g., chillers, boilers). In particular, the performance of the secondary components determines the entering fluid conditions for primary components, which in turn determine the energy efficiencies of the primary equipment. Accurate energy calculations cannot be performed without appropriate models of the system heat and mass transfer components.

For example, the load on a chiller is typically described as the sum of zone sensible and latent loads, plus any heat gain from ducts, plenums, fans, pumps, and piping. However, the energy consumption of the chiller is determined not only by the load but also by the return chilled water temperature and flow rate. The return water condition is determined by the cooling coil performance and the part-load operating strategy of the air and water distribution system. The cooling coil might typically be controlled to maintain a constant leaving air temperature by modulating the water flow through the coil. In such a scenario, the cooling coil model must be able to calculate the leaving air humidity, leaving water temperature, and leaving water flow rate given the cooling coil design characteristics, entering air temperature and humidity, entering airflow, and entering water temperature.

Virtually all building energy simulation programs include, and require, models of heat and mass transfer components. In general, these models are relatively simple. While a coil designer might use a detailed tube-by-tube analysis of conduction and convection heat transfer and condensation on fin surfaces to develop an optimal combination of fin and tube geometry, an energy analyst is more interested in determining the changes in leaving fluid states as operating conditions vary during the year. In addition, the energy analyst is likely to have limited design data on the equipment and, therefore, requires a model with very few parameters that depend on equipment geometry and detailed design characteristics.

A typical approach to modeling heat and mass transfer components for energy calculations is based on an **effectiveness-NTU heat exchanger model** (Kays and London 1984). The effectiveness-NTU model is described in most heat transfer textbooks and is briefly discussed in Chapter 3. It is particularly appropriate for describing the leaving fluid conditions when the entering fluid conditions and equipment design characteristics are known. In addition, this model requires only a single parameter to describe the characteristics of the exchanger—the overall transfer coefficient  $UA$ —which can be determined from limited design performance data.

Because the classical effectiveness methods were developed for sensible heat exchangers, they are used to perform energy calculations for a variety of sensible heat exchangers in HVAC systems. For typical finned-tube air-heating coils, the crossflow configuration with both fluid streams unmixed is most appropriate. The same configuration typically applies to air-to-air heat exchangers. For liquid-to-liquid exchangers, tube-in-tube equipment can be modeled as parallel or counterflow, depending on flow directions; and shell-and-tube equipment can be modeled as either counter- or crossflow, depending on the extent of baffling and the number of tube passes.

The energy analyst must determine the  $UA$  to describe the operations of a specific heat exchanger. There are typically two approaches to determine this important parameter: direct calculation and from manufacturers' data. Given detailed information about the materials, geometry, and construction of the heat exchanger, it is possible to apply fundamental heat transfer principles to calculate the overall heat transfer coefficient. An alternative to direct calculation, and the method most appropriate for energy estimation, is to use manufacturers' performance data or direct measurements of installed performance. In reporting the design performance of a heat exchanger, a manufacturer typically gives the rate of heat transfer under various operating conditions, with the operating conditions described in terms of entering fluid flow rates and temperatures. The effectiveness and  $UA$  can be calculated from the given heat transfer rate and entering fluid conditions.

**Example 3.** An energy analyst seeks to perform an evaluation of a hot water heating system that includes a hot water heating coil. The energy analysis program uses an effectiveness-NTU model of the coil and requires the  $UA$  of the coil as an input parameter. While detailed information on the coil geometry and heat transfer surfaces is not available, the manufacturer states that the 1-row hot water heating coil will deliver 240 kW of heat under the following design conditions:

#### Design Performance

Entering water temperature  $t_{hi} = 80^\circ\text{C}$

Water mass flow rate = 5.0 kg/s

Entering air temperature  $t_{ci} = 20^\circ\text{C}$

Air mass flow rate = 8.0 kg/s

Design heat transfer  $q = 240 \text{ kW}$

**Solution:** The solution proceeds by first determining the heat exchanger  $UA$  from the design data, and then using the  $UA$  to predict performance at the off-design conditions. The effectiveness-NTU relationships are used for both steps. The key assumption is that the  $UA$  is constant for both operating conditions. This example uses the nomenclature as described in Chapter 3 in the section on Overall Heat Transfer.

- a) An examination of the flow rates and fluid specific heats allows calculation of the capacity rates  $C_h$  and  $C_c$  at design conditions and the capacity rate ratio  $Z$ .

$$C_h = (\dot{m}c_p)_h = (5.0)(4.195) = 20.97 \text{ kW/K}$$

$$C_c = (\dot{m}c_p)_c = (8.0)(1.007) = 8.05 \text{ kW/K}$$

$$C_{max} = C_h \quad C_{min} = C_c$$

$$Z = \frac{C_{min}}{C_{max}} = 0.384$$

- b) The effectiveness can be directly calculated from the heat transfer definition.

$$\varepsilon = \frac{(t_{co} - t_{ci})}{(t_{hi} - t_{ci})} = \frac{q / C_c}{(t_{hi} - t_{ci})} = \frac{240 / 8.05}{(80 - 20)} = 0.497$$

- c) The effectiveness-NTU relationships for a crossflow heat exchanger with both fluids unmixed allows calculation of the effectiveness in terms of the capacity rate ratio  $Z$  and the NTU [the relationships are available from most heat transfer textbooks and specifically can be found in Kays and London (1984)].

Given the effectiveness and capacity rate ratio, the NTU can be determined to be  $NTU = 0.804$ .

- d) The heat transfer  $UA$  is then determined from the definition of the NTU.

$$UA = C_{min}NTU = (8.05)(0.804) = 6.47 \text{ kW/K}$$

### Application to Cooling and Dehumidifying Coils

The analysis of air-cooling and dehumidifying coils requires coupled, nonlinear heat and mass transfer relationships. These relationships form the basis for all HVAC components with moisture transfer, including cooling coils, cooling towers, air washers, and evaporative coolers. While the complex heat and mass transfer theory that is presented in many textbooks is often required for cooling coil design, simpler models based on effectiveness concepts are usually more appropriate for energy estimation. For example, the bypass factor is a form of effectiveness in the approach of the leaving air temperature to the apparatus dew-point, or coil surface, temperature.

While the effectiveness-NTU method is typically developed and applied in the analysis of sensible heat exchangers, it can also be used to analyze other types of exchangers such as cooling and dehumidifying coils that couple heat and mass transfer. By redefining the state variables, the capacity rates, and the overall exchange coefficient of these enthalpy exchangers, the effectiveness concept may be used to calculate heat transfer rates and leaving fluid states. For sensible heat exchangers, the state variable is temperature, the capacity is the product of mass flow and fluid specific heat, and the overall transfer coefficient is the conventional overall heat transfer coefficient. For cooling and dehumidifying coils, the state variable becomes moist air enthalpy, the capacity has units of mass flow, and the overall heat transfer coefficient is modified to reflect enthalpy exchange. This approach forms the basis for models by Threlkeld (1970), Elmahdy and Mitalas (1977), Braun (1988), and Brandemuehl (1993). The same principles also underlie the coil model described in Chapter 21 of the 2000 *ASHRAE Handbook—Systems and Equipment*.

The effectiveness model is based on the observation that, for a given set of entering air and liquid conditions, the heat and mass transfer are bounded by thermodynamic maximum values. Figure 5 shows the limits for leaving air states on a psychrometric chart. Specifically, the leaving chilled water temperature cannot be warmer than the entering air temperature and the leaving air temperature and humidity cannot be lower than the conditions of saturated moist air at the temperature of the entering chilled water.

Figure 5 also shows that the performance of a cooling coil requires the evaluation of two different effectivenesses to identify the leaving air temperature and humidity. An overall effectiveness can be used to describe the approach of the leaving air enthalpy to the minimum possible value. An air-side effectiveness, related to the coil bypass factor, describes the approach of the leaving air temperature to the effective wet coil surface temperature.

The effectiveness analysis is accomplished for wet coils by establishing a common state variable for both the moist air and liquid streams. As implied by the lower limit of the entering chilled water temperature, this common state variable is the moist air enthalpy. In other words, all liquid and coil temperatures are transformed to the enthalpy of saturated moist air at the liquid or coil temperature. Changes in liquid temperature can similarly be expressed in terms of changes in saturated moist air enthalpy through a saturation specific heat  $c_{p,sat}$  defined by the following:

$$c_{p,sat} = \frac{\Delta h_{l,sat}}{\Delta t_l} \quad (23)$$

Using the definition of Equation (23), the basic effectiveness relationships discussed in Chapter 3 can be written as

$$= C_a(h_{a,ent} - h_{a,lv}) = C_l(h_{l,sat,lv} - h_{l,sat,ent}) \quad (24)$$

$$l = \varepsilon C_{min}(h_{a,ent} - h_{l,sat,ent}) \quad (25)$$

$$C_a = \dot{m}_a \quad (26)$$

$$C_l = \frac{(\dot{m}c_p)_l}{c_{p,sat}} \quad (27)$$

$$C_{min} = \min(C_a, C_l) \quad (28)$$

where

- $q$  = heat transfer from air to water, kW
- $C$  = fluid capacity, kg/s
- $\dot{m}_a$  = dry air mass flow rate, kg/s
- $\dot{m}_l$  = liquid mass flow rate, kg/s
- $c_{p,l}$  = liquid specific heat, kJ/(kg·K)
- $c_{p,sat}$  = saturation specific heat, defined by Equation (23), kJ/(kg·K)
- $h_a$  = enthalpy of moist air, kJ/kg
- $h_{l,sat}$  = enthalpy of saturated moist air at the temperature of the liquid, kJ/kg

The cooling coil effectiveness of Equation (25) is defined, then, as the ratio of moist air enthalpies in Figure 5. As in the case of sensible heat exchangers, the effectiveness is also a function of the physical coil characteristics and can be obtained by modeling the coil as a counterflow heat exchanger. However, since the heat transfer calculations are performed based on enthalpies, the overall transfer coefficient must be based on enthalpy potential rather than temperature potential. The enthalpy-based heat transfer coefficient  $UA_h$  is related to the conventional temperature-based coefficient by the specific heat:

$$q = UA\Delta t = UA_h\Delta h$$

$$UA_h = \frac{UA\Delta t}{\Delta h} = \frac{UA}{c_p} \quad (29)$$

A similar analysis can be performed to evaluate the air-side effectiveness, which identifies the leaving air temperature. While the overall enthalpy-based effectiveness is based on an overall heat transfer coefficient between the chilled water and the air, the air-side effectiveness is based on a heat transfer coefficient between the coil surface and the air.

As with sensible heat exchangers, the overall heat transfer coefficients  $UA$  can be determined either from direct calculation from coil properties or from manufacturers' performance data. While a sensible heat exchanger is modeled with a single effectiveness and

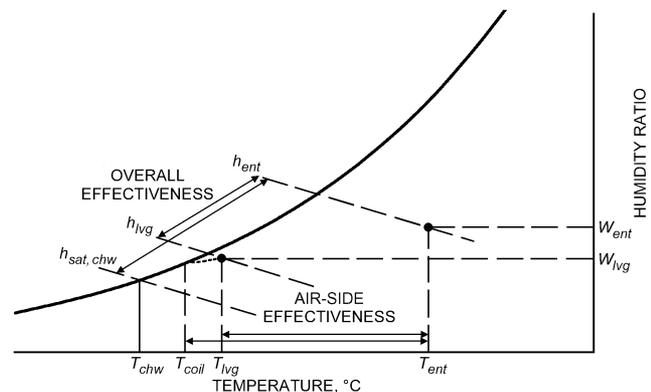

Fig. 5 Psychrometric Schematic of Cooling Coil Processes

can be described by a single parameter  $UA$ , a wet cooling and dehumidifying coil requires two parameters to describe the two effectivenesses shown in Figure 5. These two parameters are the internal and external  $UAs$ —one describes the heat transfer between the chilled water and the air-side surface through the pipe wall and the other between the surface and the moist air. These two parameters can be determined from the sensible and latent capacity of a cooling coil at a single rating condition. A significant advantage of the effectiveness-NTU method is that the component can be described with as little as one measured data point or one manufacturer’s design calculation.

**PRIMARY SYSTEM COMPONENTS**

Primary HVAC systems consume energy and deliver heating and cooling to a building, usually through secondary systems. Primary equipment generally includes chillers, boilers, cooling towers, cogeneration equipment, and plant-level thermal storage equipment. In particular, primary equipment generally represents the major energy-consuming equipment of a building, so accurate characterization of building energy use relies on accurate modeling of primary equipment energy consumption.

**Modeling Strategies**

The energy consumption characteristics of primary equipment generally depend on equipment design, load conditions, environmental conditions, and equipment control strategies. For example, chiller performance depends on the basic equipment design features (e.g., heat exchange surfaces, compressor design), the temperatures and flow through the condenser and evaporator, and the methods for controlling the chiller at different loads and operating conditions (e.g., inlet guide vane control on centrifugal chillers to maintain leaving chilled water temperature set point). In general, these variables that dictate energy consumption vary constantly and require calculations on an hourly basis.

**Regression Models.** While many secondary components (e.g., heat exchangers, valves) are readily described by fundamental engineering principles, the complex nature of most primary equipment has discouraged the use of first-principle models for energy calculations. Instead, the energy consumption characteristics of primary equipment have traditionally been modeled using simple equations developed by regression analysis of manufacturers’ published design data. Because published data are often available only for full-load design conditions, additional correction functions are used to correct the full-load data to part-load conditions. The functional form of the regression equations and correction functions takes many forms, including exponentials, Fourier series, and, most of the time, second- or third-order polynomials. The selection of an appropriate functional form depends on the behavior of the equipment. In some cases, energy consumption is calculated using direct interpolation from tables of data. However, this method often requires excessive data input and computer memory.

The typical approach to modeling primary equipment in energy simulation programs is to assume the following functional form for equipment power consumption:

$$P = \text{PIR} \times \text{Load} \tag{30}$$

$$\text{PIR} = \text{PIR}_{nom} f_1(t_a, t_b, \dots) f_2(\text{PLR})$$

$$C_{avail} = C_{nom} f_3(t_a, t_b, \dots) \tag{31}$$

$$\text{PLR} = \frac{\text{Load}}{C_{avail}}$$

where

- $P$  = equipment power, kW
- $\text{PIR}$  = energy input ratio

- $\text{PIR}_{nom}$  = energy input ratio under nominal full-load conditions
- Load = power delivered to the load, kW
- $C_{avail}$  = available equipment capacity, kW
- $C_{nom}$  = nominal equipment capacity, kW
- $f_1$  = function relating full-load power at off-design conditions ( $t_a, t_b, \dots$ ) to full-load power at design conditions
- $f_2$  = fraction full-load power function, relating part-load power to full-load power
- $f_3$  = function relating available capacity at off-design conditions ( $t_a, t_b, \dots$ ) to nominal capacity
- $t_a, t_b$  = various operating temperatures that affect power
- PLR = part-load ratio

The part-load ratio is defined as the ratio of the load to the available equipment capacity at given off-design operating conditions. Like the power, the available, or full-load, capacity will be a function of operating conditions.

The particular forms of the off-design functions  $f_1$  and  $f_3$  depend on the specific type of primary equipment. For example, for fossil-fuel boilers, full-load capacity and power (or fuel use) can be affected by the thermal losses to ambient temperature. However, these off-design functions are typically considered to be unity in most building simulation programs. For chillers, both capacity and power are affected by the condenser and evaporator temperatures. These two temperatures are often characterized in terms of their secondary fluids. For direct expansion air-cooled chillers, the operating temperatures are typically the wet-bulb temperature of the air entering the evaporator and the dry-bulb temperature of the air entering the condenser. For liquid chillers, the temperatures are usually the leaving chilled water temperature and the entering condenser water temperature.

As an example, consider the performance of a direct expansion (DX) packaged single-zone rooftop unit. The nominal rated performance of these units is typically given for an outdoor air temperature of 35°C and evaporator entering coil conditions of 26.7°C dry-bulb temperature and 19.4°C wet-bulb temperature. However, the performance changes as the outdoor temperature and entering coil conditions vary. To account for these effects, the DOE-2.1E simulation program expresses the off-design functions  $f_1$  and  $f_3$  with biquadratic functions of the outdoor dry-bulb temperature and the coil entering wet-bulb temperature.

$$\hat{f}_1(t_{wb, ent}, t_{oa}) = a_0 + a_1 t_{wb, ent} + a_2 t_{wb, ent}^2 + a_3 t_{oa} + a_4 t_{oa}^2 + a_5 t_{wb, ent} t_{oa} \tag{32}$$

$$\hat{f}_3(t_{wb, ent}, t_{oa}) = c_0 + c_1 t_{wb, ent} + c_2 t_{wb, ent}^2 + c_3 t_{oa} + c_4 t_{oa}^2 + c_5 t_{wb, ent} t_{oa} \tag{33}$$

The constants in Equations (32) and (33) are given in Table 4.

The fraction full-load power function  $f_2$  represents the change in equipment efficiency at part-load conditions and depends heavily on the control strategies used to match load and capacity. Figure 6 shows several possible shapes of these functional relationships. (Notice that these curves are similar to the fan part-load curves of Figure 3.) Curve 1 represents equipment with constant efficiency, independent of load. Curve 2 represents equipment that is most efficient in the middle of its operating range. Curve 3 represents equipment that is most efficient at full load. Note that these types of curves apply to both boilers and chillers.

**Table 4 Correlation Coefficients for Off-Design Relationships**

Correlation	0	1	2	3	4	5
$f_1$	-1.063931	0.0306584	0.0001269	0.0154213	0.0000497	0.0002096
$f_3$	0.8740302	0.0011416	0.0001711	-0.002957	0.0000102	0.0000592

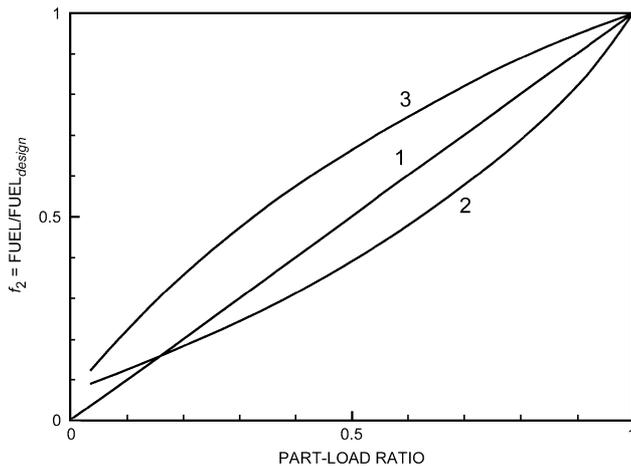

Fig. 6 Possible Part-Load Power Curves

**First-Principle Models.** As with the secondary components, engineering first principles can also be used to develop models of primary equipment. Lebrun et al. (1999), Gordon and Ng (1994, 1995), Gordon et al. (1995), and others have sought to develop such models in which unknown model parameters are extracted from measured or published manufacturers' data.

The energy analyst is often faced with choosing the appropriate model for the job. For example, a complex boiler model is not appropriate if the boiler in question operates at virtually constant efficiency. By similar arguments, a regression-based model might be appropriate when the user has a full dataset of reliable in-situ measurements of the plant. However, first-principle physical models generally have several advantages over pure regression models:

- Physical models allow confident extrapolation outside the range of available data.
- Regression is still required to obtain values for unknown physical parameters. However, the values of these parameters usually have physical significance. The engineer can capitalize on this significance to estimate default parameter values, diagnose errors in data analysis through checks for realistic parameter values, and even evaluate potential performance improvements.
- The number of unknown parameters is generally much smaller than the number of unknown coefficients in the typical regression model. For example, the standard ARI compressor model requires as many as 30 coefficients, 10 coefficients each for the regressions of capacity, power, and refrigerant flow. By comparison, a physical compressor model may have as few as four or five unknown parameters. As a result, the physical models require fewer measured data.
- Data on part-load operation of chillers and boilers are notoriously difficult to obtain. Part-load corrections often represent the greatest uncertainty in the regression models, while causing the greatest effect on annual energy predictions. By comparison, physical models of full-load operation often allow direct extension to part-load operation with little additional required data.

While physical models of primary HVAC equipment are generally based on fundamental engineering analysis and found in many HVAC textbooks, the models described here are specifically based on the work of Bourdouxhe et al. (1994a, 1994b, 1994c) in the development of the ASHRAE *HVAC 1 Toolkit* (Lebrun et al. 1999). The behavior of each elementary component is characterized by a limited number of physical parameters, such as heat exchanger heat transfer area or centrifugal compressor impeller blade angle. Values of these parameters are identified, or tuned, based on regression fits of overall performance compared to measured or published data.

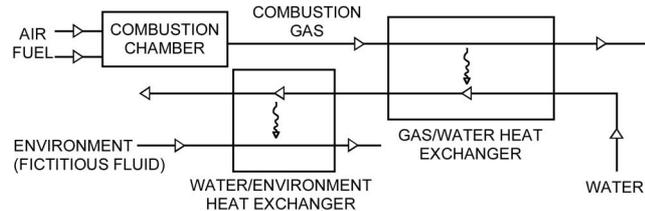

Fig. 7 Boiler Modeled with Elementary Components

While physical models are based on physical characteristics, the values obtained through a regression analysis of manufacturers' data are not necessarily representative of the actual measured values. Strictly speaking, the parameter values are regression coefficients with somewhat fictitious values, identified to minimize the error in overall system performance. In other words, errors in the fundamental models of the equipment are offset by over or under-estimation of the parameter values.

### Boiler Model

The thermal model of a water boiler operating in a steady-state regime is shown in Figure 7. It consists of an adiabatic combustion chamber and two heat exchangers. These three components interact through the following fluids: air, fuel, combustion gas, water, and a fictitious fluid representing the environment.

The adiabatic combustion chamber and the two heat exchangers can be modeled using classical thermodynamic principles. For example, the boiler heat exchangers can be described using effectiveness-NTU models. That is, knowing the flow rates and entering fluid temperatures, the heat transfer is calculated using a single overall heat transfer coefficient  $UA$ . For the water/environment heat exchanger, the environment is considered to be an isothermal reservoir and can be modeled as a fictitious fluid with infinite capacitance. The values of the overall heat transfer coefficients of the two heat exchangers are selected, or tuned to manufacturer's data, to represent the behavior of a particular boiler.

Most boilers are equipped with combustion control systems that vary fuel input to satisfy changing heating loads. The model of Figure 7 can reflect the physical effects of varying fuel, fluid flow, and stand-by losses to realistically show the degradation of performance at part-load operation. In addition, single-stage boilers with on-off control and two-stage boilers with two distinct firing rates can be modeled as "quasi-static" systems, where the cyclic operation is represented by a linear combination of two steady-state regimes.

### Vapor Compression Chiller Models

Figure 8 shows a schematic of a vapor compression chiller. In this case, the components include two heat exchangers, an expansion valve, and a compressor with a motor and transmission. The components of a chiller are linked through the refrigerant. For energy estimating, a simplified approach is sufficient to represent the refrigerant as a "perfect" fluid with fictitious property values. That is, refrigerant liquid is modeled as incompressible, and vapor properties are described by ideal gas laws with effective average values of property parameters, such as specific heat.

**Condenser and Evaporator Modeling.** Both condensers and evaporators are modeled as classical heat exchangers. The two heat exchangers are each assumed to have a constant overall heat transfer coefficient. In addition, the models used in chiller systems suffer from one additional assumption—the refrigerant fluid is assumed to be isothermal for both heat exchangers, which effectively ignores the superheated and subcooled regions of the heat exchanger. The assumption of an isothermal refrigerant is particularly crude for the condenser, which sees very high refrigerant temperatures from the compressor discharge. The effect of the

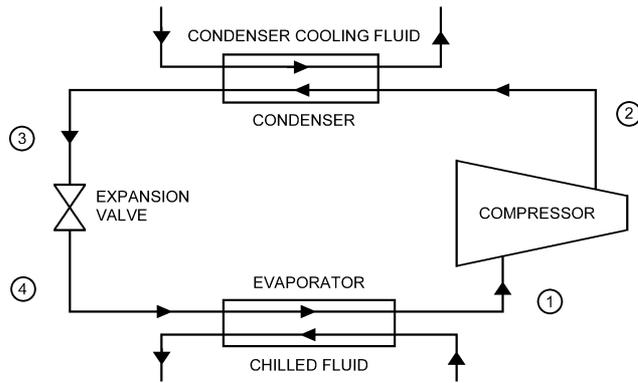

Fig. 8 Chiller Model Using Elementary Components

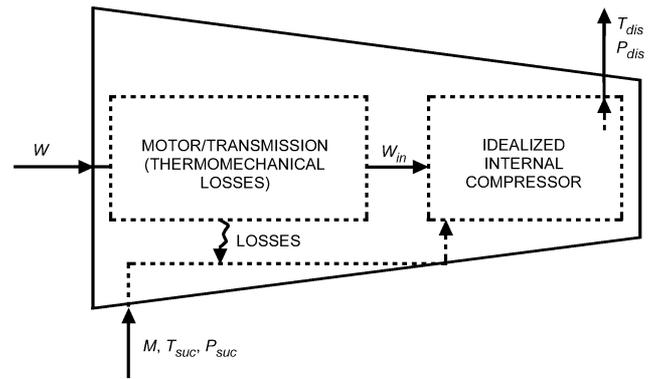

Fig. 9 General Schematic of Compressor

assumption is to significantly underestimate the mean temperature difference between refrigerant and water in the heat exchanger. Fortunately, this systematic error is compensated by a significant overestimate of the corresponding heat transfer coefficient.

**General Compressor Modeling.** The modeling of real compressors requires the description of many thermomechanical losses within the compressor. Such losses could include heat loss, fluid friction, throttling losses in valves, or motor and transmission inefficiencies. While some of these losses can be modeled within the compressor, others are too complex or unknown to describe in a model for energy calculations.

The general approach used here for compressor modeling is described in the Figure 9. The compressor is described by two distinct internal elements: an idealized internal compressor and a motor-transmission element to account for unknown losses. Schematically, the motor-transmission subsystem represents an inefficiency of energy conversion. The losses from these inefficiencies are assumed to heat the fluid prior to compression. Mathematically, it can be modeled by the following linear relationship:

$$W = W_{lo} + (1 + \alpha)W_{in} \quad (34)$$

where

- $W$  = electrical power for a hermetic or semihermetic compressor, or shaft power for an open compressor
- $W_{in}$  = idealized internal compressor power (depends on type of compressor)
- $W_{lo}$  = constant electromechanical loss
- $\alpha$  = proportional power loss factor

$W_{lo}$  and  $\alpha$  are empirical parameters determined by performing a regression analysis on manufacturers' data. Other parameters are also required to model  $W_{in}$ , the idealized internal compressor power, depending on the type of compressor.

The following sections describe different modeling techniques for reciprocating, screw, and centrifugal compressors. Detailed modeling techniques are available in the ASHRAE *HVAC 1 Toolkit* (Lebrun et al. 1999) and associated references.

**Modeling the Reciprocating Compressor.** The conceptual schematic for a reciprocating compressor, for use with the general model, is shown in Figure 10. The refrigerant enters the compressor at state 1 and is heated to state 1a by the thermomechanical losses of the motor-transmission model in Figure 9. The refrigerant undergoes an isentropic compression process to state 2s, followed by a throttling process to the compressor discharge at state 2. The throttling valve is a simplified approach to model the known losses within the compressor due to pressure drops across the suction and discharge valves. Perhaps a more accurate model would include pressure losses at both the inlet and outlet of the compressor, but analysis of compressor data reveals that this simpler model is ade-

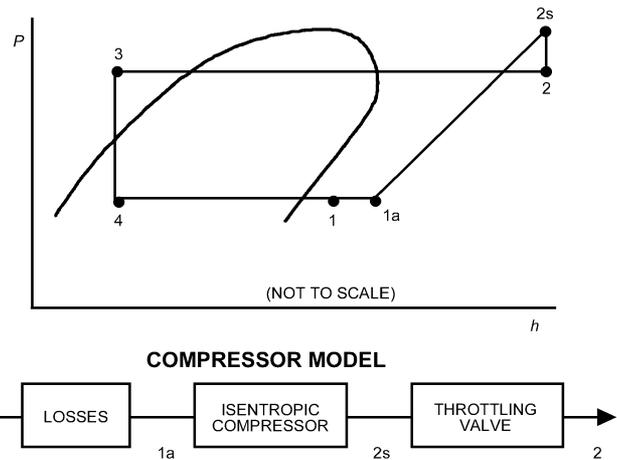

Fig. 10 Schematic of Reciprocating Compressor Model

quate for modeling of typical reciprocating compressors. In fact, many compressors can be adequately modeled with no throttling valve at all.

The refrigerant flow rate through the system must be determined to predict chiller and compressor performance. In general, volumetric flow depends on the pressure difference across the compressor. The compressor refrigerant flow rate is a decreasing function of the pressure ratio due to the re-expansion of the vapor in the clearance volume. With the refrigerant vapor modeled as an ideal gas, the volumetric flow rate is given by the following:

$$V = V_s \left[ 1 + C_f - C_f \left( \frac{P_{ex}}{P_{suc}} \right)^{1/\gamma} \right] \quad (35)$$

where

- $V$  = volumetric flow rate
- $V_s$  = swept volumetric flow rate (geometric displacement of the compressor)
- $C_f$  = clearance factor =  $V_{clearance}/V_s$
- $P_{ex}/P_{suc}$  = cylinder pressure ratio
- $\gamma$  = specific heat ratio

$V_s$  and  $C_f$  must be identified using data for the actual reciprocating compressor.

While the models discussed apply to full-load operation, Equation (35) is also valid at part-load conditions. However, the internal power use can be different at part load depending on the particular strategy for capacity modulation, such as on-off cycling, cylinder

unloading, hot-gas bypass, or variable-speed motor. In most cases, simple physical models can be developed to describe these methods, which generally vary the swept volumetric rate. Additional thermomechanical losses can also be modeled flow but often involve additional parameters. For example, the effect of cylinder unloading can be modeled by the following relationship:

$$W_{in} = W_{in, FL} + \left(1 - \frac{N_c}{N_{c, FL}}\right) W_{pump} \quad (36)$$

where

- $N_c$  = number of cylinders in use
- $N_{c, FL}$  = number of cylinders in use in full-load regime
- $W_{pump}$  = internal power of the compressor when all the cylinders are unloaded ("pumping" power)
- $W_{in, FL}$  = full-load power

The variable  $W_{pump}$  characterizes the part-load regime of the reciprocating compressor, and it is assumed to be constant throughout the entire part-load range.

In summary, a realistic physical model of a reciprocating compressor, covering both full-load and part-load operations, can be developed based on six parameters: the constant and proportional loss terms of the motor-transmission model  $W_{lo}$  and  $\alpha$ , the swept volumetric flow rate  $V_s$  of the compressor cylinders, the cylinder clearance volume factor  $C_f$ , the fictitious exhaust valve flow area  $A_{ex}$ , and the zero-load pumping power of the unloaded compressor  $W_{pump}$ . The entire chiller can then be modeled with two additional parameters for the overall heat transfer coefficients of the condenser and evaporator.

**Modeling of Other Compressors and Chillers.** From a modeling perspective, the thermodynamic processes of a screw compressor are similar to those of a reciprocating compressor. Physically, the screw compressor transports an initial volumetric flow rate of refrigerant vapor to a higher pressure and density by squeezing it into a smaller space. A realistic physical model of a variable-volume-ratio, twin-screw compressor, covering both full-load and part-load operations, can be developed based on five parameters: the constant and proportional loss terms of the motor-transmission model of Equation (34), the swept volumetric flow rate of the compressor screw, the internal leakage area, and a pumped pressure differential for diverted flow at part-load (Lebrun et al. 1999). The entire chiller can then be modeled with two additional parameters for the overall heat transfer coefficients of the condenser and evaporator.

An idealized internal model of a centrifugal compressor, to be used in conjunction with Equation (34) and Figure 9, can be based on an ideal analysis of a single-stage compressor composed of an isentropic impeller and isentropic diffuser. In addition to the thermomechanical loss parameters of Equation (34), only three additional parameters are required by this centrifugal compressor model: the peripheral speed of the impeller, the inclination of the vanes at the impeller exhaust, and the impeller exhaust area.

The refrigerant cycle of an absorption chiller is the same as for a vapor compression cycle, except for the absorption-generation subsystem in place of the compressor. The absorption-generation subsystem includes an absorber, a steam-fired generator, a recovery heat exchanger, a pump, and a control valve. All components except the pump and control valve can be modeled as heat exchangers.

### Cooling Tower Model

A cooling tower is used in primary systems to reject heat from the chiller condenser. The controls typically control the tower fans and pumps to maintain a desired water temperature entering the condenser. Like cooling and dehumidifying coils in secondary systems, the performance of a cooling tower has a strong influence on the energy consumption of the chiller. In addition, tower fans consume electrical energy directly.

Fundamentally, a cooling tower is a direct contact heat and mass exchanger. Equations describing the fundamental processes are given in Chapter 5 and in many HVAC textbooks. Chapter 36 of the 2000 *ASHRAE Handbook—Systems and Equipment* describes the specific performance of cooling towers. In addition, cooling tower performance subroutines are available in Lebrun et al. (1999) and Klein et al. (1994).

For energy calculations, cooling tower performance is typically described in terms of the outdoor wet-bulb temperature, the temperature drop of the water flowing through the tower (the range), and the difference between the leaving water temperature and the air wet-bulb temperature (the approach). While simple models assume constant range and approach, more sophisticated models use rating performance data to relate leaving water temperature to the outdoor wet-bulb temperature, water flow, and airflow. Simple cooling tower models, such as those based on a single overall transfer coefficient that can be directly inferred from a single tower rating point, are often appropriate for energy calculations.

## SYSTEM MODELING

### OVERALL MODELING STRATEGIES

In developing a simulation model for building energy prediction, two basic issues must be considered—(1) modeling of components or subsystems and (2) the overall modeling strategy. Modeling of components, which was discussed in the section on Component Modeling and Loads, results in sets of equations describing the individual components. The overall modeling strategy refers to the **sequence** and **procedures** used to solve these equations. The accuracy of results and the computer resources required to achieve these results depend on the modeling strategy.

In most building energy programs, the load models are executed for every space for every hour of the simulation period. (Practically all models use 1 h as the time step, which excludes any information on phenomena occurring in a shorter time span.) The load model is followed by running models for every secondary system, one at a time, for every hour of the simulation. Finally, the plant simulation model is executed again for the entire period. Each sequential execution processes the **fixed** output of the preceding step.

This procedure is illustrated in Figure 11. The solid lines represent data passed from one model to the next. The dashed lines represent information, usually provided by the user, about one model passed to the preceding model. For example, the system information consists of a piecewise-linear function of zone temperature that gives the system capacity.

Because of this loads-systems-plants sequence, certain phenomena cannot be modeled precisely. For example, if the heat balance method for computing loads is used, and some component in the system simulation model cannot meet the load, the program can only report the current load. In actuality, the space temperature should readjust until the load matches the equipment capacity, but this cannot be modeled because the loads have been precalculated and fixed. If the weighting factor method is used for loads, this problem is partially overcome, because loads are continually readjusted during the system simulation. However, the weighting factor

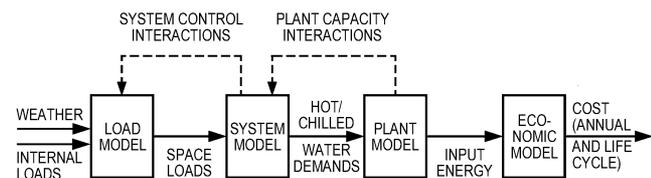

Fig. 11 Overall Modeling Strategy

technique is based on linear mathematics, and wide departures of room temperatures from those used during execution of the load program can introduce errors.

A similar problem arises in plant simulation. For example, in an actual building, as the load on the central plant varies the supply chilled water temperature also varies. This variation in turn affects the capacity of the secondary system equipment. In an actual building, when the central plant becomes overloaded, space temperatures should rise to reduce the load. However, in most energy estimating programs, this condition cannot occur; thus, only the overload condition can be reported. These are some of the penalties associated with decoupling of the load, system, and plant models.

An alternative strategy, in which all calculations are performed at each time step, is conceivable. Here the load, system, and plant equations are solved simultaneously at each time interval. With this strategy, unmet loads and imbalances cannot occur; conditions at the plant are immediately reflected to the secondary system and then to the load model, forcing them to readjust to the instantaneous conditions throughout the building. The results of this modeling strategy are superior to those currently available, although the magnitude and importance of the improvement are uncertain.

The principal disadvantage of the alternative approach, and the reason that it has not been widely used, is that it demands more computing resources. However, programs that, to one degree or another, implement simultaneous solution of the loads, system, and plant models have been developed by Clarke (1985), Park et al. (1985), Klein et al. (1994), and Metcalfe et al. (1995).

An economic model, as shown in Figure 11, calculates energy costs (and sometimes capital costs) based on the estimated required input energy. Thus, the simulation model calculates energy usage and cost for any given input weather and internal loads. By applying this model (i.e., determining output for given inputs) at each hour (or other suitable interval), the hour-by-hour energy consumption and cost can be determined. Maintaining running sums of these quantities yields monthly or annual energy usage and costs.

These models only compare design alternatives; a large number of uncontrolled and unknown factors usually rule out such models for accurate prediction of utility bills. For example, Miller (1980) found that the dynamics of control of components may have at least minor effects on predicted energy use. The section on Bibliography lists several models, which are also described in Walton (1983) and York and Cappiello (1981). Generally, the load models tend to be the most complex and time-consuming, while the central plant model is the least complex.

Because the detailed models are computationally intensive, several simplified methods have been developed. These methods include the degree-day method, the bin method, and correlation methods, and they are presented in the next two sections.

## DEGREE-DAY AND BIN METHODS

**Degree-day methods** are the simplest methods for energy analysis and are appropriate if the building use and the efficiency of the HVAC equipment are constant. Where efficiency or conditions of use vary with outdoor temperature, the consumption can be calculated for different values of the outdoor temperature and multiplied by the corresponding number of hours; this approach is used in various **bin methods**. When the indoor temperature is allowed to fluctuate or when interior gains vary, models other than simple steady-state models must be used.

Even in an age when computers can easily calculate the energy consumption of a building, the concepts of degree-days and balance point temperature remain valuable tools. The severity of a climate can be characterized concisely in terms of degree-days. Also, the degree-day method and its generalizations can provide a simple estimate of annual loads, which can be accurate if the indoor temperature and internal gains are relatively constant and if the heating

or cooling systems operate for a complete season. For these reasons, basic steady-state methods continue to be important.

### Balance Point Temperature

The balance point temperature  $t_{bal}$  of a building is defined as that value of the outdoor temperature  $t_o$  at which, for the specified value of the interior temperature  $t_i$ , the total heat loss  $q_{gain}$  is equal to the heat gain from sun, occupants, lights, and so forth.

$$q_{gain} = K_{tot}(t_i - t_{bal}) \quad (37)$$

where  $K_{tot}$  is the total heat loss coefficient of the building in W/K. For any of the steady-state methods described in this section, heat gains must be the average for the period in question, not for the peak values. In particular, solar radiation must be based on averages, not peak values. The balance point temperature is therefore obtained as

$$t_{bal} = t_i - \frac{q_{gain}}{K_{tot}} \quad (38)$$

Heating is needed only when  $t_o$  drops below  $t_{bal}$ . The rate of energy consumption of the heating system is

$$q_h = \frac{K_{tot}}{\eta_h} [t_{bal} - t_o(\theta)]^+ \quad (39)$$

where  $\eta_h$  is the efficiency of the heating system, also designated on an annual basis as the annual fuel use efficiency (AFUE),  $\theta$  is time, and the plus sign above the bracket indicates that only positive values are to be counted. If  $t_{bal}$ ,  $K_{tot}$ , and  $\eta_h$  are constant, the annual heating consumption can be written as an integral:

$$Q_{h, yr} = \frac{K_{tot}}{\eta_h} \int [t_{bal} - t_o(\theta)]^+ d\theta \quad (40)$$

This integral of the temperature difference conveniently summarizes the effect of outdoor temperatures on a building. In practice, it is approximated by summing averages over short time intervals (daily or hourly); the result is termed **degree-days** or **degree-hours**.

### Annual Degree-Day Method

**Annual Degree-Days.** If daily average values of outdoor temperature are used for evaluating the integral, the degree-days for heating  $DD_h(t_{bal})$  are obtained as

$$DD_h(t_{bal}) = (1 \text{ day}) \sum_{\text{days}} (t_{bal} - t_o)^+ \quad (41)$$

with dimensions of K·days. Here the summation is to extend over the entire year or over the heating season. It is a function of  $t_{bal}$ , reflecting the roles of  $t_i$ , heat gain, and loss coefficient. The balance point temperature  $t_{bal}$  is also known as the **base** of the degree-days. In terms of degree-days, the annual heating consumption is

$$Q_{h, yr} = \frac{K_{tot}}{\eta_h} DD_h(t_{bal}) \quad (42)$$

Heating degree-days or degree-hours for a balance point temperature of 18.3°C have been widely tabulated based on the observation that this has represented average conditions in typical buildings in the past. The 18.3°C base is assumed whenever  $t_{bal}$  is not indicated explicitly. The extension of degree-day data to different bases is discussed later.

Cooling degree-days can be calculated using an equation analogous to Equation (41) for heating degree-days as

$$DD_c(t_{bal}) = (1 \text{ day}) \sum_{\text{days}} (t_o - t_{bal})^+ \quad (43)$$

While the definition of the balance point temperature is the same as that for heating, in a given building its numerical value for cooling is generally different from that for heating because  $q_i$ ,  $K_{tot}$ , and  $t_i$  can be different. According to Claridge et al. (1987),  $t_{bal}$  can include both solar and internal gains as well as losses to the ground.

Calculating cooling energy consumption using degree-days is more difficult than heating. For cooling, the equation analogous to Equation (42) is

$$Q_{c, yr} = \frac{K_{tot}}{\eta_h} DD_c(t_{bal}) \quad (44)$$

for a building whose  $K_{tot}$  does not change. That assumption is generally acceptable during the heating season, when windows are closed and the air exchange rate is fairly constant. However, during the intermediate or cooling season, heat gains can be eliminated, and the onset of mechanical cooling can be postponed by opening windows or increasing the ventilation. (In buildings with mechanical ventilation, this is called the **economizer mode**.) Mechanical air conditioning is needed only when the outdoor temperature extends beyond the threshold  $t_{max}$ . This threshold is given by an equation analogous to Equation (38), with the replacement of the closed window heat transmission coefficient  $K_{tot}$  by its value  $K_{max}$  for open windows:

$$t_{max} = t_i - \frac{q_{gain}}{K_{max}} \quad (45)$$

$K_{max}$  varies considerably with wind speed, but a constant value can be assumed for simple cases. The resulting sensible cooling load is shown schematically in Figure 12 as a function of  $t_o$ . The solid line is the load with open windows or increased ventilation; the dashed line shows the load if  $K_{tot}$  were kept constant. The annual cooling load for this mode can be calculated by breaking the area under the solid line into a rectangle and a triangle, or

$$Q_c = K_{tot}[DD_c(t_{max}) + (t_{max} - t_{bal})N_{max}] \quad (46)$$

where  $DD_c(t_{max})$  are the cooling degree-days for base  $t_{max}$ , and  $N_{max}$  is the number of days during the season when  $t_o$  rises above  $t_{max}$ .

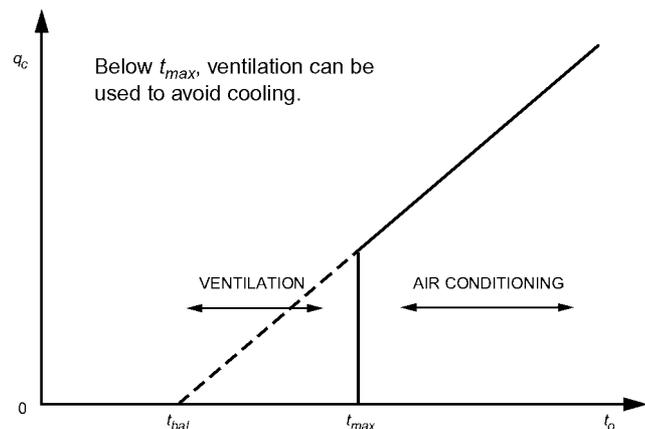

Fig. 12 Cooling Load as Function of Outdoor Temperature  $t_o$

This is merely a schematic model of air conditioning. In practice, heat gains and ventilation rates vary, as does the occupant behavior in using the windows and the air conditioner. Also, in commercial buildings with economizers, the extra fan energy for increased ventilation must be added to the calculations. Finally, air-conditioning systems are often turned off during unoccupied periods. Therefore, cooling degree-hours better represent the period when equipment is operating than cooling degree-days because degree-days assume uninterrupted equipment operation as long as there is a cooling load.

Latent loads can form an appreciable part of a building's cooling load. The degree-day method can be used to estimate the latent load during the cooling season on a monthly basis by adding the following term to Equation (46):

$$q_{latent} = \dot{m} h_{fg} (W_o - W_i) \quad (47)$$

where

- $q_{latent}$  = monthly latent cooling load, kW
- $m$  = monthly infiltration (total airflow), kg/s
- $h_{fg}$  = heat of vaporization of water, kJ/kg
- $W_o$  = outdoor humidity ratio (monthly averaged)
- $W_i$  = indoor humidity ratio (monthly averaged)

The degree-day method assumes that  $t_{bal}$  is constant, which is not well satisfied in practice. Solar gains are zero at night, and internal gains tend to be highest during the evening. The pattern for a typical house is shown in Figure 13. As long as  $t_o$  always stays below  $t_{bal}$ , the variations average out without changing the consumption. But for the situation in Figure 13,  $t_o$  rises above  $t_{bal}$  from shortly after 10:00 A.M. to 10:00 P.M.; the consequences for energy consumption depend on the thermal inertia and on the control of the HVAC system. If this building had low inertia and if temperature control were critical, heating would be needed at night and cooling during the day. In practice, this effect is reduced by thermal inertia and by the dead band of the thermostat, which allows  $t_i$  to float.

The closer  $t_o$  is to  $t_{bal}$ , the greater the uncertainty. If the occupants keep the windows closed during mild weather,  $t_i$  will rise above the set point. If they open the windows, the potential benefit of heat gains is reduced. In either case, the true values of  $t_{bal}$  become uncertain. Therefore, the degree-day method, like any steady-state method, is unreliable for estimating the consumption during mild weather. In fact, the consumption becomes most sensitive to occupant behavior and cannot be predicted with certainty.

Despite these problems, the degree-day method (using an appropriate base temperature) can give remarkably accurate results for the annual heating energy of single-zone buildings dominated by

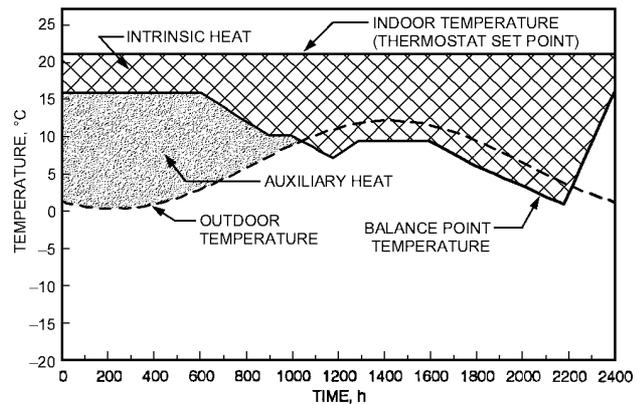

Fig. 13 Variation of Balance Point Temperature and Internal Gains for a Typical House (Nisson and Dutt 1985)

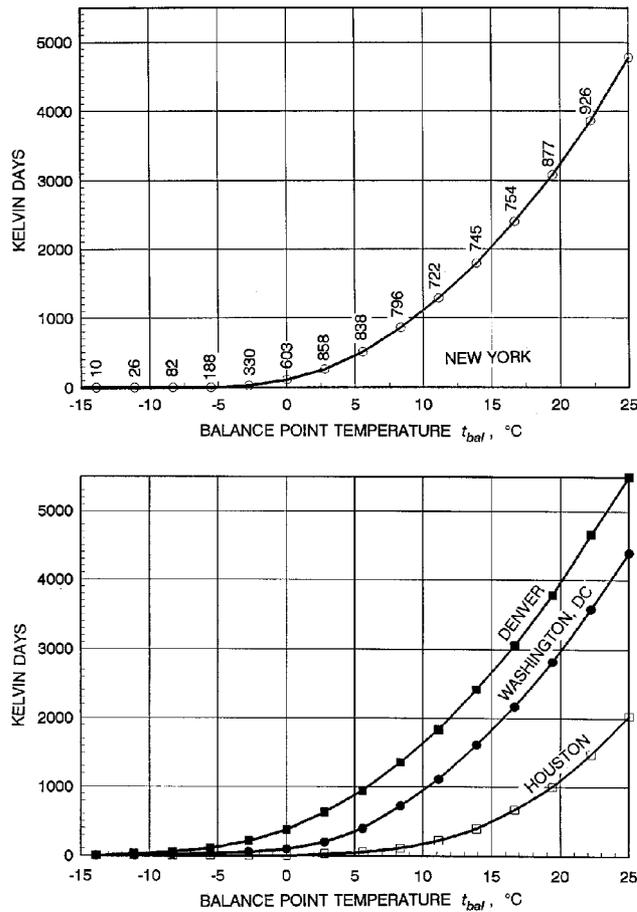

Fig. 14 Annual Heating Days  $DD_h(t_{bal})$  as Function of Balance Temperature  $t_{bal}$

losses through the walls and roof and/or ventilation. Typical buildings have time constants that are about 1 day, and a building's thermal inertia essentially averages over the diurnal variations, especially if  $t_i$  is allowed to float. Furthermore, the energy consumption in mild weather is small; hence, a relatively large error here has only a small effect on the total for the season.

**Variable-Base Annual Degree-Days.** The calculation of  $Q_h$  from degree-days  $DD_h(t_{bal})$  depends on the value of  $t_{bal}$ . This value varies widely from one building to another because of widely differing personal preferences for thermostat settings and setbacks and because of different building characteristics. In response to the fuel crises of the 1970s, heat transmission coefficients have been reduced, and thermostat setback has become common. At the same time, the energy use by appliances has increased. These trends all reduce  $t_{bal}$  (Fels and Goldberg 1986). Hence, in general, degree days with the traditional base 18.3°C are not to be used.

Figure 14A shows how the heating degree-days vary with  $t_{bal}$  for a particular site, in this case, New York. The plot is obtained by evaluating Equation (41) with data for the number of hours per year during which  $t_o$  is within 2.8 K temperature intervals centered at 25°C, 22.2°C, 19.4°C, 16.6°C, ..., -13.9°C. The data for the number of hours in each interval, or **bin**, are included as labels in this plot. Analogous curves, without these labels, are shown in Figure 14B for three other sites: Houston, Washington, and Denver. If the annual average of  $t_o$  is known, the cooling degree-days to any base below  $22 \pm 1.4^\circ\text{C}$  can also be found.

**Seasonal Efficiency.** The seasonal efficiency  $\eta_h$  of heating equipment depends on such factors as steady-state efficiency, sizing, cycling effects, and energy conservation devices. Sometimes it is much lower than and other times it is comparable to steady-state efficiency. Alereza and Kusuda (1982) developed expressions to estimate the seasonal efficiency for a variety of furnaces, if information on rated input and output is available. These expressions correlate seasonal efficiency with variables determined by using the equipment simulation capabilities of a large hourly simulation program and typical equipment performance curves supplied by the National Institute of Standards and Technology (NIST):

$$\eta = \frac{\eta_s CF_{pl}}{1 + \alpha_D} \quad (48)$$

where

$\eta_s$  = steady-state efficiency (rated output/input)

$\alpha_D$  = fraction of heat loss from ducts

$CF_{pl}$  = part-load correction factor

The dimensionless term  $CF_{pl}$  is a characteristic of the part-load efficiency of the heating equipment, which may be calculated as follows:

#### Gas Forced-Air Furnaces

With pilot

$$CF_{pl} = 0.6328 + 0.5738(\text{RLC}) - 0.3323(\text{RLC})^2$$

With intermittent ignition

$$CF_{pl} = 0.7791 + 0.1983(\text{RLC}) - 0.0711(\text{RLC})^2$$

With intermittent ignition and loose stack damper

$$CF_{pl} = 0.9276 + 0.0732(\text{RLC}) - 0.0284(\text{RLC})^2$$

#### Oil Furnaces Without Stack Damper

$$CF_{pl} = 0.7092 + 0.6515(\text{RLC}) - 0.4711(\text{RLC})^2$$

#### Resistance Electric Furnaces

$$CF_{pl} = 1.0$$

These equations are based on many annual simulations for the equipment. The dimensionless ratio RLC of building design load to the capacity (rated output) of the equipment is defined as follows:

$$\text{RLC} = \frac{\text{BLC}}{\text{CHT}}(t_{bal} - t_{od})(1 + \alpha_D)$$

where

BLC = building loss coefficient, W/K

$t_{od}$  = outside design temperature, °C

CHT = capacity (rated output) of heating equipment, W

The building loss coefficient BLC can be defined as design-day heat loss/( $t_{bal} - t_{od}$ ). The design-day heat loss includes both infiltration and ground losses. Duct losses as a percentage of the design-day heat loss are added via the factor  $(1 + \alpha_D)$ . RLC assumes values in the range 0 to 1.0, appropriate for typical cases when the heating equipment is oversized. Seasonal efficiency is also discussed by Chi and Kelly (1978), Parker et al. (1980), and Mitchell (1983).

#### Monthly Degree-Days

Many formulas have been proposed for estimating the degree-days relative to an arbitrary base when detailed data are not available. The basic idea is to assume a typical probability distribution of

temperature data, characterized by its average  $\bar{t}_o$  and by its standard deviation  $\sigma$  Erbs et al. (1983) developed a model that needs as input only the average  $\bar{t}_o$  for each month of the year. The standard deviations  $\sigma_m$  for each month are then estimated from the correlation

$$\sigma_m = 3.54 - 0.0290\bar{t}_o + 0.0644\sigma_{yr} \quad (49)$$

This is a dimensional equation with  $t$  and  $\sigma$  in °C;  $\sigma_{yr}$  is the standard deviation of the monthly average temperatures about the annual average  $t_{o, yr}$ :

$$\sigma_{yr} = \sqrt{\frac{1}{12} \sum_1^{12} (\bar{t}_{o, yr} - \bar{t}_o)^2} \quad (50)$$

To obtain a simple expression for the degree-days, a normalized temperature variable  $\phi$  is defined as

$$\phi = \frac{\bar{t}_{bal} - \bar{t}_o}{\sigma_m \sqrt{N}} \quad (51)$$

where  $N$  = number of days in the month ( $N$  has units of day/month and  $\phi$  has units of  $\sqrt{\text{month}/\text{day}}$ ). While temperature distributions can be different from month to month and location to location, most of this variability can be accounted for by the average and the standard deviation of  $\bar{t}_o$ . Being centered around  $\bar{t}_o$  and scaled by  $\sigma_m$ , the quantity  $\phi$  eliminates these effects. In terms of  $\phi$ , the monthly heating degree-days for any location are well approximated by

$$DD_h(t_{bal}) = \sigma_m N^{1.5} \left[ \frac{\phi}{2} + \frac{\ln(e^{-a\phi} + e^{a\phi})}{2a} \right] \quad (52)$$

where  $a = 1.698\sqrt{\text{day}/\text{month}}$ .

For nine locations spanning most climatic zones of the United States, Erbs et al. (1983) verified that the annual heating degree days can be estimated with a maximum error of 175 K·days if Equation (52) is used for each month. For cooling degree-days, the largest error is 150 K·days. Such errors are quite acceptable, representing less than 5% of the total.

Table 5 lists monthly heating degree-days for New York City, using the model of Erbs et al. (1983), given monthly averages of  $t_o$  as reproduced in column 2 of Table 5. The degree-days are based on a balance temperature of 15.6°C. Column 2 lists the given values of monthly average outdoor temperature, and  $N$  is the number of days in the month. Intermediate quantities are shown in columns 4 and 5, and  $t_{o, yr}$  and  $\sigma_{yr}$  are shown at the bottom. Column 6 shows the monthly and annual results.

Table 6 contains degree-day data for several sites and monthly averaged outdoor temperatures needed for the algorithm. More complete tabulations of the latter are contained in Cinquemani et al. (1978) and in local climatological data summaries available from the National Climatic Data Center, Asheville, NC (NOAA 1973 and www.ncdc.noaa.gov). Monthly degree-day data at various bases, as well as other climatic information for 209 U.S. and 14 Canadian cities, may be found in Appendix 3 to Balcomb et al. (1982).

**Bin Method**

For many applications, the degree-day method should not be used, even with the variable-base method, because the heat loss coefficient  $K_{tot}$ , the efficiency  $\eta$  of the HVAC system, or the balance point temperature  $t_{bal}$  may not be sufficiently constant. The efficiency of a heat pump, for example, varies strongly with outdoor temperature; or the efficiency of the HVAC equipment may be affected indirectly by  $t_o$  when the efficiency varies with the load, a common situation for boilers and chillers. Furthermore, in most commercial buildings, the occupancy has a pronounced pattern, which affects heat gain, indoor temperature, and ventilation rate.

In such cases, a steady-state calculation can yield good results for the annual energy consumption if different temperature intervals and time periods are evaluated separately. This approach is known as the bin method because the consumption is calculated for several values of the outdoor temperature  $t_o$  and multiplied by the number of hours  $N_{bin}$  in the temperature interval (bin) centered around that temperature:

<sup>a</sup>Cycling Capacity Adjustment Factor =  $1 - C_d(1 - x)$ , where  $C_d$  = degradation coefficient (default = 0.25 unless part load factor is known) and  $x$  = building heat loss per unit capacity at temperature bin. Cycling capacity = 1 at the balance point and below. The cycling capacity adjustment factor should be 1.0 at all temperature bins if the manufacturer includes cycling effects in the heat pump capacity (Column E) and associated electrical input (Column H).

<sup>f</sup>Column L = Column C × Column D

<sup>g</sup>Column M = Column L - Column J

<sup>h</sup>Column N = Column K + Column M

$$Q_{bin} = N_{bin} \frac{K_{tot}}{\eta_h} [t_{bal} - t_o]^+ \quad (53)$$

The superscript plus sign indicates that only positive values are counted; no heating is needed when  $t_o$  is above  $t_{bal}$ . Equation (53) is evaluated for each bin, and the total consumption is the sum of the  $Q_{bin}$  over all bins.

In the United States, the necessary weather data are available in ASHRAE (1995) and USAF (1978). The bins are usually in 2.8 K increments (when derived from 5°F bins) and are often collected in three daily 8 h shifts. Mean coincident wet-bulb temperature data (for each dry-bulb bin) are used to calculate latent cooling loads from infiltration and ventilation. The bin method considers both occupied and unoccupied building conditions and gives credit for internal loads by adjusting the balance point. For example, a calculation could be performed for 5°C outdoors (representing all occurrences from 3.6 to 6.4°C) and with building operation during the midnight to 0800 shift (5°C outdoors, representing all occurrences from 4°C). Because there are 23 2.8 K bins between -23 and 40.4°C and 3 8 h shifts, 69 separate operating points are calculated. For many applications, the number of calculations can be reduced. A residential heat pump (heating mode), for example, could be calculated for just the bins below 18.3°C without the three-shift

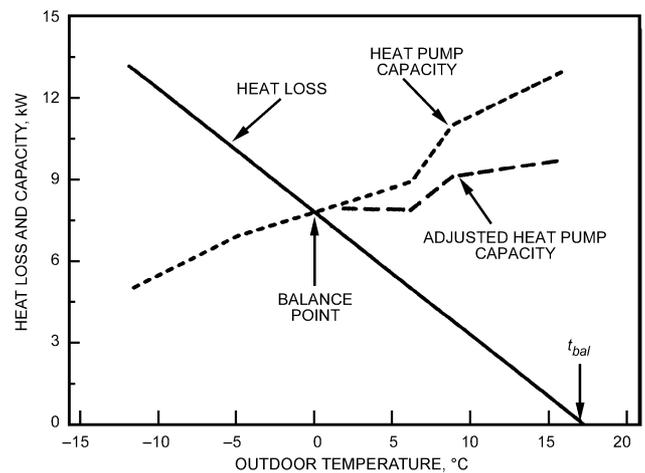

Fig. 15 Heat Pump Capacity and Building Load

breakdown. The data included in Table 7 are samples of annual totals for a few sites, but ASHRAE (1995) and USAF (1978) include monthly data and data further separated into time intervals during the day.

Equipment performance may vary with load. For heat pumps, the U.S. Department of Energy has adopted test procedures to determine the effect of dynamic operations. The bin method uses these results for a specific heat pump to adjust the integrated capacity for the effect of part-load operation. Figure 15 compares the adjusted heat pump capacity to the building heat loss in Example 4 below. This type of curve must be developed for each model heat pump as applied to an individual profile. The heat pump cycles on and off above the balance point temperature to meet the house load, while supplemental heat is required at lower temperatures. This cycling can reduce performance, depending on the part-load factor at a given temperature. The cycling capacity adjustment factors used in this example to account for cycling degradation can be calculated from the equation in footnote a of Table 8.

Frosting and the necessary defrost cycle can reduce performance over steady-state conditions that do not include frosting. The effects of frosting and defrosting are already integrated into many (but not all) manufacturers' published performance data. Example 4 assumes that the manufacturer's data already accounts for the frosting/defrosting losses (as indicated by the characteristic notch of the capacity curve in Figure 15) and shows how to adjust an integrated performance curve for cycling losses.

**Example 4.** Estimate the energy requirements for a residence in Nashville, Tenn., with a design heat loss of 11 700 W at 30°C design temperature difference. The inside design temperature is 21°C. It is estimated that internal heat gains average 1250 W. Weather data in terms of hours for each bin are shown in Table 7. Assume the selection of a 10.5 kW heat pump having the characteristics given in Columns E and H of Table 8 and in Figure 15.

**Solution:** The design heat loss is based on no internal heat generation. The heat pump system energy input is the net heat requirement of the space (i.e., the envelope loss minus the internal heat generation). The net heat loss per degree and the heating/cooling balance temperature may be computed:

$$K_{tot} = HL/\Delta t = 11\,700/30 = 390 \text{ W/K}$$

From Equation (38),

$$t_{bal} = 21 - (1250/390) = 17.8^\circ\text{C}$$

Table 8 is then computed, resulting in 7618 kWh.

The **modified bin method** (Knebel 1983) extends the basic bin method to account for weekday/weekend and partial-day occupancy effects, to calculate net building loads (conduction, infiltration, internal loads, and solar loads) at four temperatures, rather than interpolate from design values, and to better describe secondary and primary equipment performance.

## CORRELATION METHODS

One way to simplify energy analyses is to correlate energy requirements to various inputs. Typically, the result of a correlation is a simple equation that may be used in a calculator or small computer program or to develop a graph that provides a quick insight into the energy requirements. Examples of correlation methods are in ASHRAE *Standard* 90.1, which includes several empirical equations that may be used to predict energy consumption by many types of buildings.

The accuracy of correlation methods depends on the size and accuracy of the database and the statistical means used to develop the correlation. A database generated from measured data can lead to accurate correlations (Lachal et al. 1992). The key to the proper use of a correlation is that the case being studied matches the cases used in developing the database. Inputs to the correlation (the independent variables) indicate the factors that are considered to have significant impact on energy consumption. A correlation is invalid either when an input parameter is used beyond its valid range (corresponding to extrapolation rather than interpolation) or when some

important feature of the building/system is not included in the available inputs to the correlation.

## SIMULATING SECONDARY AND PRIMARY SYSTEMS

Traditionally, most energy analysis programs include a set of preprogrammed models that represent various systems, such as variable air volume, terminal reheat, multizone, etc. In this scheme, the equations for each system are arranged so they can be solved sequentially. If this is not possible, then the smallest number of equations that must be solved simultaneously is solved using an appropriate technique. Furthermore, individual equations may vary from hour to hour in the simulation, depending on controls and operating conditions. For example, a dry coil uses different equations than a wet coil.

The primary disadvantage of this scheme is that it is relatively inflexible—in order to modify a system, the program source code may have to be modified and recompiled. Alternative strategies (Klein et al. 1994, Park et al. 1985) have viewed the system as a series of components (e.g. fan, coil, pump, duct, pipe, damper, thermostat) that may be organized in a component library. Users of the program specify the connections between the components. The program then resolves the specification of components and connections into a set of simultaneous equations.

A refinement of component-based modeling is known as equation-based modeling (Sowell and Moshier 1995, Buhl et al. 1993). In this scheme, the models do not follow well-defined rules for a solution, and input and output variables are not predetermined.

## MODELING OF SYSTEM CONTROLS

From a mathematical viewpoint, controls represent equations that must be satisfied at each point during the simulation. For example, the room thermostat can be represented as a function relating heating and cooling delivery to space temperature. Similarly, cooling coil reset controls can be modeled as a relationship between outside or zone temperature and coil discharge temperature. An accurate secondary system model must ensure that all controls are properly represented and that the governing equations are satisfied at each simulation time step. This often creates a need for iteration or, alternately, for use of values from an earlier solution point.

The controls on space temperature affect the interaction between loads calculations and the secondary system simulation. A realistic model might require a dead band in space temperature in which no heating or cooling is called for; within this range, the true space sensible load is zero, and the true space temperature must be adjusted accordingly. If the thermostat has proportional control between zero and full capacity, the space temperature will rise in proportion to the load during cooling and fall similarly during heating. Capacity to heat or cool also varies with space temperature after the control device has reached its maximum because capacity is proportional to the **difference** between supply and space temperatures. Failure to properly model these phenomena results in overestimating required energy.

## INTEGRATION OF SYSTEM MODELS

Energy calculations for secondary systems involve construction of the complete system from the set of HVAC components. For example, a VAV system is a single-path system that controls zone temperature by modulating the airflow while maintaining a constant supply air temperature. VAV terminal units, located at each zone, adjust the quantity of air reaching each zone depending on its load requirements. Reheat coils may be included to provide required heating for perimeter zones.

This VAV system simulation consists of a central air-handling unit and a VAV terminal unit with reheat coil located at each zone,

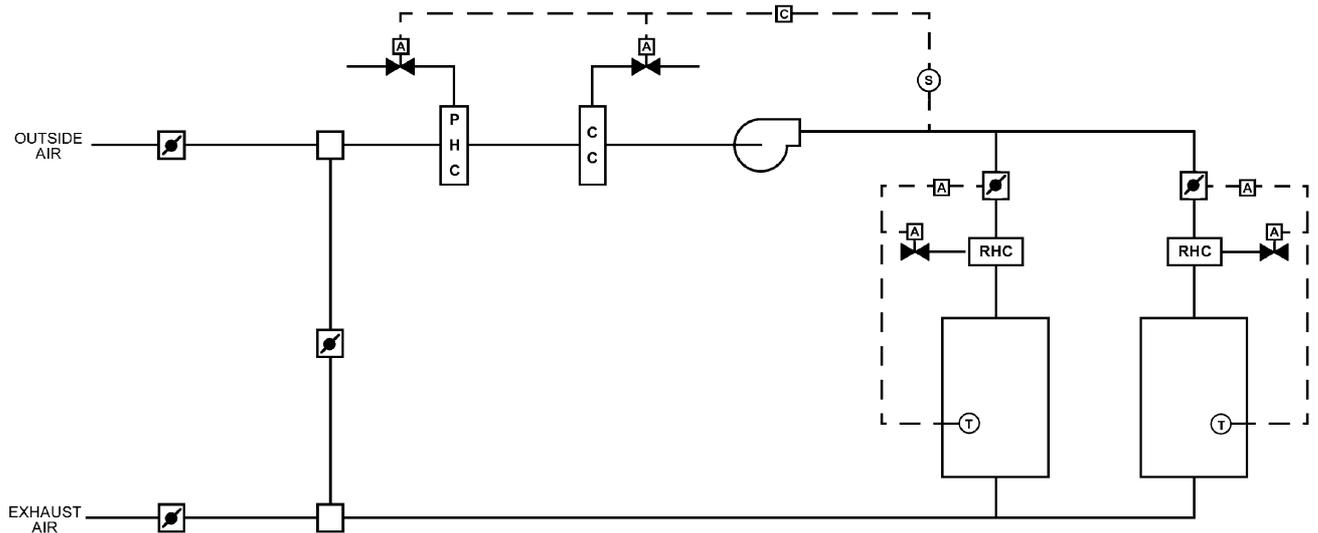

Fig. 16 Schematic of Variable Air Volume System with Reheat

as shown in Figure 16. The central air-handling unit includes a fan, a cooling coil, a preheat coil, and an outside air economizer. The supply air leaving the air-handling unit is controlled to a fixed set point. The VAV terminal unit at each zone varies the airflow to meet the cooling load. As the zone cooling load decreases, the VAV terminal unit decreases the zone airflow until the unit reaches its minimum position. If the cooling load continues to decrease, the reheat coil will be activated to meet the zone load. As the supply air volume leaving the unit decreases, the fan power consumption will also be reduced. A variable-speed drive is used to control the supply fan.

The simulation is based on system characteristics and zone design requirements. For each zone, the inputs include the sensible and latent loads, the zone set point temperature, and the minimum zone supply air mass flow. System characteristics include the supply air temperature set point, the entering water temperature of the reheat, preheat and cooling coils, the minimum mass flow of outside air, and the economizer temperature/enthalpy set point for minimum airflow.

The algorithm for performing the calculations for this VAV system is shown in Figure 17. The algorithm directs sequential calculations of system performance. Calculations proceed from the zones forward along the return air path to the cooling coil inlet and back through the supply air path to the cooling coil discharge.

Moving back along the supply air path, the fan entering air temperature is calculated by setting fan outlet air temperature to the system design supply air temperature. The known fan inlet air temperature is then used as both the cooling coil and preheat coil discharge air temperature set point. Moving forward along the return air path, the cooling coil entering air temperature can be determined by sequentially moving through the economizer cycle and the preheat coil.

Unlike temperature, the humidity ratio at any point in a system cannot be explicitly determined due to the dependence of the cooling coil performance on the mixed air humidity ratio. The latent load defines the difference between zone humidity and supply air humidity. However, the humidity ratio of the supply air depends on the humidity ratio entering the coil, which in turn depends on that of the return air. This calculation must be performed either by solving simultaneous equations or, as in this case, by an iterative process.

Assuming a trial value for the humidity ratio at the cooling coil discharge (e.g., 13°C, 90% rh), the humidity ratio at all other points throughout the system can be calculated. With known cooling coil inlet air conditions and a design discharge air temperature, the inverted cooling coil subroutine iterates on the coil fluid mass flow

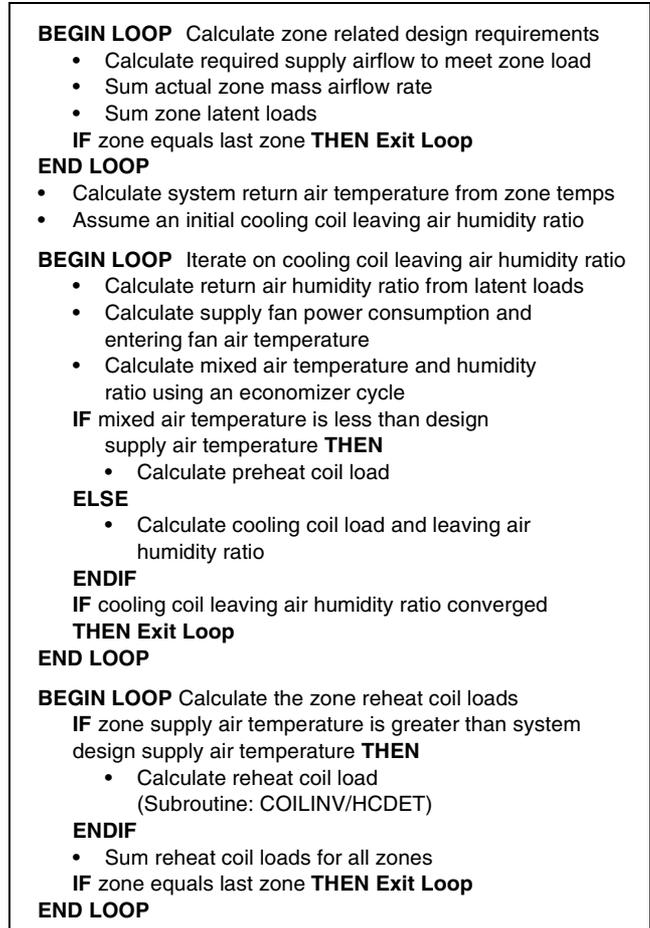

Fig. 17 Algorithm for Calculating Performance of VAV with System Reheat

to converge on the discharge air temperature with the discharge air humidity ratio as an output. The cooling coil discharge air humidity ratio is then compared to the previous discharge humidity ratio. This iterative process continues calculating through the loop several

times until the values of the cooling coil discharge air humidity ratio stabilize within a specified tolerance.

This basic algorithm for simulation of a VAV system might be used in conjunction with a heat balance type of load calculation. For a weighting factor approach, it would have to be modified to allow zone temperatures to vary and consequently zone loads to be readjusted. It should also be enhanced to allow for possible limits on reheat temperature and/or cooling coil limits, zone humidity limits, outside air control (economizers), and/or heat-recovery devices, zone exhaust, return air fan, heat gain in the return air path because of lights, the presence of baseboard-type heaters, and more realistic control profiles. Most current building energy programs incorporate these and other features as user options, as well as algorithms for other types of systems.

## INVERSE MODELING

### CATEGORIES OF INVERSE METHODS

Inverse methods for energy-use estimation in buildings and related HVAC&R equipment can be classified into three broad categories. These approaches are widely disparate in data requirements, in time and effort needed to develop the associated models, in user skill, and in the sophistication and reliability that they provide.

#### Empirical or “Black-Box” Approach

With this approach, a simple or multi-variate regression model is identified between measured energy use and the various influential parameters (climatic variables, building occupancy). The form of the regression models can be either purely statistical or loosely based on some basic engineering formulation of energy use in the building. In any case, the identified model coefficients are such that no (or very little) physical meaning can be assigned to them. This approach can be used with any time scale—monthly, daily, hourly or subhourly—provided appropriate data are available. Single-variate, multivariate, change point, Fourier series, and artificial neural network (ANN) models fall under this category, as noted in Table 1.

Model identification is relatively straightforward, usually requires little effort, and can be used in several diverse types of circumstances. The empirical approach is thus the most widely used inverse approach. Although more sophisticated regression techniques such as maximum likelihood and two-stage regression schemes can be used for model identification, least-squares regression is most common. The purely statistical approach is usually adequate for evaluating demand-side management (DSM) programs to identify simple and conventional energy conservation measures in an actual building (lighting retrofits, air handler retrofits such as CV to VAV retrofits) and for baseline model development in energy conservation measurement and verification (M&V) projects (Fels 1986; MacDonald and Wasserman 1989; Ruch and Claridge 1991; Reddy et al. 1997; Claridge 1998b; Kissock et al. 1998; Katipamula et al. 1998; Dhar 1995; Dhar et al. 1998, 1999a, 1999b; Miller and Seem 1991; Kreider and Wang 1991; Krarti et al. 1998). It is also appropriate for modeling equipment such as pumps and fans, and even more elaborate equipment such as chillers and boilers, provided the necessary performance data are available (Phelan et al. 1996, Braun 1992, Englander and Norford 1992, Lorenzetti and Norford 1993). Although this approach allows detection or flagging of equipment or system faults, it is usually of limited value for diagnosis and on-line control (with ANN as a possible exception).

#### Calibrated Simulation Approach

With this approach, one uses an existing building simulation computer program and “tunes” or calibrates the various physical inputs to the program so that observed energy use matches closely

with that predicted by the simulation program. Once that is achieved, more reliable predictions can be made than with the statistical approaches. The calibrated simulation approach is advocated in cases where only whole-building metering is available and M&V calls for estimating the energy savings of individual retrofits. Practitioners of this approach have largely tended to adopt existing and widely used forward simulation programs such as DOE-2 to subsequently perform the calibration with performance data. Hourly subaggregated monitored energy data (most compatible with the time step adopted by most building energy simulation programs) allow the development of the most accurate calibrated model, but analysts are usually forced to work with less data. Tuning can be done with monthly data or data that span only a few weeks or months over the year, but the resulting model is very likely to be increasingly less accurate with decrease in performance data.

The main reservations with the widespread use of calibrated simulation are that it is labor-intensive, requires a high level of user skill and knowledge in both simulation and practical building operation, is time-consuming, and is often dependent on the person doing the calibration. Several practical difficulties prevent achieving a calibrated simulation or a simulation that nearly reflects the actual building performance, including (1) the measurement and adaptation of weather data for use by the simulation programs (e.g., converting global horizontal solar into beam and diffuse solar radiation), (2) the choice of methods used to calibrate the model, and (3) the choice of methods used to measure the required input parameters for the simulation (i.e., the weight of the building, infiltration coefficients, and shading coefficients). Truly “calibrated” models have been achieved in only a few applications because they require a very large number of input parameters, a high degree of expertise, and enormous amounts of computing time, patience, and financial resources. Bronson et al. (1992), Haberl and Bou-Saada (1998), Kaplan et al. (1990), Corson (1992), Bou-Saada and Haberl (1995a, 1995b), Manke et al. (1996), and Norford et al. (1994) provide examples of different methods used to calibrate simulation models.

In recent years, Katipamula and Claridge (1993) and Liu and Claridge (1998) have suggested that models simpler than those used in the detailed simulation programs such as DOE-2 could also serve the intended purpose while allowing model calibration to be done much faster. Typically, the building is divided into two zones: an exterior or perimeter zone and an interior or a core zone. The core zone is assumed to be insulated from the envelope heat losses/gains, while the solar heat gains, infiltration heat loss/gain, and conduction gains/losses from the roof are taken to appear as loads on the external zone only. Given the internal load schedule, the building description, the type of HVAC system, and the climatic parameters, the HVAC system loads can be estimated for each hour of the day and for as many days of the year as needed by the simplified systems model. Since there are fewer parameters to vary, the calibration process is much faster. Therefore, these models have a significant advantage over general-purpose models in buildings where the HVAC systems can be adequately modeled. These studies, based on the ASHRAE Simplified Energy Analysis Procedure (Knebel 1983), illustrate the applicability of this method both to baseline model development for M&V purposes and as a diagnostic tool for identifying potential operational problems and for estimating potential savings from optimized operating parameters.

#### Gray-Box Approach

With this approach, a physical model is first formulated to represent the structure or physical configuration of the building or HVAC&R equipment or system, and then important parameters representative of certain key and aggregated physical parameters and characteristics are identified by a statistical analysis

(Rabl and Riahle 1992). This approach requires a high level of user expertise both in setting up the appropriate modeling equations and in the estimation of these parameters. Often an intrusive experimental protocol is necessary for proper parameter estimation that also requires a certain amount of user expertise. This approach has great potential, especially for fault detection and diagnosis (FDD) and on-line control, but its applicability to whole-building energy use is limited. Examples of parameter estimation studies as applied to building energy use are Sonderegger (1977), Hammersten (1984), Subbarao (1988), Rabl (1988), Reddy (1989), Andersen and Brandemuehl (1992), Braun (1990), Reddy et al. (1999), Gordon and Ng (1995), and Guyon and Palomo (1999).

**TYPES OF INVERSE MODELS**

We distinguish between two types of models: steady-state and dynamic. **Steady-state models** are those that do not consider such effects such as thermal mass or capacitance that cause short-term temperature transients. Generally these models are appropriate for monthly, weekly, or daily data and are often used for baseline model development. **Dynamic models** capture effects such as building warm-up or cool-down periods and peak loads and are appropriate for building load control, FDD, and equipment control. A simple criterion to determine whether a model is steady-state or dynamic is to look for the presence of time-lagged variables, either in the response or regressor variables. Steady-state models do not contain time-lagged variables.

**Steady-State Models**

There are several types of steady-state models used for both building and equipment energy use. They are single-variate, multivariate, polynomial, and physical models.

**Single-Variate Models.** Single-variate models (i.e., models with one regressor variable only) are perhaps the most widely used. They formulate energy use in a building as a function of one driving force that impacts building energy use. An important aspect in identifying statistical models of baseline energy use is the choice of the functional form and the independent (or regressor) variables. Extensive studies (Fels 1986, Kisscock et al. 1993, Katipamula et al. 1994, Reddy et al. 1997) have clearly indicated that the outdoor dry-bulb temperature is the most important regressor variable, especially at monthly time scales but also at daily time scales.

The simplest steady-state inverse model is one developed by regressing monthly utility consumption data against average billing-period temperatures. The model must identify the balance point temperatures (or change points) at which energy use switches from weather-dependent to weather-independent behavior. In its simplest form, the 18.3°C degree-day model is a change-point model that has a fixed change point at 18.3°C. Other examples include three- and five-parameter Princeton Scorekeeping Methods (PRISM) based on the variable-base degree-day concept (Fels 1986). An allied modeling approach for

commercial buildings is the four-parameter (4-P) model developed by Ruch and Claridge (1991), which is based on the monthly mean temperature (and not degree-days). Table 9 shows the appropriate model functional forms. The three parameters are a weather-independent base-level use, a change point, and a temperature-dependent energy use, characterized as a slope of a line that is determined by regression. The four parameters include a change point, a slope above the change point, a slope below the change point, and the energy use associated with the change point. An inverse bin method has also been proposed to handle more than four change points (Thamilseran and Haberl 1995).

Figure 18 shows several types of steady-state, single-variate inverse models. Figure 18A shows a simple one-parameter, or constant, model, and Table 9 gives the equivalent notation for calculating the constant energy use using this model. Figure 18B shows a steady-state two-parameter (2-P) model where  $b_0$  is the y-axis intercept and  $b_1$  is the slope of the regression line for positive values of  $x$ , where  $x$  represents the ambient air temperature. The 2-P model represents cases when either heating or cooling is always required.

Figure 18C shows a three-parameter, change-point model. This model is typical of natural gas energy use in a single-family residence that uses gas for space heating and domestic water heating. In the notation of Table 9 for the three-parameter model,  $b_0$  represents the baseline energy use and  $b_1$  is the slope of the regression line for values of ambient temperature less than the change point  $b_2$ . In this type of notation, the superscript plus sign indicates that only positive values of the parenthetical expression are considered. Figure 18D shows a three-parameter model for cooling energy use, and Table 9 provides the appropriate analytic expression.

Figure 18E and Figure 18F illustrate four-parameter models for heating and cooling, respectively. The appropriate expressions for calculating the heating and cooling energy consumption using a four-parameter model are found in Table 9;  $b_0$  represents the baseline energy exactly at the change point  $b_3$ , and  $b_1$  and  $b_2$  are the lower and upper region regression slopes for ambient air temperature below and above the change point  $b_3$ . Figure 18G illustrates a 5-P model (Fels 1986). Such a model is useful for modeling buildings that are electrically heated and cooled. The 5-P model has two change points and a base level consumption value.

The advantage of these steady-state inverse models is that their use can be easily automated and applied to large numbers of buildings where monthly utility billing data and average daily temperatures for the billing period are available. Steady-state single-variate inverse models have also been applied with success to daily data (Kisscock et al. 1998). In such a case, the variable-base degree-day method and the monthly mean temperature models described earlier for utility billing data analysis become identical in their functional form. Single-variate models can also be applied to daily data to compensate for differences such as weekday and weekend use by separating the data accordingly and identifying models for each period separately.

**Table 8 Single-Variate Models Applied to Utility Billing Data**

Model Type	Independent Variable(s)	Form	Examples
One-parameter or constant (1-P)	None	$E = b_0$	Non-weather-sensitive demand
Two-parameter (2-P)	Temperature	$E = b_0 + b_1(T)$	
Three-parameter (3-P)	Degree-days/ Temperature	$E = b_0 + b_1(DD_{BT})$ $E = b_0 + b_1(b_2 - T)^+$ $E = b_0 + b_1(T - b_2)^+$	Seasonal weather-sensitive use (fuel in winter, electricity in summer for cooling)
Four-parameter change point (4-P)	Temperature	$E = b_0 + b_1(b_3 - T)^+ - b_2(T - b_3)^+$ $E = b_0 - b_1(b_3 - T)^+ + b_2(T - b_3)^+$	Energy use in commercial buildings
Five-parameter (5-P)	Degree-days/ Monthly mean temperature	$E = b_0 - b_1(DD_{TH}) + b_2(DD_{TC})$ $E = b_0 + b_1(b_3 - T)^+ + b_2(T - b_4)^+$	Heating and cooling supplied by same meter

Note: DD denotes degree days and T is the monthly mean daily outdoor dry-bulb temperature.

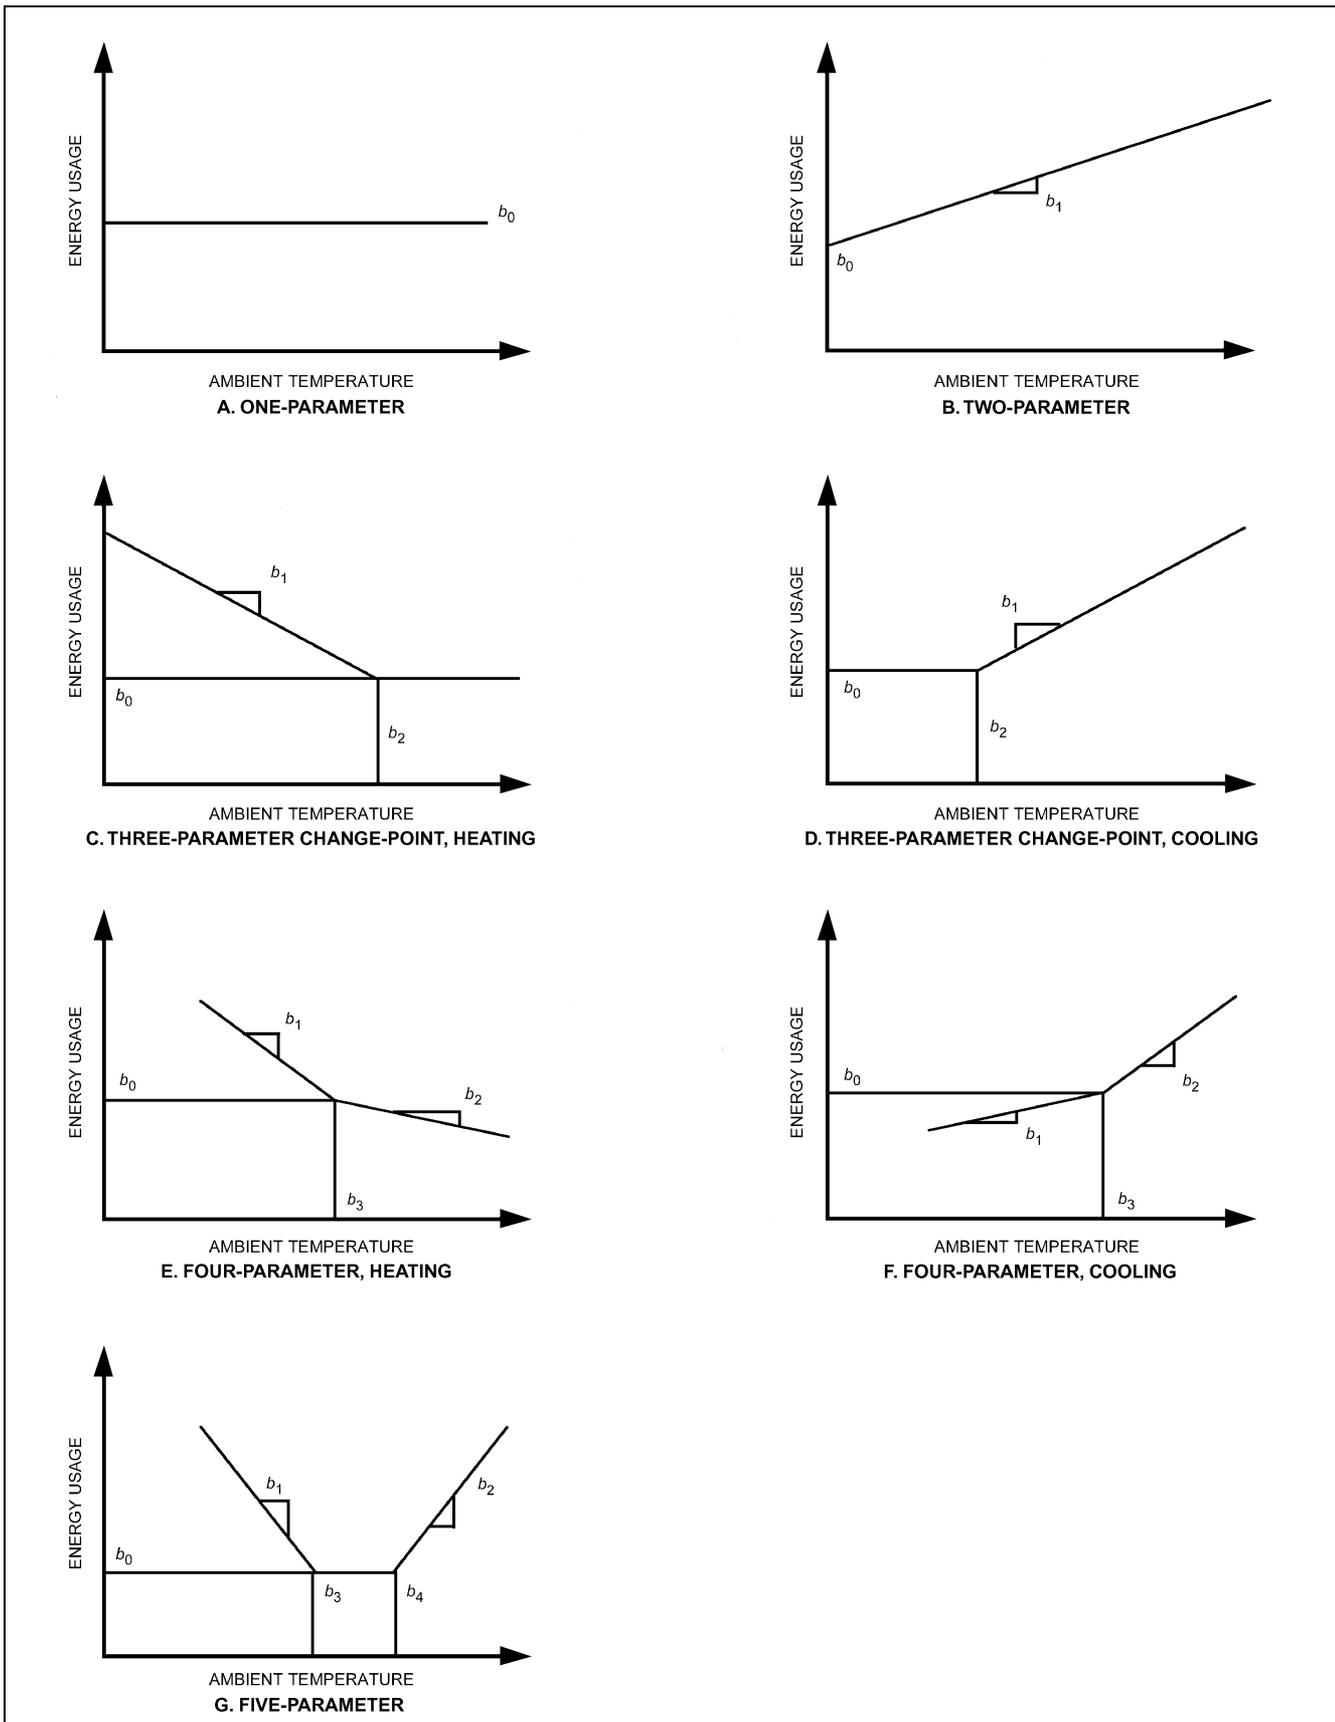

Fig. 18 Steady-State, Single-Variate Models Appropriate for Modeling Energy Use in Residential and Commercial Buildings

Disadvantages of steady-state single-variate inverse models include insensitivity to dynamic effects (e.g., thermal mass), insensitivity to variables other than temperature (e.g., humidity and solar gain), and inappropriateness for some buildings (e.g., buildings with strong on/off schedule-dependent loads or buildings with multiple change points). Moreover, the use of a single-variable, 3-P model such as the PRISM model (Fels 1986) has a physical basis only when energy use above a base level is linearly proportional to degree-days. This is a good approximation in the case of heating energy use in residential buildings where the heating load never exceeds the capacity of the heating system. However, commercial buildings, in general, have higher internal heat generation with simultaneous heating and cooling energy use and are strongly influenced by HVAC system type and control strategy. This makes energy use in commercial buildings less strongly influenced by outdoor air temperature alone. Therefore, it is not surprising that blind use of single-variate models has had mixed success at modeling energy use in commercial buildings (MacDonald and Wasserman 1989).

Change-point regression models work best with heating data from buildings with systems that have little or no part-load nonlinearities (i.e., systems that become less efficient as they begin to cycle on-off with part loads). In general, change-point regression models do not predict cooling loads as well because outdoor humidity has a large influence on latent loads on the cooling coil. Other factors that decrease the accuracy of change-point models include solar effects, thermal lags, and on-off HVAC schedules. Four-parameter models exhibit a better statistical fit than three-parameter models in buildings with continuous, year-round cooling or heating (e.g., grocery stores and office buildings with high internal loads). However, every model should be checked to ensure that the regression is not falsely indicating an unreasonable relationship.

A major advantage of using a steady-state inverse model to evaluate the effectiveness of energy conservation retrofits lies in its ability to factor out year-to-year weather variations by using a normalized annual consumption (NAC) (Fels 1986). Basically, the annual energy conservation savings can be calculated by comparing the difference obtained by multiplying the preretrofit and postretrofit parameters by the weather conditions for the average year. Typically, 10 to 20 years of average daily weather data from a nearby weather service site are used to calculate 365 days of average weather conditions, which are then used to calculate the average preretrofit and postretrofit conditions.

Utilities and government agencies have found it advantageous to prescreen many buildings against test regression models. Such inverse models can be used to develop comparative figures of merit for buildings in a similar standard industrial code (SIC) classification. In such applications, a minimum goodness of fit is usually established that determines whether the monthly utility billing data are well fitted by the one-, two-, three-, four- or five-parameter model being tested. Comparative figures of merit can then be determined by dividing the parameters by the conditioned floor area to yield average daily energy use per unit area of conditioned space. For example, an area-normalized comparison of base-level parameters across residential buildings would be used to analyze weather-independent energy use. Such information can be used by energy auditors to focus their efforts on those systems needing assistance (Haberl and Komor 1990a, 1990b).

**Multivariate Models.** Two types of steady-state, multivariate models have been reported:

1. **Standard multiple-linear or change-point regression models**, where the set of data observations is treated without retaining the time series nature of the data (Katipamula et al. 1998).
2. **Fourier series models** that retain the time-series nature of the building energy use data and capture the diurnal and seasonal cycles according to which buildings are operated (Seem and Braun 1991; Dhar 1995; Dhar et al. 1998, 1999a, 1999b).

These models are a logical extension to single-variate models, provided that the choice of the variables to be included and their functional forms are based on the engineering principles on which HVAC systems and other systems in commercial buildings operate. The goal of modeling energy use by the multivariate approach is to characterize building energy use with a few readily available and reliable input variables. These input variables should be selected with care. The model should contain variables not affected by the retrofit and likely to change (for example, climatic variables) from preretrofit to postretrofit periods. Other less obvious variables, such as changes in operating hours, in base load, and in occupancy levels, should be included in the model if these are not energy conservation measures (ECMs) but variables that may change during the postretrofit period.

Environmental variables that meet the above criteria for modeling heating and cooling energy use include outdoor air dry-bulb temperature, solar radiation, and outdoor specific humidity. Some of these parameters are difficult to estimate or measure in an actual building and hence are not good candidates for regressor variables. Further, some of the variables vary little. Although their effect on energy use may be important, an inverse model will implicitly lump their effect into the parameter that represents constant load. In commercial buildings, internally generated loads, such as the heat given off by people, lights, and electrical equipment, also impact heating and cooling energy use. Such internal loads are difficult to measure in their entirety given the ambiguous nature of occupant loads and latent loads. However, monitored electricity used by internal lights and equipment is a good surrogate for total internal sensible loads (Reddy et al. 1999). For example, when the building is fully occupied, it is also likely to be experiencing high internal electric loads, and vice versa.

The effect of environmental variables is important for such buildings as offices but may be less so for mixed-use buildings (e.g., hotels and hospitals) and buildings such as retail buildings, schools, and assembly buildings. Differences in HVAC system behavior during occupied and unoccupied periods can be modeled by a dummy or indicator variable (Draper and Smith 1981). For some office buildings, there seems to be little need to include such a dummy variable, but its inclusion in the general functional form will provide added flexibility.

Several standard statistical tests exist for evaluating the goodness-of-fit of the model and the degree of influence that each of the independent variables exerts on the response variable (Draper and Smith 1981, Neter et al. 1989). Although energy use is in fact dependent on several variables, there are strong practical incentives for identifying the simplest model that results in acceptable accuracy. Multivariate models require more metering and are unusable if even one of the variables becomes unavailable. In addition, some of the regressor variables may be linearly correlated. This condition, called **multicollinearity**, can result in large uncertainty in the estimates of the regression coefficients (i.e., unintended error) and can also lead to poorer model prediction accuracy compared to a model where the regressors are not linearly correlated.

Several authors recommend using **principal component analysis** (PCA) to overcome multicollinearity effects. PCA was one of the strongest analysis methods in the ASHRAE Predictor Shoot-out I and II contests (Kreider and Haberl 1994, Haberl and Thamilsaran 1996). Analysis of multiyear monitored daily energy use in a grocery store found a clear superiority of PCA over multivariate regression models (Ruch et al. 1993), but this conclusion is unproven for commercial building energy use in general. A more general evaluation by Reddy and Claridge (1994) of both analysis techniques using synthetic data from four different geographic locations in the U.S. found that injudicious use of PCA may exacerbate rather than overcome problems associated with multicollinearity. Draper and Smith (1981) also caution against indiscriminate use of PCA.

The functional basis of air-side heating and cooling use in various HVAC system types has been addressed by Reddy et al. (1995) and subsequently applied to monitored data in commercial buildings (Katipamula et al. 1994, 1998). Because the quadratic and cross-product terms of the engineering equations are not usually picked up by the multivariate models, one is often left with models for energy use that are strictly **linear**.

In addition to  $T_o$ , internal electric equipment and lighting load  $E_{int}$ , solar loads  $q_{sol}$ , and latent effects via the outdoor dew-point temperature  $T_{dp}$  are candidate regressor variables. In commercial buildings, a major portion of the latent load is due to fresh air ventilation. However, this load appears only when the outdoor air dew-point temperature exceeds the cooling coil temperature. Hence, the term  $(T_{dp} - T_s)^+$  (where the + sign indicates that the term is to be set to zero if negative, and  $T_s$  is the mean surface temperature of the cooling coil, typically about 11 to 13°C) is a more realistic descriptor of the latent loads than is  $T_{dp}$  alone. The use of  $(T_{dp} - T_s)^+$  as a regressor in the model is a simplification that seems to yield good accuracy.

Therefore, a multivariate linear regression model with an engineering basis has the following structure:

$$Q_{bldg} = \beta_0 + \beta_1(T_o - \beta_3)^- + \beta_2(T_o - \beta_3)^+ + \beta_4(T_{dp} - \beta_6)^- + \beta_5(T_{dp} - \beta_6)^+ + \beta_7 q_{sol} + \beta_8 E_{int} \quad (54)$$

Based on the above discussion,  $\beta_4 = 0$ . Introducing indicator variable terminology (Draper and Smith 1981), Equation (54) becomes identical to

$$Q_{bldg} = a + bT_o + cI + dIT_o + eT_{dp}^+ + fq_{sol} + gE_{int} \quad (55)$$

where the indicator variable  $I$  is introduced to handle the change in slope of the energy use due to  $T_o$ . The variable  $I$  is set equal to 1 for  $T_o$  values to the right of the change point (i.e., for high  $T_o$  range) and set equal to 0 for low  $T_o$  values. As with the single-variate segmented models (i.e., 3-P and 4-P models), a search method is used in order to determine the change point that minimizes the total sum of squares of residuals (Fels 1986, Kissock et al. 1993).

Another finding from the Katipamula et al. (1994) study was that the model given by Equation (55), appropriate for VAV systems, could be simplified for constant volume HVAC systems:

$$Q_{bldg} = a + bT_o + eT_{dp}^+ + fq_{sol} + gE_{int} \quad (56)$$

Note that instead of using  $(T_{dp} - T_s)^+$ , one could equally use the absolute humidity potential  $(W_o - W_s)^+$ , where  $W_o$  is the outdoor absolute humidity, and  $W_s$ , the absolute humidity level at the dew point of the cooling coil, is typically about 0.009 kg/kg. A final aspect to be kept in mind is that the term  $T_{dp}^+$  should be omitted from the regressor variable set when regressing heating energy use because there are no latent loads on a heating coil.

The above multivariate models have been found to be very accurate for daily time scales and slightly less so for hourly time scales. This is because changes in the way the building is operated during the day and the night lead to different relative effects of the various regressors on energy use, which cannot be accurately modeled by one single hourly model. Breaking up the energy use data into hourly bins corresponding to each hour of the day and then identifying 24 individual hourly models leads to appreciably greater accuracy (Katipamula et al. 1994).

**Polynomial Models.** Historically, polynomial models have been widely used as pure statistical models to model the behavior of such equipment as pumps, fans, and chillers (Stoecker and Jones 1982). The theoretical aspects of calculating pump performance are well understood and documented. Pump capacity and efficiency are calculated from measurements of pump pressure, flow rate, and pump

electrical power input. Phelan et al. (1996) have studied the predictive ability of linear and quadratic models for electricity consumed by pumps and water mass flow rate and concluded that quadratic models are superior to linear models. For fans, Phelan et al. (1996) have studied the predictive ability of linear and quadratic polynomial single-variate models of fan electricity consumption as a function of the supply air mass flow rate and concluded that, although quadratic models are superior in terms of predicting energy use, the linear model seems to be the better overall predictor of both energy and demand (i.e., maximum monthly power consumed by the fan). This is a noteworthy conclusion given that a third-order polynomial is warranted analytically as well as from monitored field data presented by previous authors (e.g., Englander and Norford 1992, Lorenzetti and Norford 1993).

Polynomial models have been used to correlate chiller (or evaporator) thermal cooling capacity or load  $Q_{evap}$  and the electrical power consumed by the chiller (or compressor)  $E_{comp}$  with the relevant number of influential physical parameters. For example, based on the functional form of the DOE-2 building simulation software (York and Cappiello 1982), models for part-load performance of energy equipment and plant,  $E_{comp}$  can be modeled as the following triquadratic polynomial:

$$E_{comp} = a + bQ_{evap} + cT_{cond}^{in} + dT_{evap}^{out} + eQ_{evap}^2 + fT_{cond}^{in}{}^2 + gT_{evap}^{out}{}^2 + hQ_{evap}T_{cond}^{in} + iT_{evap}^{out}Q_{evap} + jT_{cond}^{in}T_{evap}^{out} + kQ_{evap}T_{cond}^{in}T_{evap}^{out} \quad (57)$$

In this model, there are 11 model parameters to identify. However, since all of them are unlikely to be statistically significant, a step-wise regression to the sample data set yields the optimal set of parameters to retain in a given model. Other authors, such as Braun (1992), have used slightly different polynomial forms.

**Physical Models.** In contrast to polynomial models, which have no physical basis (merely a convenient statistical one), physical models are based on fundamental thermodynamic or heat transfer considerations. These types of models are usually associated with the parameter estimation approach. Often such models are preferred because they generally have fewer parameters. Furthermore, their mathematical formulation can be traced to actual physical principles that govern the performance of the building or equipment. Hence the model coefficients tend to be more robust, leading to sounder model predictions. Only a few studies have used steady-state physical models for parameter estimation relating to commercial building energy use (for example, Reddy et al. 1999). Unlike in single-family residences, it is difficult to perform elaborately planned experiments in large buildings and obtain representative values of indoor fluctuations.

A physical model of a chiller has been proposed by Gordon and Ng (1994, 1995) and Gordon et al. (1995). It is a simple, analytical, universal model for chiller performance based on thermodynamic considerations and linearization of heat losses. The model predicts the dependence of chiller COP [defined as the ratio of chiller (or evaporator) thermal cooling capacity  $Q_{evap}$  divided by the electrical power consumed by the chiller (or compressor)  $E_{comp}$ ] with certain key (and easily measurable) parameters such as the fluid (water or refrigerant) return temperature from the condenser  $T_{cond}^{in}$ , the fluid temperature leaving the evaporator (or the chilled water supply temperature to the building)  $T_{evap}^{out}$ , and the thermal cooling capacity of the evaporator. The complete Gordon-Ng model is a three-parameter model that takes the following form:

$$\left( \frac{1}{\text{COP}} + 1 - \frac{T_{cond}^{in}}{T_{evap}^{out}} \right) Q_{evap} = -A_0 + A_1 T_{cond}^{in} - A_2 \frac{T_{cond}^{in}}{T_{evap}^{out}} \quad (58)$$

The three parameters are identified by multiple linear regression. Results of applying such models to field monitored data are fully described by the Gordon et al. papers as well as by Phelan et al. (1996) and Haberl et al. (1997).

### Dynamic Models

In general, steady-state inverse models are used with monthly and daily data containing one or more independent variables. Dynamic inverse models are usually used with hourly or subhourly data in cases where the thermal mass of a building is sufficiently significant to delay the heat gains or losses. Dynamic models traditionally required the solution of a set of differential equations. The disadvantages of dynamic inverse models include their complexity and the need for more detailed measurements to tune the model. Unlike steady-state inverse models, dynamic inverse models usually require a high degree of user interaction and knowledge of the building or system being modeled.

Several residential energy studies using dynamic inverse models based on parameter estimation approaches have been reported, most of them involving intrusive data gathering. Rabl (1988) has classified the various types of dynamic inverse models used for whole-building energy use and drawn attention to the common underlying features of these models. There are essentially four different types of model formulations: thermal network models, time series models, differential equation models, and modal models. They all qualify as parameter-estimation approaches. Table 1 lists several pertinent studies in each category. A few studies (Hammersten 1984, Rabl 1988, Reddy 1989) have evaluated these different approaches with the same data set. A number of papers have reported results of applying such different techniques such as thermal network models and ARMA models to residential and commercial building energy use (see Table 1). Examples of dynamic inverse models for commercial building are found in Rabl (1988), Andersen and Brandemuehl (1992), and Braun (1990).

Dynamic inverse models based on pure statistical approaches have also been reported. Two examples are machine learning (Miller and Seem 1991) and artificial neural networks (Miller and Seem 1991, Kreider and Wang 1991, Kreider and Haberl 1994).

Neural networks are considered to be intuitive because they learn by example rather than by following programmed rules. The ability to “learn” is one of the key aspects of neural networks. A neural network consists of one input layer (which can contain one or more inputs), one or more hidden layers, and an output or target layer. One challenge of this technology is to construct a net with sufficient complexity to learn accurately without imposing excessive computational time.

The weights of a net are initiated with small random numbers. Then, the weights are adjusted iteratively or “trained” so that the application of a set of inputs produces the desired set of outputs. Usually a network is trained with a training data set that consists of many input-output pairs. Artificial neural networks have been trained by a wide variety of methods (McClelland and Rumelhart 1988, Wasserman 1989). One such training method is called **back propagation**.

Neural networks have been useful in predicting energy use in commercial buildings for such reasons as

- Prediction of what a properly operating building should be doing compared to actual operation. If there is a difference, it can be used in an expert system to produce early diagnoses of building operation problems.
- Prediction of what a building, prior to an energy retrofit, would have consumed under present conditions. When compared to the measured consumption of the retrofitted building, the difference represents a good estimate of the energy savings due to the retrofit. This represents one of the few ways that actual energy savings

can be determined after the preretrofit building configuration has ceased to exist.

## EXAMPLES OF INVERSE METHODS

### Modeling of Utility Bill Data

The following example (taken from Sonderegger 1998) illustrates a utility bill analysis. Assume that values of the utility bills over an entire year have been measured. To obtain the equation coefficients through regression, the utility bills must be normalized by the length of the time interval between utility bills. This is equivalent to expressing all utility bills, degree-days, and other independent variables by their daily averages.

An appropriate software program is used in which one assumes values for heating and cooling balance points; from these, the corresponding heating and cooling degree-days for each utility bill period are determined. Repeated regression is done till the regression equation represents the best fit to the meter data. The model coefficients are then assumed to be tuned. Some computer programs allow direct determination of these optimal model parameters without the user’s manual tuning of the parameters.

A widely used statistic to gage the goodness-of-fit of the model is the **coefficient of determination**  $R^2$ . A value of  $R^2 = 1$  indicates a perfect correlation between actual data and the regression equation; a value of  $R^2 = 0$  indicates no correlation. For purposes of tuning for a performance contract, as a rule of thumb the value of  $R^2$  should never be less than 0.75.

When more than one independent variable is included in the regression, the value of  $R^2$  is no longer sufficient to determine the goodness-of-fit. The standard error of the estimate of the coefficients becomes the more important determinant. The smaller the standard error compared to the coefficient’s magnitude, the more reliable the coefficient estimate. To facilitate the significance of individual coefficients, the so-called **t-statistics**, or simply **t-values**, are used. These are simply the ratio of the coefficient estimate divided by the standard error of the estimate.

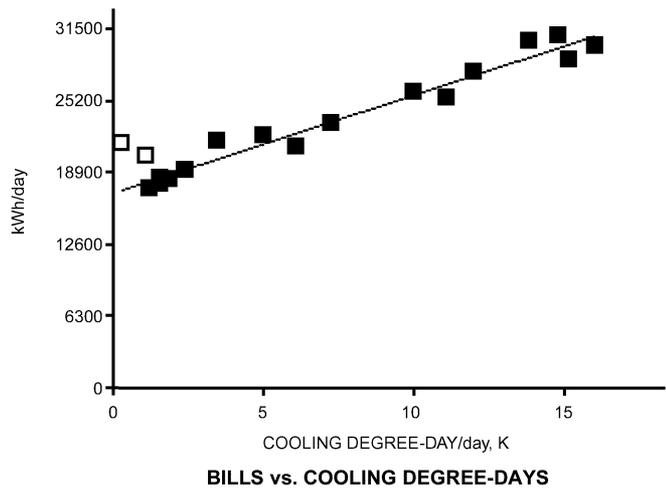

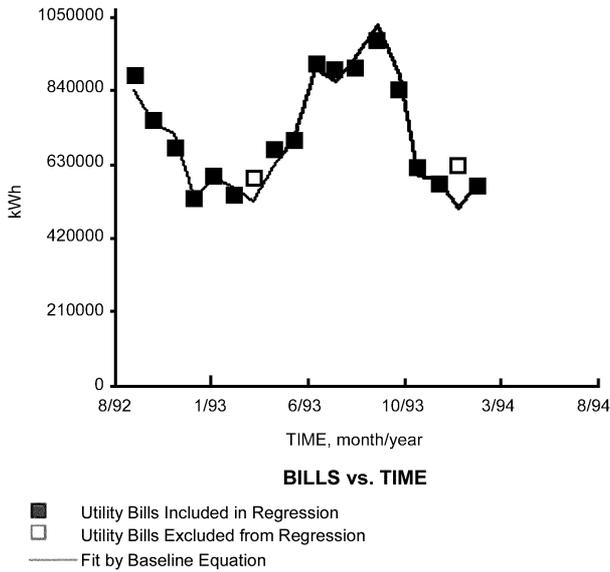

The coefficient of each variable included in the regression has a *t*-statistic. For a coefficient to be statistically meaningful, the absolute value of its *t*-statistic must be at least 2.0. Another way of stating this is that under no circumstances should a variable be included in a regression if the standard error of its coefficient estimate is greater than half the magnitude of the coefficient. The latter is true even when including a variable that increases the  $R^2$ . Generally speaking, including more variables in a regression results in a higher  $R^2$ , but the significance of most individual coefficients will likely decrease.

Figure 19 illustrates how well a regression fit captures measured baseline energy use in a hospital building. Cooling degree-days are found to be a significant variable, with the best fit for a base temperature of 12.2°C.

There are good reasons why individual utility bills may be unsuitable to develop a baseline and should be excluded from the regression. For example, a bill may be atypically high because of a one-time equipment malfunction that was subsequently repaired. However, it is often tempting to look for reasons to exclude bills that fall far from “the line” and not question those that are close to it. For example, bills for periods containing vacations or production shutdowns may look anomalously low, but excluding them from the regression would result in a chronic overestimate of the future baseline during the same period.

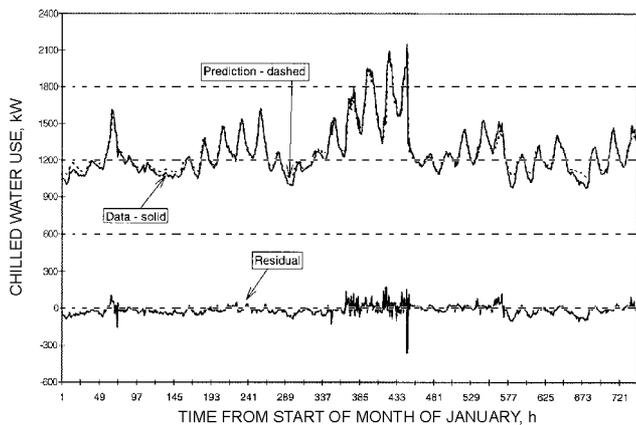

### Neural Network Models

Figure 20 shows results for a single neural network typical of several hundred networks constructed for an academic engineering center located in central Texas. The cooling load is created by solar gains, internal gains, outdoor air sensible heat, and outdoor

Note: Utility bills excluded from the regression due to a degree-day threshold.

**Fig. 19 Variable-Base Degree-Day Model Identification Using Electricity Utility Bills at a Hospital**  
(Sonderegger 1998)

**Fig. 20 Neural Network Prediction of Whole Building, Hourly Chilled Water Consumption for a Commercial Building**

air humidity loads. The neural network is used to predict the pre-retrofit energy consumption for comparison with measured consumption of the retrofitted building. Six months of preretrofit data were available with which to train a network. The solid lines show the known building consumption data while the dashed lines show the neural network predictions. This figure shows that a neural network trained for one period (September 1989) can predict energy consumption well into the future (here, January 1990).

The network used for this prediction had two hidden layers. The input layer contained eight neurons that receive eight different types of input data as listed below. The output layer consisted of one neuron that gave the output datum (chilled water consumption). Each training fact (i.e., training data set), therefore, contained eight input data (independent variables) and one pattern datum (dependent variable). The eight hourly input data used in each hour's data vector were selected on physical bases (Kreider and Rabl 1994) and were as follows:

- Hour number (0 to 2300)
- Ambient dry-bulb temperature

- Horizontal insolation
- Humidity ratio
- Wind speed
- Weekday/weekend binary flag (0, 1)
- Past hour's chilled water consumption
- Second past hour's chilled water consumption

These measured independent variables were able to predict the chilled water use to an RMS error of less than 4% (JCEM 1992).

The choice of an optimal network's configuration for a given problem remains an art. The number of hidden neurons and layers must be sufficient to meet the requirement of the given application. However, if too many neurons and layers are used, the network tends to memorize data rather than learning, that is, finding the underlying patterns in the data. Further, choosing an excessively large number of hidden layers significantly increases the required training time for certain learning algorithms. Anstett and Kreider (1993), Kreider and Wang (1991), Wang and Kreider (1992), and Krarti et al. (1998) report additional case studies for commercial buildings.

**Closing Remarks**

Steady-state and dynamic inverse models can be used with energy management and control systems to predict energy use (Kreider and Haberl 1994). Hourly or daily comparisons of measured energy use against predicted energy use can be used to determine whether systems are being left on unnecessarily or are in need of maintenance. Combinations of predicted energy use and a knowledge-based system can indicate above-normal energy use and diagnose the possible cause of the malfunction if sufficient historical information has been previously gathered (Haberl and Claridge 1987). Hourly systems that use artificial neural networks have also been constructed (Kreider and Wang 1991).

Table 10 presents a decision diagram for selecting a forward or inverse model where use of the model, degree of difficulty in understanding and applying the model, time scale for the data used by the model, calculation time, and input variables used by the models are the criteria used to choose a particular model.

Table 9 Capabilities of Different Forward and Inverse Modeling Methods

Methods	Usage <sup>a</sup>	Difficulty	Time Scale <sup>b</sup>	Calc. Time	Variables <sup>c</sup>	Accuracy
Simple linear regression	ES	Simple	D, M	Very fast	<i>T</i>	Low
Multiple linear regression	D, ES	Simple	D, M	Fast	<i>T, H, S, W, t</i>	Medium
ASHRAE bin method and inverse bin method	ES	Moderate	H	Fast	<i>T</i>	Medium
Change point models	D, ES	Simple	H, D, M	Fast	<i>T</i>	Medium
ASHRAE TC 4.7 modified bin method	ES, DE	Moderate	H	Medium	<i>T, S, tm</i>	Medium
Artificial Neural Networks	D, ES, C	Complex	S, H	Fast	<i>T, H, S, W, t, tm</i>	High
Thermal network	D, ES, C	Complex	S, H	Fast	<i>T, S, tm</i>	High
Fourier series analysis	D, ES, C	Moderate	S, H	Medium	<i>T, H, S, W, t, tm</i>	High
ARMA model	D, ES, C	Moderate	S, H	Medium	<i>T, H, S, W, t, tm</i>	High
Modal analysis	D, ES, C	Complex	S, H	Medium	<i>T, H, S, W, t, tm</i>	High

## TERMINOLOGY

**ASPECT ratio.** Ratio of length to width of an opening or core of a grille.

**Axial flow jet.** Stream of air whose motion is approximately symmetrical along a line, although some spreading and drop or rise can occur from diffusion and buoyancy effects.

**Coefficient of discharge.** Ratio of area at vena contracta to area of opening.

**Cold air.** General term used for supply air at 1.5 to 4.5°C.

**Core area.** Total plane area of that portion of a grille, included within lines tangent to the outer edges of the outer openings, through which air can pass.

**Damper.** Device used to vary the volume of air passing through a confined cross section by varying the cross-sectional area.

**Diffuser.** Outlet discharging supply air in various directions and planes.

**Diffusion.** Distribution of air within a space by an outlet discharging supply air in various directions and planes.

**Draft.** Undesired local cooling of a body caused by low temperature and movement of air.

**Drop.** Vertical distance that the lower edge of a horizontally projected airstream drops between the outlet and the end of its throw.

**Effective area.** Net area of an outlet or inlet device through which air can pass; equal to the free area times the coefficient of discharge.

**Entrainment.** Movement of room air into the jet caused by the airstream discharged from the outlet (secondary air motion).

**Entrainment ratio.** Total air divided by the air discharged from the outlet.

**Envelope.** Outer boundary of an airstream moving at a perceptible velocity.

**Exhaust opening or inlet.** Any opening through which air is removed from a space.

**Free area.** Total minimum area of the openings in the air outlet or inlet through which air can pass.

**Grille.** A covering for any area through which air passes.

**Induction.** See Entrainment.

**Isothermal jet.** Air jet with the same temperature as the surrounding air.

**Lower zone.** Room volume below the stratification level created by displacement ventilation.

**Nonisothermal jet.** Air jet with an initial temperature different from the surrounding air.

**Outlet velocity.** Average velocity of air emerging from the outlet, measured in the plane of the opening.

**Primary air.** Air delivered to the outlet by the supply duct.

**Radius of diffusion.** Horizontal axial distance an airstream travels after leaving an air outlet before the maximum stream velocity is reduced to a specified terminal level (e.g., 0.25, 0.5, 0.75, or 1.0 m/s).

**Register.** Grille equipped with a damper or control valve.

**Spread.** Divergence of the airstream in a horizontal and/or vertical plane after it leaves the outlet.

**Stagnant zone.** Area characterized by low air motion and stratification. This does not imply poor air quality.

**Supply opening or outlet.** Any opening through which supply air is delivered into a ventilated space being heated, cooled, humidified, or dehumidified. Supply outlets are classified according to their location in a room as sidewall, ceiling, baseboard, or floor outlets. However, because numerous designs exist, they are more accurately described by their construction features. (See Chapter 17 of the 2000 *ASHRAE Handbook—Systems and Equipment*.)

**Temperature differential.** Temperature difference between primary and room air.

**Terminal velocity.** Maximum airstream velocity at the end of the throw.

**Throw.** Horizontal or vertical axial distance an airstream travels after leaving an air outlet before the maximum stream velocity is reduced to a specified terminal velocity (e.g., 0.25, 0.5, 0.75, or 1.0 m/s), defined by *ASHRAE Standard 70*.

**Total air.** Mixture of discharged air and entrained air.

**Upper zone.** Room volume above the stratification level created by displacement ventilation.

**Vane.** Thin plate in the opening of a grille.

**Vane ratio.** Ratio of the depth of a vane to the space between two adjacent vanes.

**Vena contracta.** Smallest area of a fluid stream leaving an orifice.

## PRINCIPLES OF JET BEHAVIOR

## AIR JET CLASSIFICATION

As a rule, air supplied into rooms through the various types of outlets (e.g., grilles, ceiling diffusers, perforated panels) is distributed by turbulent air jets. These air jets are the primary factor affecting room air motion; Baturin (1972), Christianson (1989), and Murakami (1992) have further information on the relationship between the air jet and the occupied zone. If the air jet is not obstructed by walls, ceiling, or other obstructions, it is considered a **free jet**. If the air jet is attached to a surface, it is an **attached air jet**.

The preparation of this chapter is assigned to TC 5.3, Room Air Distribution.

Characteristics of the air jet in a room might be influenced by reverse flows created by the same jet entraining the ambient air. This air jet is called a **confined jet**. If the temperature of the supplied air is equal to the temperature of the ambient room air, the air jet is called an **isothermal jet**. A jet with an initial temperature different from the temperature of the ambient air is called a **nonisothermal jet**. The air temperature differential between supplied and ambient room air generates thermal forces in jets, affecting (1) the trajectory of the jet, (2) the location at which the jet attaches and separates from the ceiling/floor, and (3) the throw of the jet. The significance of such effects depends on the ratio between the thermal buoyancy of the air and inertial forces (characterized by the Archimedes number  $Ar$ ).

Depending on diffuser type, air jets can be classified as follows:

- **Compact** air jets are formed by cylindrical tubes, nozzles, square or rectangular openings with a small aspect ratio (unshaded or shaded by perforated plates), grilles, etc. Compact air jets are three-dimensional and axisymmetric at least at some distance from the diffuser opening. The maximum velocity in the cross section of the compact jet is on the axis.
- **Linear** air jets are formed by slots or rectangular openings with a large aspect ratio. The jet flows are approximately two-dimensional. Air velocity is symmetric in the plane at which air velocities in the cross section are maximum. At some distance from the diffuser, linear air jets tend to transform into compact jets.
- **Radial** air jets are formed by ceiling cylindrical air diffusers with flat disks or multidiffusers that direct the air horizontally in all directions.
- **Conical** air jets are formed by cone-type or regulated multidiffuser ceiling-mounted air distribution devices. They have an axis of symmetry. The air flows parallel to the conical surface (the angle at the top of the cone is  $120^\circ$ ) with the maximum velocities in the cross section perpendicular to the axis.
- **Incomplete radial** air jets are formed by outlets with grilles having diverging vanes and a forced angle of expansion. At a distance, this jet tends to transform into a compact one.
- **Swirling** air jets are formed by diffusers with vortex-forming devices. These devices create rotation, which has, in addition to the axial component of velocity vectors, tangential and radial ones. Depending on the type of air diffuser, swirling jets can be compact, conical, or radial.

### Isothermal Jets

The shape of jets at a short distance from the outlet face is very similar whether the outlet is round, rectangular, grille-like, or a perforated panel. The jet discharged from a round opening forms an expanding cone; jets from rectangular outlets rapidly pass from a rectangular to an elliptical cross-sectional shape and then to a circular shape, at a rate depending primarily on the aspect ratio and jet width. Even for wide-angle grilles and annular outlets, the similarities permit the same performance analysis for both.

For many conditions of jet discharge, it is possible to analyze jet performance and determine (1) the angle of divergence of the jet boundary, (2) the velocity patterns along the jet axis, (3) the velocity profile at any cross section in the zone of maximum engineering importance, and (4) the entrainment ratios in the same zone (Tuve 1953).

Using the data in this section, the following must be considered:

1. Because the method of finding the jet velocities is based on several approximations, the two recommended equations [Equations (3) and (4)] must be used cautiously for extreme axial and radial distances.
2. The characteristics of the low-velocity regions of ventilating jets are not well understood, and the effects at various Reynolds numbers are not fully known for axial or radial jets.

3. The quantitative treatment of the forces governing room air diffusion problems is limited, and nonisothermal conditions involving buoyant forces are more difficult to predict.
4. Most investigations have addressed free jets, whereas airstreams in practical room air diffusion are not free streams but are influenced by walls, ceilings, floors, and other obstructions.

**Angle of Divergence.** The angle of divergence is well defined near the outlet face, but the boundary contours are billowy and easily affected by external influences. Near the outlet, as in the room, air movement has local eddies, vortices, and surges. The internal forces governing this air motion are extremely delicate (Nottage et al. 1952b).

Measured angles of divergence (spread) for discharge into large open spaces usually range from  $20$  to  $24^\circ$  with an average of  $22^\circ$ . Coalescing jets for closely spaced multiple outlets expand at smaller angles, averaging  $18^\circ$ , and jets discharging into relatively small spaces show even smaller angles of expansion (McElroy 1943). In cases where the outlet area is small compared to the dimensions of the space normal to the jet, the jet may be considered free as long as

$$X \leq 1.5 \sqrt{A_R} \quad (1)$$

where

$X$  = distance from face of outlet, m

$A_R$  = cross-sectional area of confined space normal to jet,  $m^2$

**Jet Expansion Zones.** The full length of an air jet (compact, linear, radial, or conical), in terms of the maximum or centerline velocity and temperature differential at the cross section, can be divided into four zones:

**Zone 1.** A core zone; a short zone, extending about four diameters or widths from the outlet face, in which the maximum velocity (temperature) of the airstream remains practically unchanged.

**Zone 2.** A transition zone, the length of which depends on the type of outlet, aspect ratio of the outlet, initial airflow turbulence, and so forth.

**Zone 3.** A zone of fully established turbulent flow that may be 25 to 100 equivalent air outlet diameters (widths for slot-type air diffusers) long.

**Zone 4.** A zone of diffuser jet degradation, where the maximum air velocity and temperature decreases rapidly. The distance to this zone and its length depend on the velocities and turbulence characteristics of the ambient air. In a few diameters or widths, the air velocity becomes less than  $0.25$  m/s. The characteristics of this zone are still not well understood.

Zone 3 is of major engineering importance because, in most cases, the diffuser jet enters the occupied area within this zone.

**Centerline Velocities in Zones 1 and 2.** In Zone 1, the ratio  $V_x/V_o$  is constant and equal to the ratio of the center velocity of the jet at the start of expansion to the average velocity. The ratio  $V_x/V_o$  varies from approximately 1.0 for rounded entrance nozzles to about 1.2 for straight pipe discharges; it has much higher values for diverging discharge outlets.

Experimental evidence indicates that in Zone 2,

$$\frac{V_x}{V_o} = \sqrt{\frac{1.13KH_o}{X}} \quad (2)$$

where

$V_x$  = centerline velocity at distance  $X$  from outlet, m/s

$V_o = V_c/C_d R_{fa}$  = average initial velocity at discharge from open-ended duct or across contracted stream at vena contracta of orifice or multiple-opening outlet, m/s

$V_c$  = nominal velocity of discharge based on core area, m/s

$C_d$  = discharge coefficient (usually between 0.65 and 0.90)

$R_{fa}$  = ratio of free area to gross (core) area

**Table 1 Recommended Values for Centerline Velocity Constant  $K$  for Commercial Supply Outlets**

Outlet Type	Discharge Pattern	Area $A$	$K^a$
High sidewall grilles (Figure 1A)	0° deflection <sup>b</sup>	Core	5.0
	Wide deflection	Core	3.7
High sidewall linear (Figure 1B)	Core less than 100 mm high <sup>c</sup>	Core	3.9
	Core more than 100 mm high	Core	4.4
Low sidewall (Figure 1C)	Up and on wall, no spread	Core	4.4
	Wide spread <sup>c</sup>	Core	2.6
Baseboard (Figure 1C)	Up and on wall, no spread	Duct	3.9
	Wide spread <sup>e</sup>	Duct	1.8

	Wide spread	Core	1.4
Ceiling circular directional (Fig. 1D)	360° horizontal <sup>d</sup>	Duct	1.0
	Four-way—little spread	Duct	3.3
Ceiling linear (Figure 1E)	One-way—horizontal along ceiling <sup>c</sup>	Core	4.8

<sup>a</sup>These values are representative for commercial outlets with discharge patterns as shown in Figure 1.

<sup>b</sup>Free area is about 80% of core area.

<sup>c</sup>Free area is about 50% of core area.

<sup>d</sup>Cone free area is greater than duct area.

<sup>e</sup>Face free area is greater than duct area.

$H_o$  = width of jet at outlet or at vena contracta, m

$K$  = centerline velocity constant depending on outlet type and discharge pattern (see Table 1)

$X$  = distance from outlet to measurement of centerline velocity  $V_x$ , m

The aspect ratio (Tuve 1953) and turbulence (Nottage et al. 1952b) primarily affect the centerline velocities in Zones 1 and 2. Aspect ratio has little effect on the terminal zone of the jet when  $H_o$  is greater than 100 mm. This is particularly true of nonisothermal jets. When  $H_o$  is very small, the induced air can penetrate the core of the jet, thus reducing the centerline velocities. The difference in performance between the radial outlet with a small  $H_o$  and the axial outlet with a large  $H_o$  shows the importance of the thickness of the jets.

When air is discharged from relatively large perforated panels, the constant velocity core formed by the coalescence of the individual jets extends a considerable distance from the panel face. In Zone 1, when the ratio  $X/\sqrt{A_c}$  (Distance from Panel/ $\sqrt{\text{Panel Area}}$ ) is less than 5, the following equation should be used for estimating centerline velocities (Koestel et al. 1949):

$$V_x = 1.2V_o\sqrt{C_d R_{fa}} \quad (3)$$

**Centerline Velocity in Zone 3.** In Zone 3, maximum or centerline velocities of straight flow isothermal jets can be determined with accuracy from the following equations:

$$\frac{V_x}{V_o} = \frac{KD_o}{X} = \frac{1.13K\sqrt{A_o}}{X} \quad (4)$$

$$V_x = \frac{1.13KV_o\sqrt{A_o}}{X} = \frac{1.13KQ}{X\sqrt{A_o}} \quad (5)$$

$$V_x = \frac{1.13KQ}{X\sqrt{A_c C_d R_{fa}}} \quad (6)$$

where

$K$  = proportionality constant

$D_o$  = effective or equivalent diameter of stream at discharge from open-end duct or at contracted section, m

**Table 2 Recommended Values of Centerline Velocity Constant for Standard Openings**

Type of Outlet	$K$	
	$V_o = 2.5$ to 5 m/s	$V_o = 10$ to 50 m/s
Free openings		
Round or square	5.0	6.2
Rectangular, large aspect ratio (<40)	4.3	5.3
Annular slots, axial or radial <sup>a</sup>	—	—
Grilles and grids		
Free area 40% or more	4.1	5.0
Perforated panels		
Free area 3 to 5%	2.7	3.3
Free area 10 to 20%	3.5	4.3

<sup>a</sup>For radial slots, use  $X/H$  instead of  $X/\sqrt{A}$ .  $H$  is height or width of slot.

Note:  $K$  is an index of loss in axial kinetic energy. Interpolate as required. Departures from maximum value indicate losses in Zones 1 and 2 when compared with the jet from a rounded-entrance, circular nozzle.

$A_o$  = core area  $A_c$  or duct area, m<sup>2</sup>

$A_c$  = measured gross (core) area of outlet, m<sup>2</sup>

$Q$  = discharge from outlet, m<sup>3</sup>/s

Because  $A_o$  equals the effective area of the stream, the flow area for commercial registers and diffusers, according to ASHRAE Standard 70, can be used in Equation (4) with the appropriate value of  $K$ .

Equation (4) is nondimensional and requires only that consistent units be used. Values of  $K$  are listed in Table 2 (Tuve 1953, Koestel et al. 1950).

In multiple-opening outlets and annular ring outlets, the streams coalesce into a solid jet before actual jet expansion takes place. This coalescence affects the proportionality constant  $K$  and accounts for some divergence in reported values for similar outlets.

For perforated panels of relatively large size, the values of  $K$  given in Table 2 apply only when the ratio  $X/\sqrt{A_c}$  is larger than 5 (see the section on Centerline Velocities in Zones 1 and 2).

Low-velocity test results, in the range  $V_x < 0.75$  m/s, indicate that normal values of  $K$  should be reduced about 20% for  $V_x = 0.25$  m/s, as used later in Equation (9) for throw.

**Determining Centerline Velocities.** To correlate data from all four zones, centerline velocity ratios are plotted against distance from the outlet in Figure 2.

The airflow patterns of diffusers are related to the throw  $K$ -factors and to the throw distance. In general, diffusers that have a circular airflow pattern have a shorter throw than those with a directional or crossflow pattern. During cooling, the circular pattern has a tendency to curl back from the end of the throw toward the diffuser. This action reduces the drop and ensures that the cool air remains near the ceiling.

Cross-flow airflow patterns have a longer throw, and the individual side jets react in a manner similar to jets from sidewall grilles. The airflow jets with this type of pattern have a longer throw and the airflow does not roll back to the diffuser at the end of the throw. The airflow continues to move away from the diffuser at low velocities.

The following example illustrates the use of Table 1 and Figure 2.

**Example 1.** A 300 mm by 450 mm high sidewall grille with a 280 mm by 430 mm core area is selected. From Table 1,  $K = 5$  for Zone 3. If the airflow is 0.3 m<sup>3</sup>/s, what is the throw to 0.25 m/s, 0.5 m/s, and 0.75 m/s? The grille has 80% free area.

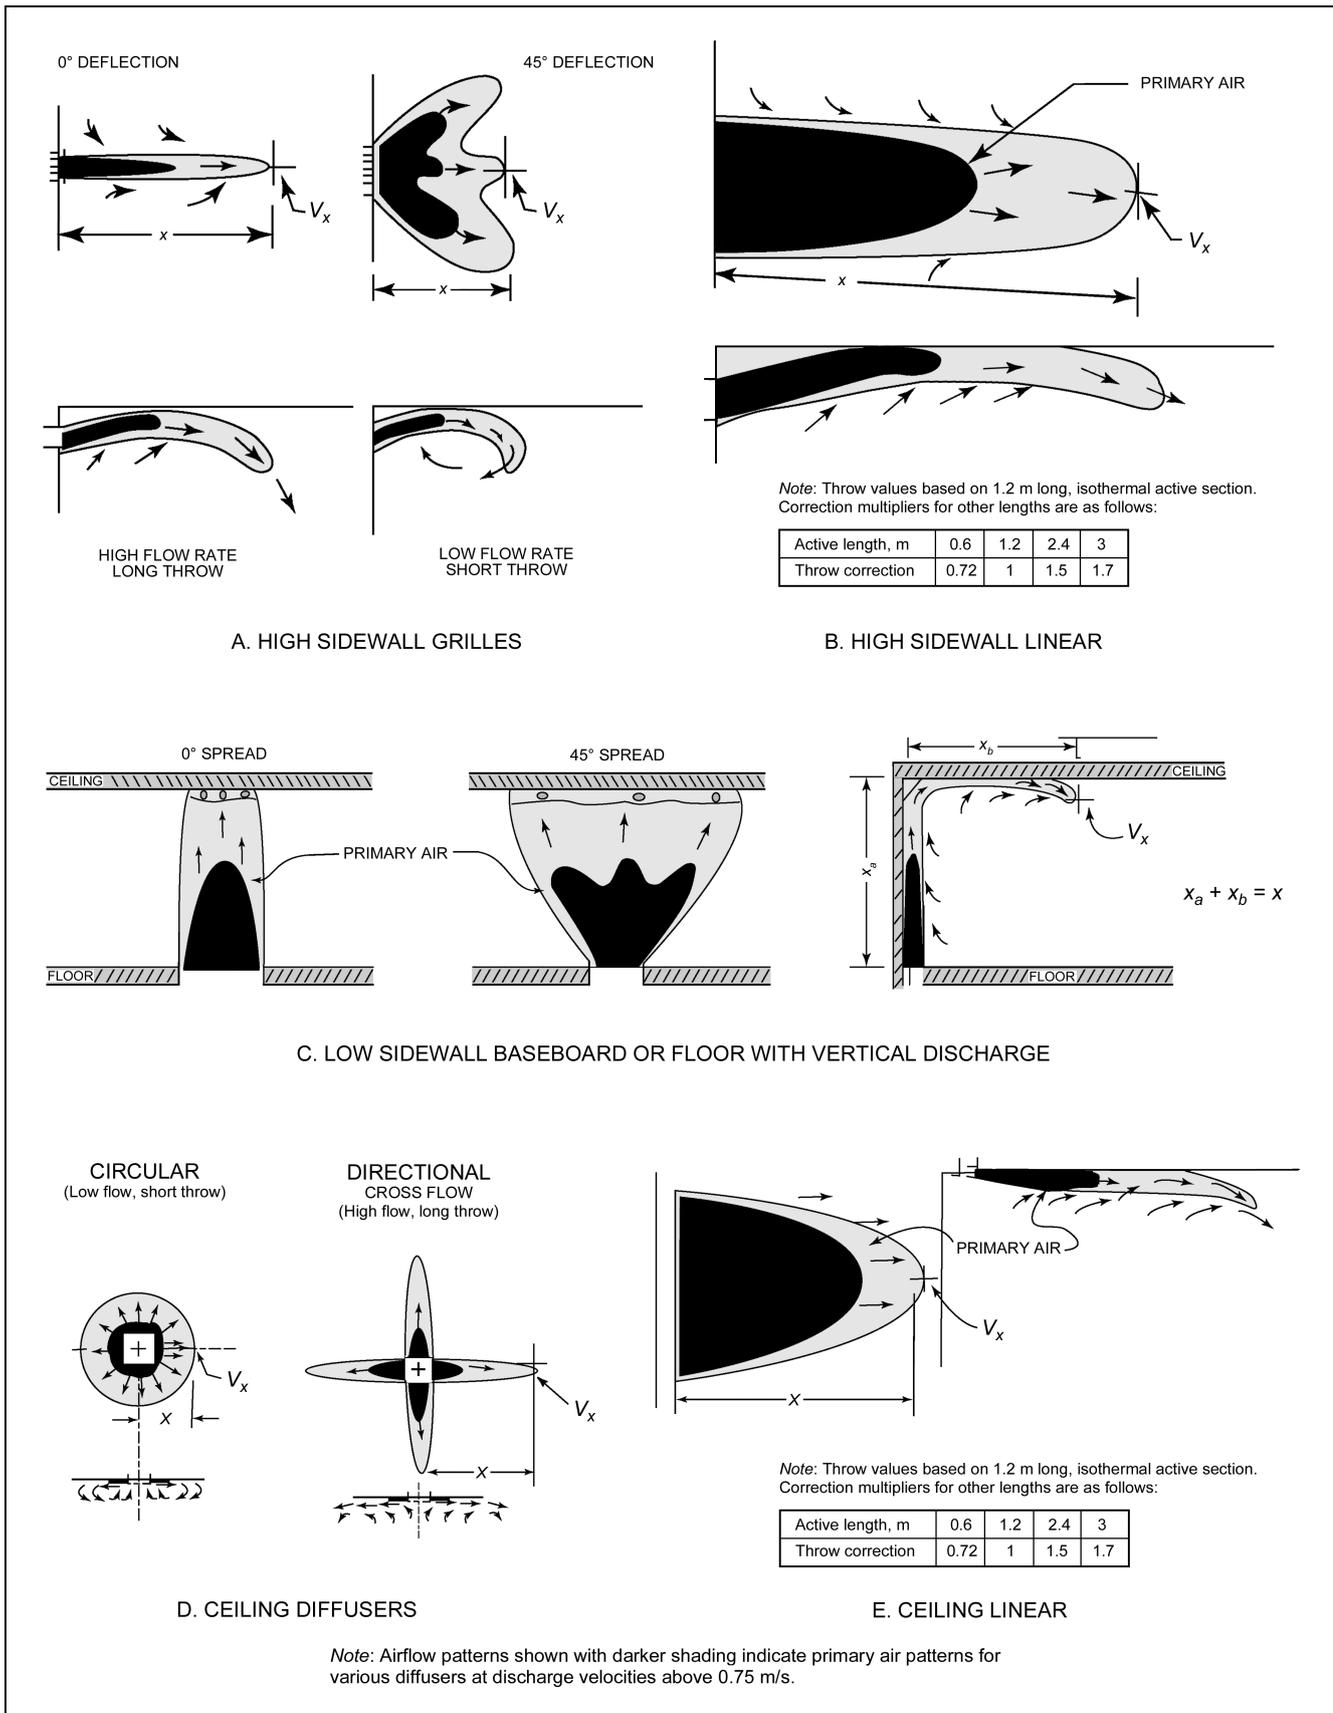

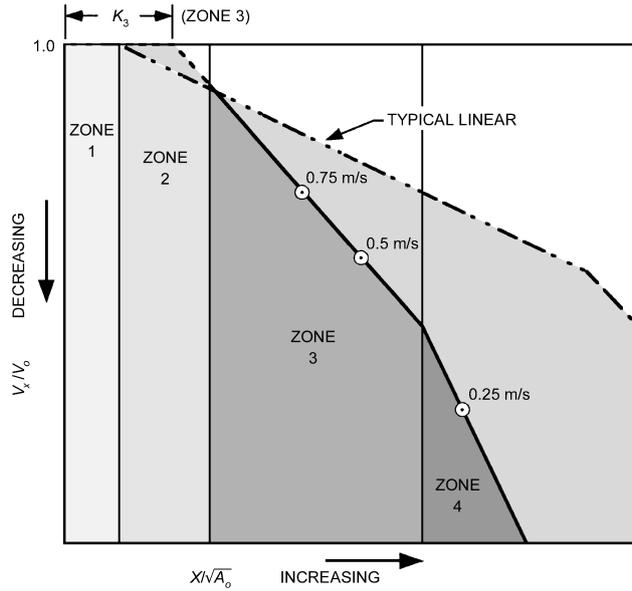

Fig. 1 Airflow Patterns of Different Diffusers

**Fig. 2 Chart for Determining Centerline Velocities of Axial and Radial Jets**

**Solution:**

From Equation (5):

$$X = \frac{1.13KQ}{V_x \sqrt{A_o}} = \frac{1.13 \times 5 \times 0.3}{V_x \sqrt{280 \times 430 / 10^6}} = \frac{4.885}{V_x}$$

Solving for 0.25 m/s throw,

$$X = \frac{4.885}{0.25} = 19.5 \text{ m}$$

But according to Figure 2, 0.25 m/s is in Zone 4, which is typically 20% less than calculated in Equation (4), or

$$X = 19.5 \times 0.80 = 15.6 \text{ m}$$

Solving for 0.50 m/s throw,

$$X = \frac{4.885}{0.50} = 9.8 \text{ m}$$

Solving for 0.75 m/s throw,

$$X = \frac{4.885}{0.75} = 6.5 \text{ m}$$

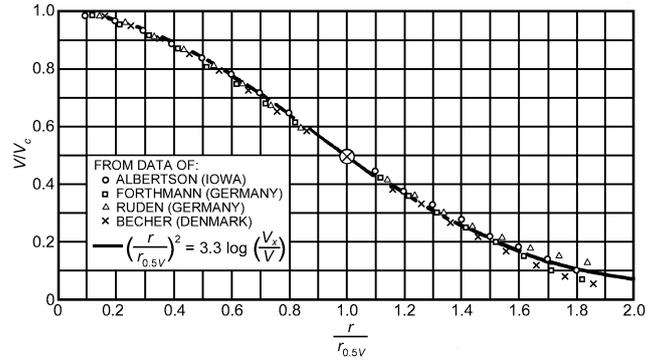

**Throw.** Equation (6) can be transposed to determine the throw  $X$  of an outlet if the discharge volume and the centerline velocity are known:

$$X = \frac{1.13K}{V_x} \frac{Q}{\sqrt{A_c C_d R_{fa}}} \quad (7)$$

Or, if  $Z = \sqrt{C_d R_{fa}}$ ,

$$X = \frac{1.13K}{V_x} \frac{Q}{Z \sqrt{A_c}} \quad (8)$$

The maximum throw  $T_V$  is usually defined as the distance from the outlet face to where the centerline velocity is 0.25 m/s. Therefore, for  $V_T = 0.25 \text{ m/s}$ ,

**Fig. 3 Cross-Sectional Velocity Profiles for Straight-Flow Turbulent Jets**

$$T_V = X = \frac{1.13K}{0.25} \frac{Q}{Z \sqrt{A_c}} \quad (9)$$

Any other terminal centerline velocity could be inserted in Equation (9) for  $T_V$ .

**Velocity Profiles of Jets.** In Zone 3 of both axial and radial jets, the velocity distribution may be expressed by a single curve (Figure 3) in terms of dimensionless coordinates; this same curve can be used as a good approximation for adjacent portions of Zones 2 and 4. Temperature and density differences have little effect on cross-sectional velocity profiles.

Velocity distribution in Zone 3 can be expressed by the Gauss error function or probability curve, which is approximated by the following equation:

$$\left( \frac{r}{r_{0.5V}} \right)^2 = 3.3 \log \frac{V_x}{V} \quad (10)$$

where

- $r$  = radial distance of point under consideration from centerline of jet
- $r_{0.5V}$  = radial distance in same cross-sectional plane from axis to point where velocity is one-half centerline velocity (i.e.,  $V = 0.5V_x$ )
- $V_x$  = centerline velocity in same cross-sectional plane
- $V$  = actual velocity at point being considered

Experiments show that the conical angle for  $r_{0.5V}$  is approximately one-half the total angle of divergence of a jet. The velocity profile curve for one-half of a straight-flow turbulent jet (the other half being a symmetrical duplicate) is shown in Figure 3. For multiple-opening outlets, such as grilles or perforated panels, the velocity profiles are similar, but the angles of divergence are smaller.

**Entrainment Ratios.** The following are equations for the entrainment of circular jets and of jets from long slots.

For third-zone expansion of circular jets,

$$\frac{Q_x}{Q_o} = \frac{2X}{1.13K \sqrt{A_o}} \quad (11)$$

By substituting from Equation (4),

$$\frac{Q_x}{Q_o} = 2 \frac{V_o}{V_x} \quad (12)$$

For a continuous slot with active sections up to 3 m and separated by 0.6 m,

$$\frac{Q_x}{Q_o} = \sqrt{\frac{2}{1.13K}} \sqrt{\frac{X}{H_o}} \quad (13)$$

or, substituting from Equation (2),

$$\frac{Q_x}{Q_o} = \sqrt{2} \frac{V_o}{V_x} \quad (14)$$

where

- $Q_x$  = total volumetric flow rate at distance  $X$  from face of outlet,  $\text{m}^3/\text{s}$
- $Q_o$  = discharge from outlet,  $\text{m}^3/\text{s}$
- $X$  = distance from face of outlet, m
- $K$  = proportionality constant
- $A_o$  = core area  $A_c$  or duct area,  $\text{m}^2$
- $H_o$  = width of slot, m

The entrainment ratio  $Q_x/Q_o$  is important in determining total air movement at a given distance from an outlet. For a given outlet, the entrainment ratio is proportional to the distance  $X$  [Equation (11)] or to the square root of the distance  $X$  [Equation (13)] from the outlet. Equations (12) and (14) show that, for a fixed centerline velocity  $V_x$ , the entrainment ratio is proportional to the outlet velocity. Equations (12) and (14) also show that, at a given centerline and outlet velocity, a circular jet has greater entrainment and total air movement than a long slot. Comparing Equations (11) and (13), the long slot should have a greater rate of entrainment. The entrainment ratio at a given distance is less with a large  $K$  than with a small  $K$ .

### Isothermal Radial Flow Jets

In a radial jet, as with an axial jet, the cross-sectional area at any distance from the outlet varies as the square of this distance. Centerline velocity gradients and cross-sectional velocity profiles are similar to those of Zone 3 of axial jets, and the angles of divergence are about the same.

A jet from a ceiling plaque has the same form as half of a free radial jet. The jet is wider and longer than a free jet, with the maximum velocity close to the surface. Koestel (1957) provides an equation for radial flow outlets.

### Nonisothermal Jets

When the temperature of introduced air is different from the room air temperature, the behavior of the diffuser air jet is affected by the thermal buoyancy due to air density difference. The trajectory of a nonisothermal jet introduced horizontally is determined by the **Archimedes number** (Baturin 1972):

$$\text{Ar} = \frac{gL_o(t_o - t_s)}{V_o^2 T_s} \quad (15)$$

where

- $g$  = gravitational acceleration rate,  $\text{m}/\text{s}^2$
- $L_o$  = length scale of diffuser outlet equal to hydraulic diameter of outlet, m
- $t_o$  = initial temperature of jet,  $^\circ\text{C}$
- $t_s$  = temperature of surrounding air,  $^\circ\text{C}$
- $V_o$  = initial air velocity of jet,  $\text{m}/\text{s}$
- $T_s$  = room air temperature, K

The paths assumed by horizontally projected heated and chilled jets influenced by buoyant forces are significant in heating and cooling with wall outlets. Koestel's equation (1955) describes the behavior of these jets.

Helander and Jakowatz (1948), Helander et al. (1953, 1954, 1957), Yen et al. (1956), and Knaak (1957) developed equations

for outlet characteristics that affect the downthrow of heated air. Koestel (1954, 1955) developed equations for temperatures and velocities in heated and chilled jets. Li et al. (1993, 1995) and Kirkpatrick and Elleson (1996) provide additional information on nonisothermal jets.

### Surface Jets (Wall and Ceiling)

Jets discharging parallel to a surface with one edge of the outlet coinciding with the surface take the form of one-half of an axial jet discharging from an outlet twice as large, similar to radial jets from ceiling plaques. Entrainment takes place almost exclusively along the surface of a half cone, and the maximum velocity remains close to the surface (Tuve 1953).

Values of  $K$  are approximately those for a free jet multiplied by  $\sqrt{2}$ ; that is, the normal maximum of 6.2 for  $K$  for free jets becomes 8.8 for a similar jet discharged parallel to and adjacent to a surface.

When a jet is discharged parallel to but at some distance from a solid surface (wall, ceiling, or floor), its expansion in the direction of the surface is reduced, and entrained air must be obtained by recirculation from the jet instead of from ambient air (McElroy 1943, Nottage et al. 1952a, Zhang et al. 1990). The restriction to entrainment caused by the solid surface induces the **Coanda effect**, which makes the jet attach to a surface a short distance after it leaves the diffuser outlet. The jet then remains attached to the surface for some distance before separating from the surface again.

In nonisothermal cases, the trajectory of the jet is determined by the balance between the thermal buoyancy and the Coanda effect, which depends on the jet momentum and the distance between the jet exit and the solid surface. The behavior of such nonisothermal surface jets has been studied by Kirkpatrick et al. (1991), Wilson et al. (1970), Oakes (1987), and Zhang et al. (1990), each addressing different factors. A more systematic study of these jets in room ventilation flows is needed to provide reliable guidelines for designing air diffusion systems.

## MULTIPLE JETS

Twin parallel air jets act independently until they interfere. The point of interference and its distance from the outlets varies with the distance between the outlets. From the outlets to the point of interference, the maximum velocity, as for a single jet, is on the centerline of each jet. After interference, the velocity on a line midway between and parallel to the two jet centerlines increases until it equals the jet centerline velocity. From this point, a maximum velocity of the combined jet stream is on the midway line, and the profile seems to emanate from a single outlet of twice the area of one of the two outlets.

Koestel and Austin (1956) determined the spacing between outlets for noninterference between the jets. For a  $K$  value of 6.5, the outlets should be placed three to eight diameters apart, with  $V_o$  values from 2.5 to 7.5  $\text{m}/\text{s}$ .

## AIRFLOW IN OCCUPIED ZONE

**Mixing Systems.** Laboratory experiments on jets usually involve recirculated air with negligible resistance to flow on the return path of the jet air. Experiments in mine tunnels of small cross-sectional areas, where the return flow of jet air to outlets meets considerable resistance, show that expansion of the jet terminates abruptly at a distance that is independent of discharge velocity and is only slightly affected by the size of the outlet. These distances are determined primarily by the size and length of the return path. In a long tunnel with a cross section of 1.5 m by 1.8 m, a jet may not travel more than 7.5 m; in a tunnel with a relatively large section (7.5 m by 18 m), the jet may travel more than 75 m. McElroy (1943) provides data on this phase of jet expansion.

Zhang et al. (1990) found that, for a given heat load and room air supply rate, air velocity in the occupied zone increases when the

outlet discharge velocity increases. Therefore, the design supply air velocity should be high enough to maintain the jet traveling in the desired direction in order to ensure good mixing before it reaches the occupied zone. Excessively high outlet air velocity would induce high air velocity in the occupied zone and result in thermal discomfort.

**Turbulence Production and Transport.** The air turbulence within a room is mainly produced at the diffuser jet region by interaction of the supply air with the room air and with the solid surfaces (walls or ceiling) in the vicinity. It is then transported to other parts of the room, including the occupied zone (Zhang et al. 1992). Meanwhile, the turbulence is also damped by viscous effect. Air in the occupied zone usually contains very small amounts of turbulent kinetic energy compared to that in the jet region. Because turbulence may cause thermal discomfort (Fanger et al. 1989), air diffusion systems should be designed so that the primary mixing between the introduced air and the room air occurs away from occupied regions.

## ROOM AIR DIFFUSION METHODS

Room air diffusion systems can be classified as mixing, displacement, unidirectional, underfloor, and task ambient conditioning.

### MIXING SYSTEMS

In mixing systems, conditioned air is normally discharged from air outlets at velocities much greater than those acceptable in the occupied zone. Conditioned air temperature may be above, below, or equal to the air temperature in the occupied zone, depending on the heating/cooling load. The diffuser jets mix with the ambient room air by entrainment, which reduces the air velocity and equalizes the air temperature. The occupied zone is ventilated either by the decayed air jet directly or by the reverse flow created by the jets. Mixing air distribution creates relatively uniform air velocity, temperature, humidity, and air quality conditions in the occupied zone.

### Outlet Classification and Performance

Straub et al. (1956) and Straub and Chen (1957) classified outlets into five groups:

- Group A.** Outlets mounted in or near the ceiling that discharge air horizontally.
- Group B.** Outlets mounted in or near the floor that discharge air vertically in a nonspreading jet.
- Group C.** Outlets mounted in or near the floor that discharge air vertically in a spreading jet.
- Group D.** Outlets mounted in or near the floor that discharge air horizontally.
- Group E.** Outlets mounted in or near the ceiling that project primary air vertically.

Analysis of outlet performance was based on primary air pattern, total air pattern, stagnant air layer, natural convection currents, return air pattern, and room air motion. Figures 4 through 8 show the room air motion characteristics of the five outlet groups; exterior walls are depicted by heavy lines. The principles of air diffusion emphasized by these figures are as follows:

1. The primary air (shown by dark envelopes in Figures 4 through 8) from the outlet down to a velocity of about 0.75 m/s can be treated analytically. The heating or cooling load has a strong effect on the characteristics of the primary air.
2. The total air, shown by gray envelopes in Figures 4 through 8, is influenced by the primary air and is of relatively high velocity (but less than 0.75 m/s). The total air is also influenced by the environment and drops during cooling or rises during heating; it is not subject to precise analytical treatment.

3. Natural convection currents form a stagnant zone from the ceiling down during cooling, and from the floor up during heating. This zone forms below the terminal point of the total air during heating and above the terminal point during cooling. Because this zone results from natural convection currents, the air velocities within it are usually low (approximately 0.1 m/s), and the air stratifies in layers of increasing temperatures. The concept of a stagnant zone is important in properly applying and selecting outlets because it considers the natural convection currents from warm and cold surfaces and internal loads.
4. A return inlet affects the room air motion only within its immediate vicinity. The intake should be located in the stagnant zone to return the warmest room air during cooling or the coolest room air during heating. The importance of the location depends on the relative size of the stagnant zone, which depends on the type of outlet.
5. The general room air motion (shown by white areas in Figures 4 through 8) is a gentle drift toward the total air. Room conditions are maintained by the entrainment of the room air into the total airstream. The room air motion between the stagnant zone and the total air is relatively slow and uniform. The highest air motion occurs in and near the total airstreams.

**Group A Outlets.** This group includes high sidewall grilles, sidewall diffusers, ceiling diffusers, linear ceiling diffusers, and similar outlets. High sidewall grilles and ceiling diffusers are illustrated in Figure 4.

The primary air envelopes (isovels) show a horizontal, two-jet pattern for the high sidewall and a 360° diffusion pattern for the ceiling outlet. Although variation of vane settings might cause a discharge in one, two, or three jets in the case of the sidewall outlet, or have a smaller diffusion angle for the ceiling outlet, the general effect in each is the same.

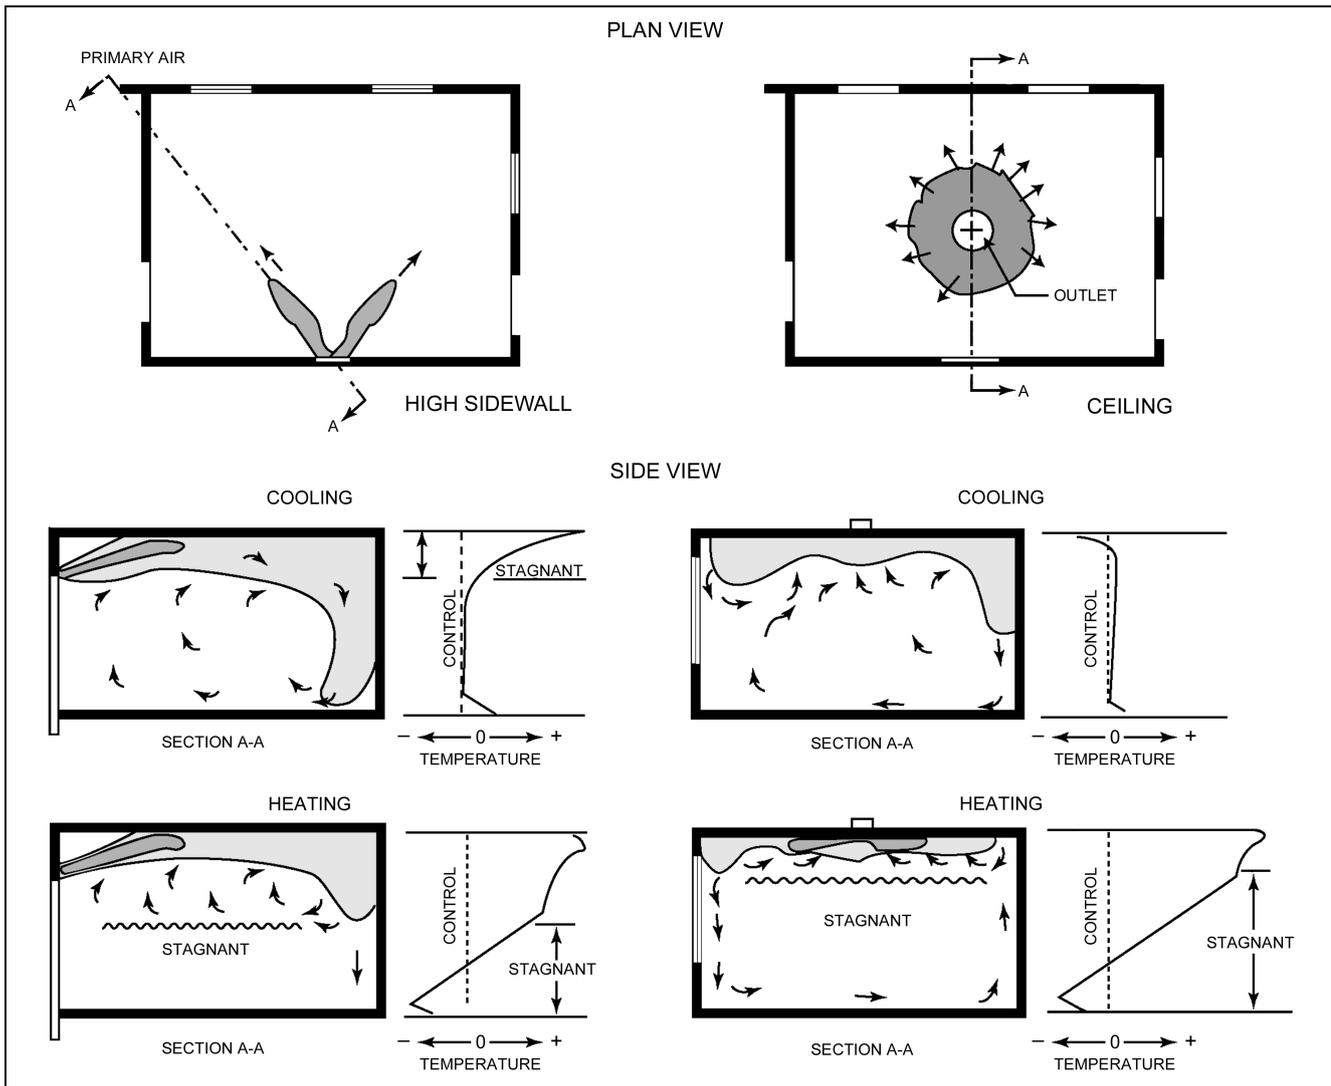

During cooling, the total air drops into the occupied zone at a distance from the outlet that depends on air quantity, supply velocity, temperature differential between supply and room air, deflection setting, ceiling effect, and type of loading within the space. Analytical methods of relating some of these factors are presented in the section on Principles of Jet Behavior.

The cooling diagram for the high sidewall outlet shows an over-throw condition, which causes the total air to drop along the opposite wall and flow slowly for some distance across the floor. Velocities of about 0.5 to 0.75 m/s may be found near the wall but will dissipate within about 100 mm of the wall.

The cooling diagram for the ceiling outlet shows that the total air movement is counteracted by the rising natural convection currents on the heated wall, and, therefore, drops before reaching the wall. On the other hand, the total air reaches the inside wall and descends for some distance along it. With this type of outlet, temperature variations in the room are minimized, with minimal stagnant volume. The maximum velocity and the maximum temperature variation occur in and near the total air envelope; therefore, the drop region becomes important because it is an area with high effective draft temperature  $\theta$  [see Equation (16)]. Consequently, how far the air drops before velocities and temperatures reach acceptable limits must be known.

Because these outlets discharge horizontally near the ceiling, the warmest air in the room is mixed immediately with the cool primary air far above the occupied zone. Therefore, the outlets are capable of handling relatively large quantities of air at large temperature differentials.

During heating, warm supply air introduced at the ceiling can cause stratification in the space if there is insufficient induction of room air at the outlet. Selecting diffusers properly, limiting the room supply temperature differential, and maintaining air supply rates at a level high enough to ensure air mixing by induction provide adequate air diffusion and minimize stratification.

**Fig. 4 Air Motion Characteristics of Group A Outlets**

(Straub et al. 1956)

Several building codes and ASHRAE *Standard 90.1* require sufficient insulation in exterior walls, so most perimeter spaces can be heated effectively by ceiling air diffusion systems. Interior spaces, which generally have only cooling demand conditions, seldom require long-term heating and are seldom a design problem.

Flow rate and velocity for both heating and cooling are the same for the outlets shown in Figure 4. The heating diagram for the sidewall unit shows that, under these conditions, the total air does not descend along the wall. Consequently, higher velocities might be beneficial in eliminating the stagnant zone, since high velocity causes some warm air to reach floor level and counteract stratification of the stagnant region.

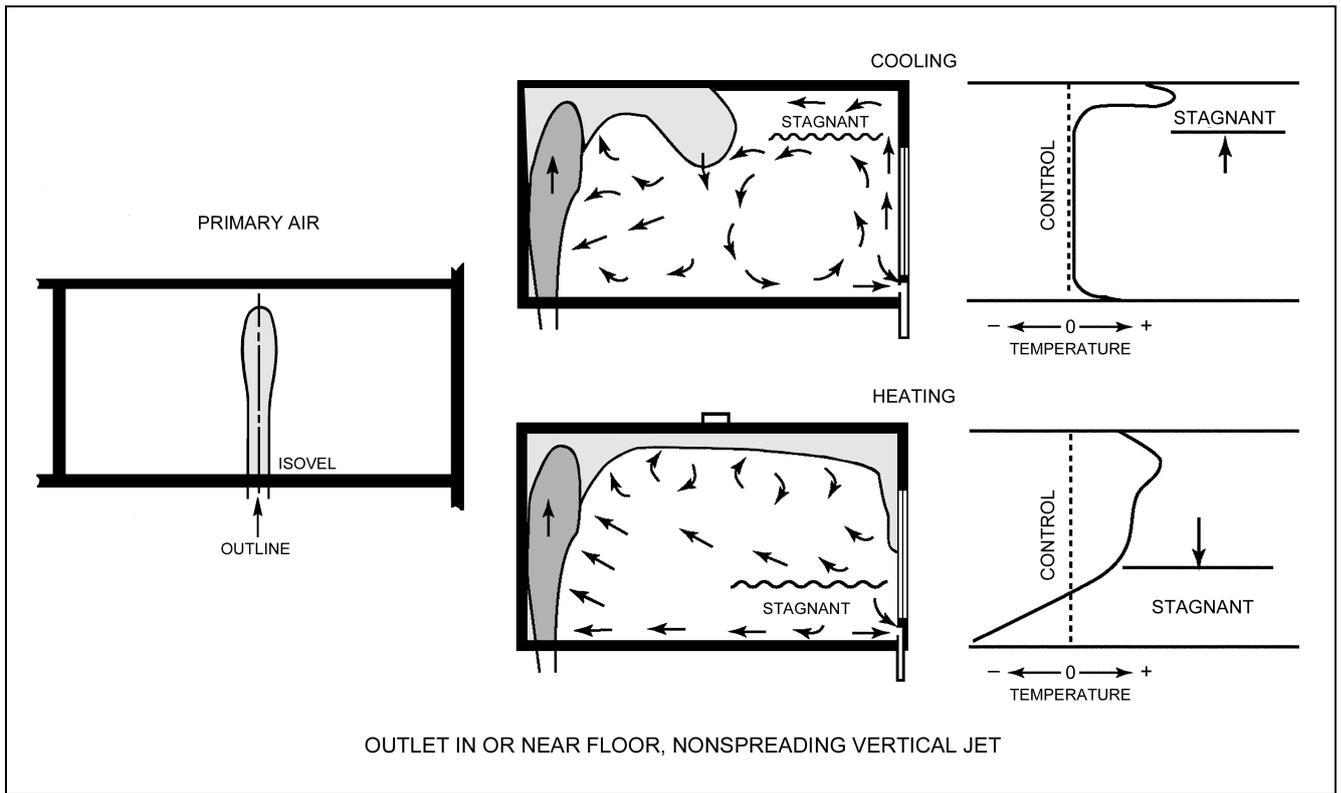

The heating diagram for the ceiling outlet shows the effect of the natural convection currents that produce a larger throw toward the cold exposed wall. The velocity of the total air toward the exposed wall complements the natural convection currents. However, the warm total air loses its downward momentum at its terminal point, and buoyancy forces cause it to rise toward the primary air. Although these forces are complementary, the heating effect of the total air replaces the cool natural convection currents with warm total air.

**Group B Outlets.** This group includes floor registers, baseboard units, low sidewall units, linear-type grilles in the floor or window-sill, and similar outlets. Figure 5 illustrates a floor outlet adjacent to an inside wall.

Because these outlets have no deflecting vanes, the primary air is discharged in a single, vertical jet. When the total air strikes the ceiling, it fans out in all directions and, during cooling, follows the ceiling for some distance before dropping toward the occupied zone. During heating, the total airflow follows the ceiling across the room, then descends partway down the exterior wall.

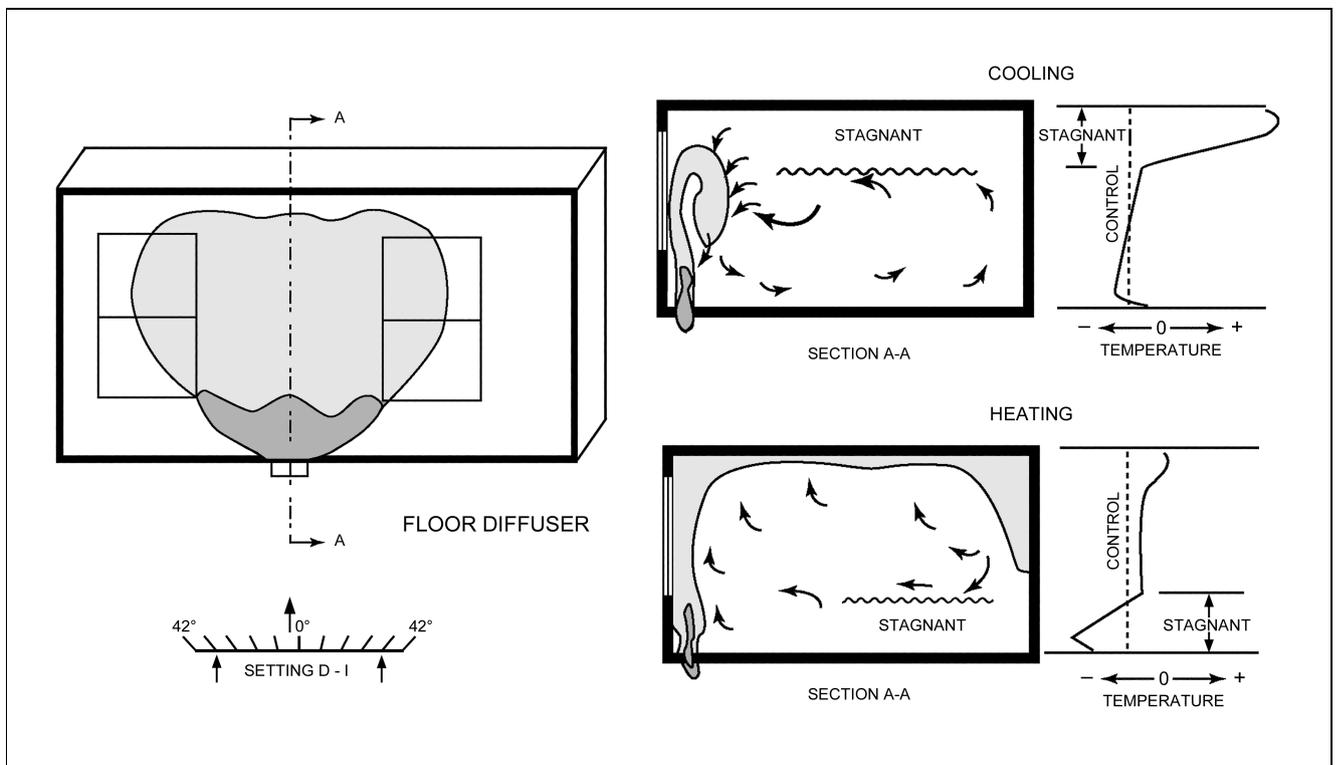

The cooling diagram shows that a stagnant zone forms outside the total air region above its terminal point. Below the stagnant zone, air temperature is uniform, effecting complete cooling. Also, the space below the terminal point of the total air is cooled satisfactorily. For example, if total airflow is projected upward for 2.4 m, the region from this level down to the floor will be cooled satisfactorily. This, however, does not apply to an extremely large space. Judgment to determine the acceptable size of the space outside the total air is needed. A distance of 4.5 to 6 m between the drop region and the exposed wall is a conservative design value.

A comparison of Figures 4 and 5 for heating shows that the stagnant region is smaller for Group B outlets than for Group A outlets

**Fig. 5 Air Motion Characteristics of Group B Outlets**

(Straub et al. 1956)

**Fig. 6 Air Motion Characteristics of Group C Outlets**

(Straub et al. 1956)

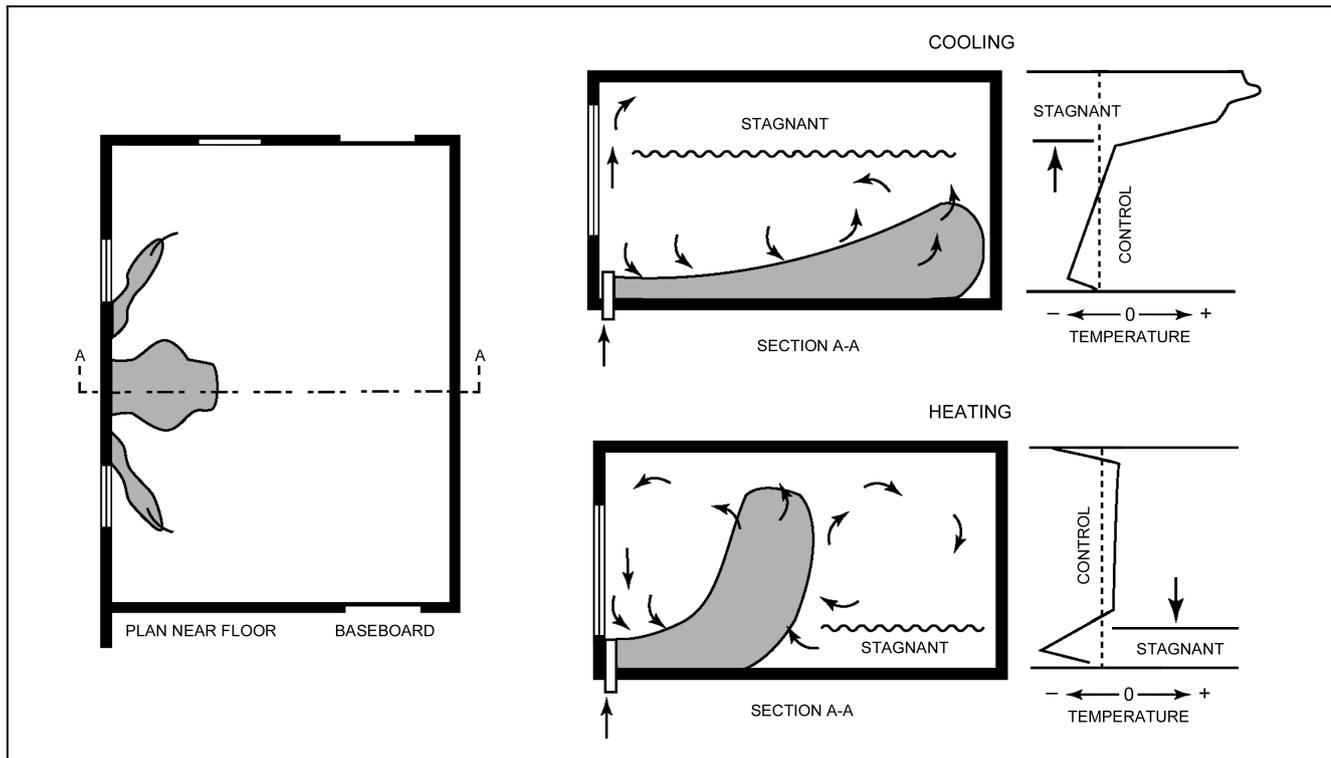

Fig. 7 Air Motion Characteristics of Group D Outlets  
(Straub et al. 1956)

because the air entrained in the immediate vicinity of the outlet is taken mainly from the stagnant region, which is the coolest air in the room. This results in greater temperature equalization and less buoyancy in the total air than would occur with Group A outlets.

While the temperature gradients for both outlet groups are about the same, the stagnant layer for Group B is lower than that for Group A.

**Group C Outlets.** This group includes floor diffusers, sidewall diffusers, linear-type diffusers, and other outlets installed in the floor or windowsill (Figure 6).

Although Group C outlets are related to Group B outlets, they are characterized by wide-spreading jets and diffusing action. Total air and room air characteristics are similar to those of Group B, although the stagnant zone formed is larger during cooling and smaller during heating. Diffusion of the primary air usually causes the total air to fold back on the primary and total air during cooling, instead of following the ceiling. This diffusing action of the outlets makes it more difficult to project the cool air, but it also provides a greater area for induction of room air. This action is beneficial during heating because the induced air comes from the lower regions of the room.

**Group D Outlets.** This group includes baseboard and low sidewall registers and similar outlets (Figure 7) that discharge the primary air in single or multiple jets. During cooling, because the air is discharged horizontally across the floor, the total air remains near the floor, and a large stagnant zone forms in the entire upper region of the room.

During heating, the total air rises toward the ceiling because of the buoyant effect of warm air. The temperature variations are uniform, except in the total air region.

**Group E Outlets.** This group includes ceiling diffusers, linear-type grilles, sidewall diffusers and grilles, and similar outlets mounted or designed for vertical downward air projection. Figure 8 shows the heating and cooling diagrams for such a ceiling diffuser.

During cooling, the total air projects to and follows the floor, producing a stagnant region near the ceiling. During heating, the

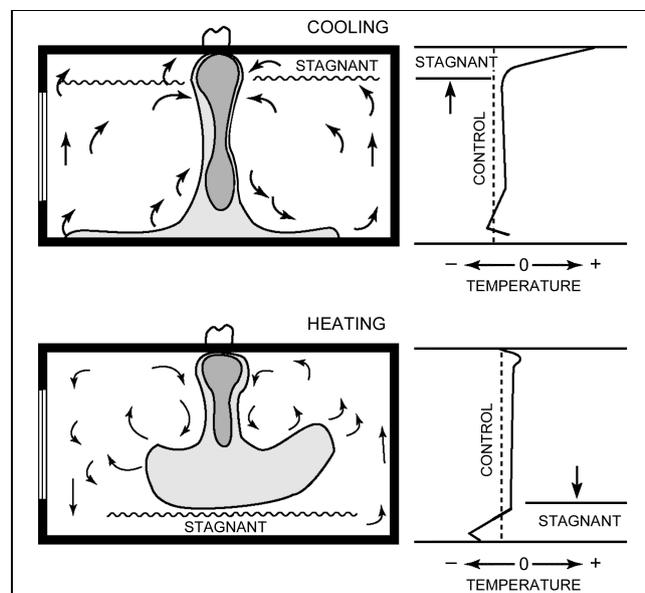

Fig. 8 Air Motion Characteristics of Group E Outlets  
(Straub et al. 1956)

total airflow reaches the floor and folds back toward the ceiling. If projected air does not reach the floor, a stagnant zone results.

### Factors Affecting Outlet Performance

**Vanes.** Vanes affect grille performance if their depth is at least equal to the distance between the vanes (vane ratio  $\geq 1$ ). If the vane ratio is less than unity, effective control by the vanes of the airstream discharged from the grille is impossible. Increasing the vane ratio

above two has little or no effect, so vane ratios should be between one and two.

A grille discharging air uniformly forward (vanes in straight position) has a spread of 14 to 24°, depending on the type of outlet, the duct approach, and the discharge velocity. Turning the vanes influences the direction and throw of the discharged airstream.

A grille with diverging vanes (vertical vanes with uniformly increasing angular deflection from the centerline to a maximum at each end of 45°) has a spread of about 60° and reduces the throw considerably. With increasing divergence, the quantity of air discharged by a grille for a given upstream total pressure decreases.

A grille with converging vanes (vertical vanes with uniformly decreasing angular deflection from the centerline) has a slightly higher throw than a grille with straight vanes, but the spread is approximately the same for both settings. The airstream converges slightly for a short distance in front of the outlet and then spreads more rapidly than air discharged from a grille with straight vanes.

In addition to vertical vanes that normally spread the air horizontally, horizontal vanes may spread the air vertically. However, spreading the air vertically risks hitting beams or other obstructions or blowing primary air into the occupied zone at excessive velocities. On the other hand, vertical deflection may increase adherence to the ceiling and reduce the drop.

**Beamed Ceilings and Obstructions.** In spaces with exposed beams, the outlets should be located below the bottom of the lowest beam level, preferably low enough to employ an upward or arched air path. The air path should be arched sufficiently to miss the beams and prevent the primary or induced airstream from striking furniture and obstacles and producing objectionable drafts (Wilson 1970). Obstructions influence airflow patterns and can reduce air distribution efficiency. Obstructions can reduce jet throw, increase air velocities in portions of the occupied zone, and create stagnant zones.

**Variable Air Volume (VAV) Systems.** The design of air distribution systems is usually based on the full load (heating/cooling). When only a partial load exists, VAV systems reduce the supply airflow, which in turn reduces the air velocity at the outlet. Therefore, the different operation modes of the system (airflow and initial temperature difference) should be considered in designing a VAV system air distribution.

## DISPLACEMENT VENTILATION

In displacement ventilation, conditioned air with a temperature slightly lower than the desired room air temperature in the occupied zone is supplied from air outlets at low air velocities (0.5 m/s or less). The outlets are located at or near the floor level, and the supply air is introduced directly to the occupied zone. Returns through which the warm room air is exhausted from the room are located at or close to the ceiling. The supply air is spread over the floor and then rises as it is heated by the heat sources in the occupied zone. Heat sources (e.g., person, computer) in the occupied zone create upward convective flows in the form of thermal plumes. These thermal plumes tend to remove heat and contaminants within the plume from the occupied zone (Figure 9).

The air volume in the plumes increases as they rise because the plumes entrain ambient air. A stratification level exists where the airflow rate in the plumes equals the supply airflow rate. Two distinct zones are thus formed within the room: one lower zone below the stratification level and with no recirculation flow (close to displacement flow), and one upper zone, with recirculation flow (Figure 9). The height of the lower zone depends on the supply airflow rate and the characteristics of heat sources and their distribution across the floor area. In a properly designed displacement ventilation system, the upper boundary of the lower zone is above the occupied zone so that the occupied zone can be ventilated effectively. For this type of system to function properly, a stable vertically stratified temperature field is essential.

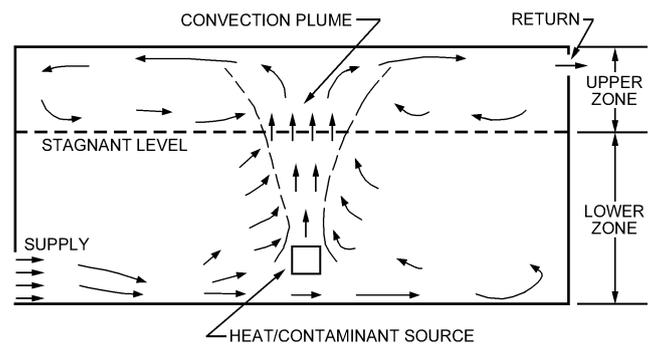

Fig. 9 Schematic of Displacement Ventilation

In contrast to mixing ventilation, displacement ventilation is designed to minimize mixing of air within the occupied zone. The objective of the displacement ventilation is to create conditions close to supply air conditions in the occupied zone. This type of ventilation was originally used in industrial buildings as an effective method for removing contaminants in the occupied zone. It is now also used for ventilating and cooling office buildings. However, local discomfort due to draft and vertical temperature gradient may be critical (Melikov and Nielsen 1989). Sandberg and Blomqvist (1989) suggest that the maximum convective cooling load in office buildings with displacement ventilation not exceed about 25 W/m<sup>2</sup> so that the maximum vertical temperature gradient in the occupied zone will not be larger than 3 K. This is equivalent to 5 L/(s·m<sup>2</sup>) at a maximum cooling differential of 4 K. Kegel and Schulz (1989) and Svensson (1989) suggest somewhat higher cooling load limits of 30 to 40 W/m<sup>2</sup>.

One way of increasing the cooling capacity of displacement ventilation systems is to recirculate some of the room air in the occupied zone through an induction circuit; that is, the room air is induced into the supply air and is mixed before discharge through the low-velocity air terminal device into the room. This reduces the room air temperature gradient for a given cooling load, thus allowing a cooling load limit of up to 50 W/m<sup>2</sup> (Jackman 1991).

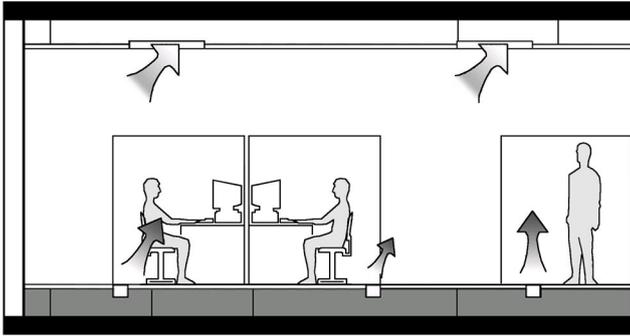

Air diffusers with a large outlet area are used to supply air at low velocity. Displacement ventilation has been compared with conventional mixing ventilation (Svensson 1989, Seppanen et al. 1989, Stymne et al. 1991). Design guidelines for displacement ventilation can be found in Scaret (1985), Jackman and Appleby (1990), Jackman (1991), and Shilkrot and Zhivov (1992).

## UNIDIRECTIONAL AIRFLOW VENTILATION

In this type of ventilation, air is either (1) supplied from the ceiling and exhausted through the floor, or vice versa; or (2) supplied through the wall and exhausted through returns at the opposite wall. The outlets are uniformly distributed over the ceiling, floor, or wall to provide a low-turbulence “plug”-type flow across the entire room. This type of system is mainly used for clean room ventilation, in which the main objective is to remove contaminant particles from the room. Details about clean room ventilation are given in Chapter 15 of the 1999 *ASHRAE Handbook—Applications*. Unidirectional flow ventilation is also used in other areas, such as computer rooms and paint booths.

## UNDERFLOOR AIR DISTRIBUTION AND TASK/AMBIENT CONDITIONING

Underfloor air distribution systems are installed with a raised floor through which conditioned air is delivered to the space through floor grilles or as part of the workstation furniture and partitions. Sometimes called localized ventilation, these systems

**Fig. 10 Underfloor Air Distribution System**

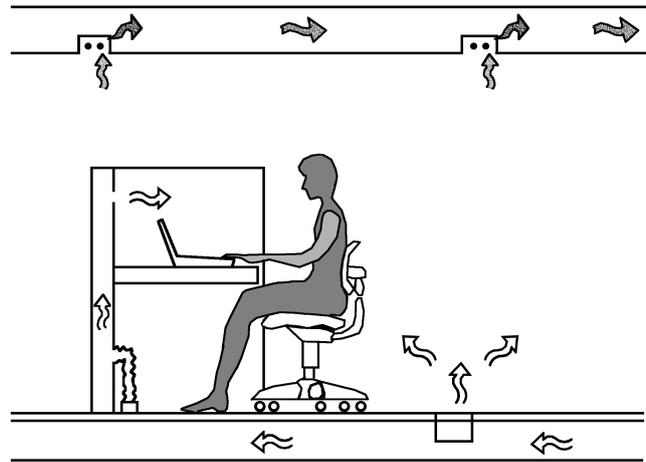

supply air to local areas that are often near building occupants or other specific locations in the space. In comparison to conventional ceiling-based air diffusion, underfloor air distribution systems generally have a larger number of supply diffusers directly in the occupied zone of the building (e.g., in floors, desks, workstation partitions, or theater seats). Air typically returns at or close to ceiling level, so that localized systems benefit from the same overall upward movement of air in the room as displacement ventilation systems. In cooling applications, this air movement efficiently removes heat and contaminant sources from the room.

Underfloor air distribution differs from displacement ventilation in that (1) it generally uses higher supply volumes, which enable higher cooling loads to be met; and (2) it supplies air at a higher velocity through smaller diffusers. Because air is delivered directly to the occupied zone, the supply air temperature is usually warmer (above about 17.5°C) than that maintained for conventional ceiling distribution in order to avoid occupant discomfort due to drafts. Bauman et al. (1999), Hanzawa and Nagasawa (1990), Houghton (1995), Loudermilk (1999), McCarry (1995, 1998), Shute (1992, 1995), Sodec and Craig (1990), Spoomaker (1990), and Tanabe and Kimura (1996) describe the results of laboratory studies, case studies of actual installations, field experiments of system performance, and present design guidelines.

A well-designed underfloor air distribution system also requires less energy and is more flexible in providing and maintaining building services than traditional overhead systems. Extremely low operational static pressures in the underfloor air supply plenum can reduce central fan energy use. Thermal storage in the exposed structural mass in the underfloor plenum (e.g., concrete slab) can save energy and reduce peak cooling loads. The use of raised flooring provides maximum flexibility and significantly lowers costs associated with reconfiguring building services, particularly in buildings having high churn rates. (Churn rate is defined as the annual percentage of workers and their associated work spaces in a building that are reconfigured or undergo significant changes.) Figure 10 shows a schematic diagram of an underfloor air distribution system.

### Task/Ambient Conditioning (TAC)

Task/ambient conditioning (TAC) is most commonly installed with underfloor air distribution (Arens et al. 1991; Bauman et al. 1991, 1993, 1995, 1998; Bauman and Arens 1996; Faulkner et al. 1993, 1999; Fisk et al. 1991; Matsunawa et al. 1995; Tsuzuki et al. 1999). TAC gives individuals some control over their local environment without adversely affecting that of nearby occupants. Typically, the occupant can control the speed, direction, and, in some cases, temperature of the incoming air supply. TAC systems have been most frequently installed in open-plan offices in which they provide supply air and, in some cases, radiant heating directly into workstations. Figure 11 shows an underfloor TAC system with a

**Fig. 11 Underfloor TAC and Personal HVAC System**  
(Matsunawa et al. 1995)

local (personal HVAC) diffuser located in the partition in front of the office worker (Matsunawa et al. 1995).

As further evidence of the benefits of providing personal control, field research has found that building occupants who have no individual control capabilities are twice as sensitive to changes in temperature as occupants who do have individual thermal control (de Dear and Brager 1999, Bauman et al. 1998).

## METHODS OF EVALUATION

### Standards for Satisfactory Conditions

The object of air diffusion in warm-air heating, ventilating, and air-conditioning is to create the proper combination of temperature, humidity, and air motion in the occupied zone of the conditioned room—from the floor to 1.8 m above floor level (Miller 1989). The effective draft temperature combines the effects of air temperature, air motion, and relative humidity in terms of their physiological effects on a human body. Variation from accepted standard limits (ASHRAE *Standard 55*) may cause occupant discomfort. Lack of uniform conditions within the space or excessive fluctuation of conditions in the same part of the space also produces discomfort. Discomfort can arise due to any of the following conditions:

- Excessive air motion (draft)
- Excessive room air temperature variations (horizontal, vertical, or both)
- Failure to deliver or distribute air according to the load requirements at different locations
- Overly rapid fluctuation of room temperature

**Draft.** Koestel and Tuve (1955) and Reinmann et al. (1959) studied the effect of air motion on comfort and defined **draft** as any localized feeling of coolness or warmth of any portion of the body due to both air movement and air temperature, with humidity and radiation considered constant. The warmth or coolness of a draft was measured above or below a controlled room condition of 24°C dry-bulb at the center of the room, 0.75 m above the floor, with air moving at about 0.15 m/s.

To define the **effective draft temperature**  $\theta$  (the difference in temperature between any point in the occupied zone and the control condition), the investigators used the following equation proposed by Rydberg and Norback (1949) and modified by Straub in discussion of a paper by Koestel and Tuve (1955):

$$\theta = (t_x - t_c) - 8(V_x - 0.15) \quad (16)$$

where

- $\theta$  = effective draft temperature, K
- $t_x$  = local airstream dry-bulb temperature, °C
- $t_c$  = average (control) room dry-bulb temperature, °C
- $V_x$  = local airstream centerline velocity, m/s

Equation (16) accounts for the feeling of coolness produced by air motion and is used to establish the neutral line in Figure 12. In summer, the local airstream temperature  $t_x$  is below the control temperature  $t_c$ . Hence, both temperature and velocity terms are negative when velocity  $V_x$  is greater than 0.15 m/s, and they both add to the feeling of coolness. If, in winter,  $t_x$  is above  $t_c$ , any air velocity above 0.15 m/s subtracts from the feeling of warmth produced by  $t_x$ . Therefore, it is usually possible to have zero difference in effective temperature between location  $x$  and the control point in winter, but not in summer.

Houghten et al. (1938) presented data that make it possible to interpret statistically the percentage of room occupants that will object to a given draft condition. Figure 12 presents the data in the form used by Koestel and Tuve (1955). The data show that a person

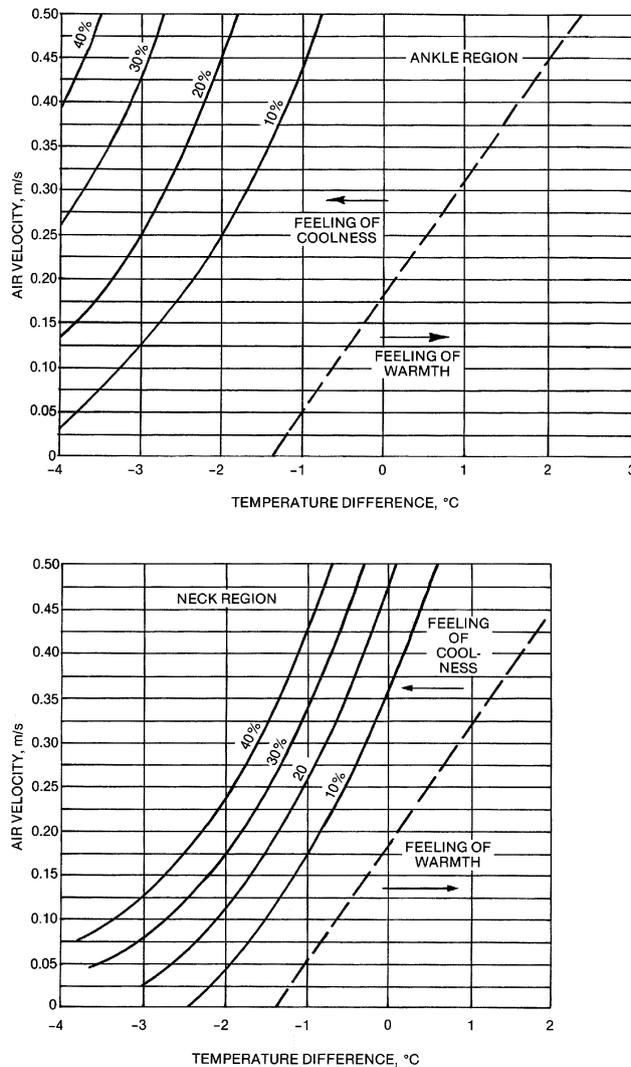

Fig. 12 Percentage of Occupants Objecting to Drafts in Air-Conditioned Room

tolerates higher velocities and lower temperatures at ankle level than at neck level. Because of this, conditions in the zone extending from approximately 0.75 to 1.5 m above the floor are more critical than conditions nearer the floor.

**Air Velocity.** Room air velocities less than 0.25 m/s are generally preferred; however, Figure 12 shows that even higher velocities may be acceptable to some occupants. ASHRAE *Standard 55* recommends elevated air speeds at elevated air temperatures. No minimum air speeds are recommended for comfort, although air speeds below 0.1 m/s are usually imperceptible.

**Temperature Gradient.** Figure 12 also shows that up to 20% of occupants will not accept an ankle-to-sitting-level gradient of about 2 K. Poorly designed or operated systems in a heating mode can create this condition, which emphasizes the importance of proper selection and operation of perimeter systems. The section on Outlet Classification and Performance describes possible regions of high room air velocities caused by various outlets; the section on Outlet Location and Selection describes how to evaluate acceptable air diffusion.

### AIR DIFFUSION PERFORMANCE INDEX (ADPI)

A high percentage of people are comfortable in sedentary (office) occupations where the effective draft temperature  $\theta$ , as defined in Equation (16), is between  $-1.5$  and  $+1$  K and the air velocity is less than 0.35 m/s. If several measurements of air velocity and air temperature are made throughout the occupied zone of an office, the ADPI is the percentage of locations where measurements were taken that meet these specifications for effective draft temperature and air velocity. If the ADPI is maximum (approaching 100%), the most desirable conditions are achieved (Miller and Nevins 1969, 1970, 1972, 1974; Miller 1971; Miller and Nash 1971; Nevins and Ward 1968; Nevins and Miller 1972).

The ADPI is based only on air velocity and the effective draft temperature (a combination of local temperature variations from the room average) and is not directly related to the dry-bulb temperature or relative humidity. These and similar effects, such as mean radiant temperature, must be accounted for separately according to ASHRAE *Standard 55*.

The ADPI is for cooling mode conditions; a measurement technique is specified in ASHRAE *Standard 113*. Heating conditions can be evaluated using ASHRAE *Standard 55* guidelines or ISO *Standard 7730*. The ADPI technique uses isothermal throw data determined under ASHRAE *Standard 70* (see Table 4) to predict what will happen under cooling conditions.

### ADPI Selection Guide

**Jet Throw.** The throw of a jet is the distance from the outlet to a point where the maximum velocity in the stream cross section has been reduced to a selected terminal velocity. To estimate ADPI, **terminal velocity**  $V_T$  was selected for all diffusers as 0.25 m/s, except in the case of ceiling slot diffusers, where it was selected as 0.5 m/s. Each manufacturer gives data for the throw of a jet from various diffusers for isothermal conditions and without a boundary wall interfering with the jet.

The throw distance of a jet is denoted by  $T_V$ , where subscript  $V$  indicates the terminal velocity for which the throw is given. The **characteristic room length**  $L$  is the distance from the diffuser to the nearest boundary wall in the principle horizontal direction of the air-flow. However, where air injected into the room does not impinge on a wall surface but collides with air from a neighboring diffuser, the characteristic length is one-half the distance between diffusers plus the distance the mixed jet travels downward to reach the occupied zone. Table 3 summarizes definitions of characteristic length for various diffusers.

The midplane between diffusers also can be considered the module line when diffusers serve equal modules throughout a

**Table 3 Characteristic Room Length for Several Diffusers**

Diffuser Type	Characteristic Length $L$
High sidewall grille	Distance to wall perpendicular to jet
Circular ceiling diffuser	Distance to closest wall or intersecting air jet
Sill grille	Length of room in direction of jet flow
Ceiling slot diffuser	Distance to wall or midplane between outlets
Light troffer diffusers	Distance to midplane between outlets plus distance from ceiling to top of occupied zone
Perforated, louvered ceiling diffusers	Distance to wall or midplane between outlets

**Table 4 Air Diffusion Performance Index (ADPI) Selection Guide**

Terminal Device	Room Load, $W/m^2$	$T_{0.25}/L$ for Maximum ADPI	Maximum ADPI	For ADPI Greater than	Range of $T_{0.25}/L$
High sidewall grilles	250	1.8	68	—	—
	190	1.8	72	70	1.5–2.2
	125	1.6	78	70	1.2–2.3
	65	1.5	85	80	1.0–1.9
Circular ceiling diffusers	250	0.8	76	70	0.7–1.3
	190	0.8	83	80	0.7–1.2
	125	0.8	88	80	0.5–1.5
	65	0.8	93	90	0.7–1.3
Sill grille, straight vanes	250	1.7	61	60	1.5–1.7
	190	1.7	72	70	1.4–1.7
	125	1.3	86	80	1.2–1.8
	65	0.9	95	90	0.8–1.3
Sill grille, spread vanes	250	0.7	94	90	0.6–1.5
	190	0.7	94	80	0.6–1.7
	125	0.7	94	—	—
	65	0.7	94	—	—
Ceiling slot diffusers (for $T_{100}/L$ )	250	0.3	85	80	0.3–0.7
	190	0.3	88	80	0.3–0.8
	125	0.3	91	80	0.3–1.1
	65	0.3	92	80	0.3–1.5
Light troffer diffusers	190	2.5	86	80	<3.8
	125	1.0	92	90	<3.0
	65	1.0	95	90	<4.5
Perforated, louvered ceiling diffusers	35–160	2.0	96	90	1.4–2.7
				80	1.0–3.4

space, and a characteristic length consideration can be based on module dimension  $d$ .

**Load Considerations.** The recommendations in Table 4 cover cooling loads of up to 250 W per square metre of floor surface. The loading is distributed uniformly over the floor up to about 22 W/m<sup>2</sup>, lighting contributes about 30 W/m<sup>2</sup>, and the remainder is supplied by a concentrated load against one wall that simulates a business machine or a large sun-loaded window. Over this range of data, the maximum ADPI condition is lower for the highest loads; however, the optimum design condition changes only slightly with the load.

**Design Conditions.** The quantity of air must be known from other design specifications. If it is not known, the solution must be obtained by trial and error.

The devices for which data were obtained are (1) high sidewall grilles, (2) cone-type circular ceiling diffusers, (3) sill grilles, (4) two- and four-slot ceiling diffusers, (5) light troffer diffusers, and (6) square-faced perforated and louvered ceiling diffusers. Table 2 summarizes the results of the recommendations on values of  $T_V/L$  by giving the value of  $T_V/L$  at which the ADPI is a maximum for

various loads, as well as a range of values of  $T_V/L$  for which ADPI is above a minimum specified value.

## SYSTEM DESIGN

### DESIGN CONSIDERATIONS

#### Noise

The noise generated by diffusers transmits to the occupied space directly and cannot be attenuated. Therefore, the diffusion system design should meet the sound level criteria specified in Chapter 46 of the 1999 *ASHRAE Handbook—Applications*.

#### Duct Approaches to Diffuser Outlets

The manner in which the airstream approaches the diffuser outlet is important. For correct air diffusion, the velocity of the airstream must be as uniform as possible over the entire cross-sectional area of the connecting duct and must be perpendicular to the outlet face. Effects of improper duct approach generally cannot be corrected by the diffuser.

If the system is designed carefully, a wall grille installed at the end of a horizontal duct and a ceiling outlet at the end of a vertical duct receive the air perpendicularly and at uniform velocity over the entire duct cross section. However, few outlets are installed in this way. Most sidewall outlets are installed either at the end of vertical ducts or in the side of horizontal ducts, and most ceiling outlets are attached either directly to the bottom of horizontal ducts or to special vertical takeoff ducts that connect the outlet with the horizontal duct. In all these cases, special devices for directing and equalizing the airflow are necessary for proper direction and diffusion of the air.

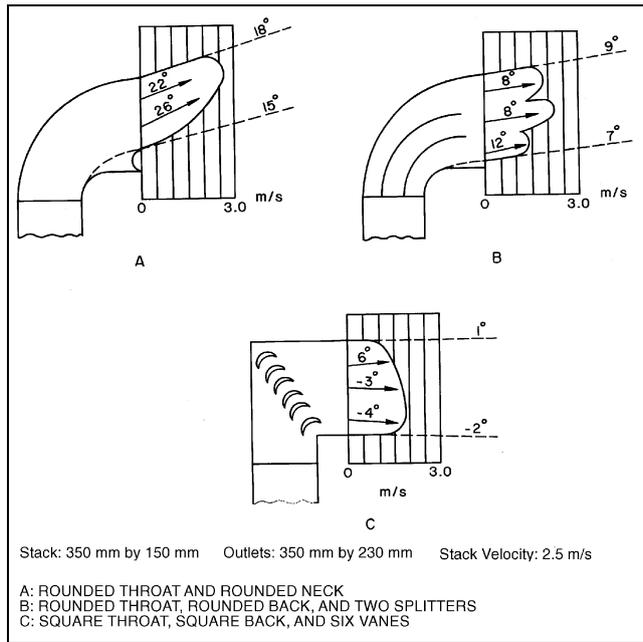

The influence of the duct approach on outlet performance has been investigated for vertical stack heads with plain openings (Nelson et al. 1940) or equipped with grilles (Nelson et al. 1942) and side outlets on horizontal ducts (Nelson and Smedberg 1943). In tests conducted with the stack heads, splitters or guide vanes in the elbows at the top of the vertical stacks are needed, regardless of the shape of the elbows (rounded, square, or expanding). Cushion chambers at the top of the stack heads are not beneficial. Figure 13 shows the direction of flow, diffusion, and velocity (measured 300 mm from the opening) of the air for various stack heads tested, expanding from a 350 mm by 150 mm stack to a 350 mm by 230 mm opening, without a grille. The air velocity for each was 2.5 m/s in the stack below the elbow, but the direction of flow and the diffusion pattern indicate performance obtained with nonexpanding elbows of similar shapes for velocities from 1 to 2 m/s.

In tests conducted with 75 mm by 250 mm, 100 mm by 230 mm, and 150 mm by 150 mm side outlets in a 150 mm by 510 mm horizontal duct at duct velocities of 1 to 7 m/s in the horizontal duct section, multiple curved deflectors produced the best flow characteristics. Vertical guide strips in the outlet were not as effective as curved deflectors. A single scoop-type deflector at the outlet did not improve the flow pattern obtained from a plain outlet and, therefore, was not desirable.

#### Return and Exhaust Openings

**Selection.** The selection of return and exhaust openings depends on (1) velocity in the occupied zone near the openings, (2) permissible pressure drop through the openings, and (3) noise.

**Velocity.** Airflow patterns and room air movement are not influenced by the location of the return and exhaust outlets beyond a distance of one characteristic length of the return or exhaust opening (e.g., square root of the opening area). Air handled by the opening approaches the opening from all directions, and its velocity decreases rapidly as the distance from the opening increases. Therefore, drafty conditions rarely occur near return openings. Table 5 shows recommended return opening face velocities.

**Fig. 13** Outlet Velocity and Air Direction Diagrams for Stack Heads with Expanding Outlets

**Table 5** Recommended Return Inlet Face Velocities

Inlet Location	Velocity Across Gross Area, m/s
Above occupied zone	> 4
Within occupied zone, not near seats	3 to 4
Within occupied zone, near seats	2 to 3
Door or wall louvers	1 to 1.5
Through undercut area of doors	1 to 1.5

**Permissible pressure drop.** Permissible pressure drop depends on the choice of the designer. Proper pressure drop allowances should be made for control or directive devices.

**Noise.** The problem of noise in return openings is the same as that in supply outlets. In computing room noise levels resulting from the operation of an air-conditioning system, the return opening must be included as part of the total grille area.

**Location.** The openings should be located to minimize short-circuiting of supply air. If air is supplied by the jets attached to the ceiling, exhaust openings should be located between the jets or at the side of the room away from the supply air jets. In rooms with vertical temperature stratification, such as foundries, computer rooms, theaters, bars, kitchens, dining rooms, and club rooms, exhaust openings should be located near the ceiling to collect warm air, odors, and fumes.

For industrial rooms with gas release, selection of exhaust opening locations depends on the density of the released gases and their temperature; locations should be specified for each application.

Exhaust outlets located in walls and doors, depending on their elevation, have the characteristics of either floor or ceiling returns. In large buildings with many small rooms, return air may be brought through door grilles or door undercuts into the corridors and then to a common return or exhaust. If the pressure drop through door returns is excessive, the air diffusion to the room may be seriously unbalanced by opening or closing the doors. Outward leakage through doors or windows cannot be counted on for dependable results.

**System Balancing**

Ducts and diffusers in a system should be sized so that the supply of air is distributed properly. However, for flexibility, use standard sizes and allow for future redistribution; the system as designed may not be self-balancing. Chapter 36 of the 1999 *ASHRAE Handbook—Applications* describes the procedures used to balance air distribution systems.

**DESIGN PROCEDURE**

1. Determine the air volumetric flow requirements based on load and room size. For VAV systems, evaluation should include the range of flow rates from minimum occupied to design load.
2. Select the tentative diffuser type and location within room.
3. Determine the room's characteristic length  $L$  (Table 3).
4. Select the recommended  $T_V/L$  ratio from Table 4.
5. Calculate the throw distance  $T_V$  by multiplying the recommended  $T_V/L$  ratio from Table 4 by the room length  $L$ .
6. Locate appropriate outlet size from the manufacturer's catalog.
7. Ensure that this outlet meets other imposed specifications, such as for noise and for static pressure.

**Example 2.**

Specifications:

- Room size 6 m by 4 m with 2.5 m ceiling
- Loading Uniform, 30 W/m<sup>2</sup> or 720 W
- Air volumetric flow  $5 \times 10^{-3}$  m<sup>3</sup>/(s·m<sup>2</sup>) or 0.12 m<sup>3</sup>/s for the one outlet
- Device High sidewall grille, located at center of 4 m endwall, 230 mm from ceiling

Calculations:

- Characteristic length  $L = 6$  m (length of room: Table 3)
- Recommended  $T_V/L = 1.5$  (Table 4)
- Throw to 0.25 m/s  $T_{50} = 1.5 \times 6 = 9$  m

Refer to the manufacturer's catalog for a size that gives this isothermal throw to 0.25 m/s. One manufacturer recommends the following sizes, when vanes are straight, discharging 0.12 m<sup>3</sup>/s: 400 mm by 100 mm, 300 mm by 125 mm, or 250 mm by 150 mm.

**OUTLET LOCATION AND SELECTION**

No criteria have been established for choosing among the six types of outlets to obtain an optimum ADPI. All outlets tested, when used according to these recommendations, can have ADPI values that are satisfactory (greater than 90% for loads less than 130 W/m<sup>2</sup>).

The design of an air distribution and air diffusion system is influenced by the same factors that influence the design of an air-conditioning plant—building use, size, and construction type. Location and selection of the supply outlets is further influenced by the interior design of the building, local sources of heat gain or loss, and outlet performance and design.

Local sources of heat gain or loss promote convection currents or cause stratification; they may, therefore, determine both the type and location of the supply outlets. Outlets should be located to neutralize any undesirable convection currents set up by a concentrated load. If a concentrated heat source is located at the occupancy level of the room, the heating effect can be counteracted (1) by directing cool air toward the heat source or (2) by locating an exhaust or return grille adjacent to the heat source. The second method is more economical for cooling applications, since heat is withdrawn at its source rather than dissipated into the conditioned space. Where lighting loads are heavy (50 W/m<sup>2</sup>) and ceilings relatively high (above 4.5 m), outlets should be located below the lighting load, and the stratified warm air should be removed by an exhaust or return fan. An exhaust fan is recommended if the wet-bulb temperature of the air is above that of the outdoors; a return fan is recommended if the wet-bulb temperature is below this temperature. These methods reduce the requirements for supply air. Enclosed lights are more

economical than exposed lights because a considerable portion of the energy is radiant.

Based on the analysis of the outlet performance tests conducted by Straub et al. (1956) and Straub and Chen (1957), the following are selection considerations for outlets in Groups A through E.

### Group A Outlets

Outlets mounted in or near the ceiling with horizontal air discharge should not be used with temperature differentials exceeding 15 K during heating. Researchers have recommended that temperature differentials not exceed 8 K during heating (Hart and Int-Hout 1980, Lorch and Straub 1983). Consequently, such outlets should be used for heating buildings located in regions where winter heating is only a minor problem and, in northern latitudes, solely for interior spaces. However, these outlets are particularly suited for cooling and can be used with high airflow rates and large temperature differentials. They are usually selected for their cooling characteristics.

The performance of these outlets is affected by various factors. Vane deflection settings reduce throw and drop by changing air from a single straight jet to a wide-spreading or fanned-out jet. Accordingly, a sidewall outlet with 0° deflection has a longer throw and a greater drop than a ceiling diffuser with a single 360° angle of deflection. Sidewall grilles and similar outlets with other deflection settings may have performance characteristics between these two extremes.

Wide deflection settings also cause a ceiling effect, which increases the throw and decreases the drop. To prevent smudging, the total air should be directed away from the ceiling, but this is rarely practicable, except for very high ceilings. For optimum air diffusion in areas with normal ceilings, total air should scrub the ceiling surface.

Drop increases and throw decreases with larger temperature differentials. For constant temperature differential, airflow rate affects drop more than velocity. Therefore, to avoid drop, several small outlets may be better in a room than one large outlet.

With the data in the section on Principles of Jet Behavior, the throw may be selected for a portion of the distance between the outlet and wall or, preferably, for the entire distance. For outlets in opposite walls, the throw should be one-half the distance between the walls. Following these recommendations, the air drops before striking the opposite wall or the opposing airstream. To counteract specific sources of heat gain or to provide higher air motion in rooms with high ceilings, it may be necessary to select a longer throw. In no case should the drop exceed the distance from the outlet to the 1.8 m level.

To maintain maximum ventilation effectiveness with ceiling diffusers, throws should be kept as long as possible. With VAV designs, some overthrow at maximum design volumes will be desirable—the highest induction can be maintained at reduced flows. Adequate induction by a ceiling-mounted diffuser prevents short-circuiting of unmixed supply air between supply outlet and ceiling-mounted returns.

### Group B Outlets

In selecting these outlets, it is important to provide enough throw to project the air high enough for proper cooling in the occupied zone. An increase in supply air velocity improves air diffusion during both heating and cooling. Also, a terminal velocity of about 0.75 m/s is found at the same distance from the floor during both heating and cooling. Therefore, outlets should be selected from the data given in the section on Principles of Jet Behavior, with throw based on a terminal velocity of 0.75 m/s.

With outlets installed near the exposed wall, the primary air is drawn toward the wall, resulting in a wall effect similar to the ceiling effect for ceiling outlets. This scrubbing of the wall increases

heat gain or loss. To reduce scrubbing, outlets should be installed some distance from the wall, or the supply air should be deflected at an angle away from the wall. However, to prevent the air from dropping into the occupied zone before it reaches maximum projection the distance should not be too large nor the angle too wide. A distance of 150 mm and an angle of 15° is satisfactory.

These outlets do not counteract natural convection currents unless sufficient outlets are installed around the perimeter of the space — preferably in locations of greatest heat gain or loss (under windows). The effect of drapes and blinds must be considered with outlets installed near windows. If installed correctly, outlets of this type handle large airflow rates with uniform air motion and temperatures.

### Group C Outlets

These outlets can be used for heating, even with severe heat load conditions. Higher supply velocities produce better room air diffusion than lower velocities, but velocity is not critical in selecting these units for heating.

To achieve the required projection for cooling, the outlets should be used with temperature differentials of less than 8 K. With higher temperature differentials, supply air velocity is not sufficient to project the total air up to the desired level.

The outlets have been used successfully for residential heating, but they may also offer a solution for applications where heating requirements are severe and cooling requirements are moderate. For throw, refer to the section on Principles of Jet Behavior.

### Group D Outlets

These outlets direct high-velocity total air into the occupied zone, and, therefore, are not recommended for comfort, particularly for summer cooling. For heating, outlet velocities should not be higher than 1.5 m/s, so that air velocities in the occupied zone will not be excessive. These outlets have been applied successfully to process installations where controlled air velocities are desired.

### Group E Outlets

The different throws shown in the heating and cooling diagrams for these outlets become critical in selecting and applying the outlets. Because the total air enters the occupied zone for both cooling and heating, outlets are used for either cooling or heating, but seldom for both.

During cooling, temperature differential, supply air velocity, and airflow rate have considerable influence on projection. Therefore, low values of each should be selected.

During heating, it is important to select the correct supply air velocity to project the warm air into the occupied zone. Temperature differential is also critical because a small temperature differential reduces variation of the throw during the cyclic fluctuation of the supply air temperature. Vane setting for deflection is as important here as it is for Group B and C outlets.

Investigations by Nevins and Ward (1968) and Miller and Nevins (1969) in full-scale interior test rooms indicate that air temperatures and velocities throughout a room cooled by a ventilating ceiling are a linear function of room load (heat load per unit area) and are not affected significantly by variations in ceiling type, total air temperature differential, or air volumetric flow rate. Higher room loading produces wider room air temperature variations and higher velocities, which decrease performance.

These studies also found no appreciable difference in the performance of air-diffusing ceilings and circular ceiling diffusers for lower room loads (65 W/m<sup>2</sup>). For higher room loads (250 W/m<sup>2</sup>), an air-diffusing ceiling system has only slightly larger vertical temperature variations and slightly lower room air velocities than a ceiling diffuser system.

When the ventilating ceiling is used at exterior exposures, the additional load at the perimeter must be considered. During heating operation, the designer must provide for the cold wall effect, as with any ceiling supply diffusion system. The sound generated by the air supply device must also be considered in total system analysis to ensure that room sound levels do not exceed the design criteria.

### RETURN AIR DESIGN FOR OPTIMUM PERFORMANCE

An HVAC system operating in the cooling mode performs best when generated heat is removed at its source rather than distributed throughout the conditioned space. Heat from solar and miscellaneous loads such as machinery and floor or desk-mounted lamps is difficult to remove at the source. However, return air flowing over ceiling-mounted lighting fixtures keeps most of that heat from being distributed into the conditioned space. In addition to increasing HVAC system efficiency, return air lighting fixtures improve light output and extend the life of the lamps. The manufacturers of fixtures, ceiling grids, and grilles give performance information (airflow rate, pressure drop, and heat removal rate) of their product. Ball et al. (1971) found that the heat removal performance of return air fixtures covers a narrow range.

With a suspended ceiling, low operating static pressure across the ceiling must be maintained. Failure to do so can result in return air being forced around the edges of the ceiling panels or, in some cases, through the ceiling panels. The result is often a soiled ceiling and a mechanical system that is choked for return air. To avoid this, the static pressure difference across the ceiling should be as low as possible. If necessary, slotted tees or grilles can be used with return air fixtures to obtain the specified pressure drop. A maximum pressure drop of 5 to 7.5 Pa is acceptable under most conditions.

At the typical air supply rates found in office interior zone spaces [usually less than  $7.5 \text{ L}/(\text{s}\cdot\text{m}^2)$ ] and with adequate induction at the supply diffusers, the location of the return diffuser has no effect on air patterns in the space. For most office spaces, it is only necessary that sufficient return outlets be provided to maintain inlet velocities within recommendations (see Table 5).

In spaces expected to operate in a cooling mode most of the time, returning the warmest air in the space can effectively reduce energy costs and increase circulation in the space. This is especially true in climates where economizer systems operate for long periods during the year. In spaces having very high ceilings, with atriums, skylights, or large vertical glass surfaces, and where the highest areas are unoccupied, air stratification may be used as an energy-saving measure by locating returns near the occupied zone.

### CEILING-MOUNTED AIR DIFFUSER SYSTEMS

For the best thermal comfort conditions and highest ventilation effectiveness in an occupied space (i.e., office or retail store), the entire system performance of air diffusers should be considered. This is particularly true for open spaces, where airstreams from diffusers may interact with each other, and for perimeter spaces, where airstreams from diffusers interact with hot or cold perimeter walls. While throw data for individual diffusers are used in system design, an air diffuser system should maintain a high quality of air diffusion in the occupied space with low temperature variation, good air mixing, and no objectionable drafts in the occupied space (typically 150 mm to 1.8 m above the floor).

Adequate ventilation requires that the selected diffusers effectively mix (by entrainment) the total air in the room with the supplied conditioned air, which is assumed to contain adequate ventilation air.

### Interior Spaces

An interior space is conditioned exclusively for cooling loads, except after unoccupied periods when the space may have cooled to below a comfortable temperature. Tests by Miller and Nevins (1970), Miller and Nash (1971), Miller (1979), and Hart and Int-Hout (1981) suggest that the air diffusion performance index (ADPI) can be improved by moving diffusers closer together (i.e., specifying more diffusers for a given space and air quantity) and by limiting the value of the supply air/room air temperature difference. In a given system of diffusers, these studies found an optimum operating range of air volumetric flow rates at a given thermal load. The operating load varies with diffuser design, ceiling height, thermal load, and diffuser orientation. This information can be obtained by constructing a mock-up representing the proposed building space, with several alternatives tested for ADPI values, in accordance with ASHRAE *Standard* 113. Usually, the diffuser manufacturer has performed these tests and can provide the best choice of design options for a particular building. For a VAV system, the diffuser spacing selection should not be based on maximum or design air volumes but rather on the air volume range in which the system is expected to operate most of the time. For VAV applications, Miller (1979) recommends that the designer consider the expected variation in the outlet air volume to ensure that ADPI values remain above a specified minimum.

### Perimeter Spaces

All-air mechanical systems that handle both heating and cooling thermal loads are commonly used in modern office buildings instead of baseboards for heating and forced air for cooling. State energy codes (most based on ASHRAE *Standard* 90 series) require that commercial buildings have exterior walls that meet minimum thermal performance criteria for a particular location. Typically, walls of new buildings have design heat losses as low as 200 to 300 W per linear metre of wall.

A successful all-air heating/cooling mechanical system requires the designer to consider several design variables that have been the subject of research by Hart and Int-Hout (1980), Lorch and Straub (1983), and Rousseau (1983). The most important design variables include

- Supply air/room air temperature difference
- Diffuser type and design
- Design heating and cooling loads
- Supply air volumetric flow rates
- Distance between diffusers and perimeter wall
- Direction of air throw (toward wall, away from wall, or both)
- Ceiling height
- Desired air diffusion performance criteria

The diffuser manufacturer is best able to recommend the use of equipment.

For an office environment in cooling mode, the design goal should be an ADPI greater than 80. The ADPI *should not* be used as a measure of performance for heating conditions. In both cases, ASHRAE *Standard* 55 recommends that the maximum temperature gradient (the difference in temperature between any two points) should not exceed 3 K.

Linear diffusers placed parallel to the perimeter wall perform well. For year-round operation, linear diffusers with two-way throw (i.e., both toward and away from the perimeter wall) work best. Lorch and Straub (1983) reported optimum performance with a diffuser that throws warm air toward the perimeter wall under heating load conditions and chilled air in both directions under cooling load conditions. All researchers found less than optimum performance with high discharge temperatures (greater than 8 K above ambient), both with one-way throw of air away from a cold wall and with one-way throw of chilled air toward the perimeter wall. Under heating

load conditions, the supply air temperature must be limited to avoid excessive thermal stratification.

To resolve any uncertainty about performance, a mockup should be constructed with provisions for a cold wall; several variations of the design should be tested so that the best diffuser wall spacing and supply air volumes can be selected. The ADPI, room temperature gradients, or both, measured in accordance with ASHRAE *Standard* 113, can help gage system performance.

The following principles provide the best air diffusion quality and minimum energy use:

- For cooling load conditions, return air should exhaust from a location that takes advantage of any thermal stratification design. In many cases, this should be a high point in order to take advantage of rising warm air. Cooling supply air should be introduced as close to the heat sources as possible. Alternately, stratification designs may condition only part of the total space. In these cases, conditioned air is supplied and exhausted as close to the occupants as possible. In either case, comfort zone temperature gradients should be maintained within 3 K.
- For heating load conditions, thermal stratification should be discouraged. Heat should be introduced at points low in the large space. Ceiling-mounted fans may reduce stratification.

**T**HE APPLICATION of computational fluid dynamics (CFD) to room air motion, as summarized by Haghighat et al. (1992), began with investigations into room air flow (Neilsen 1974) and natural convection in enclosed cavities (Catton 1978, Ostrach 1982, Markatos and Pericleous 1984, Lin and Nansteel 1987, Hadjisophocleous et al. 1988, Gadgil et al. 1984, Chen et al. 1990b). Lemaire (1987) applied the CHAMPHxN code (Pun and Spalding 1976) coupled with radiation to predict air movement and heat transfer in a room heated by a radiator.

Convective heat and mass transfer has been analyzed using a commercial code by Holmes (1982), Markatos (1983), Jones and Sullivan (1985), and Chen and Van der Kooi (1988). Murakami et al. (1988), Horstman (1988), and Chen et al. (1990a) developed numerical models of ventilation with contaminant transport.

Partitioned models (multiple zones) have also been developed to predict room air motion. Natural convection was investigated by Chang et al. (1982) and Kelkar and Patankar (1985). Contaminant transport models were used in the ventilation models of Haghighat et al. (1989, 1990).

### Theory

The basis for ventilation computational fluid dynamics analyses are the incompressible Navier-Stokes equations. These equations describe the motion of a viscous Newtonian fluid. For example, the following represent these equations in two dimensions:

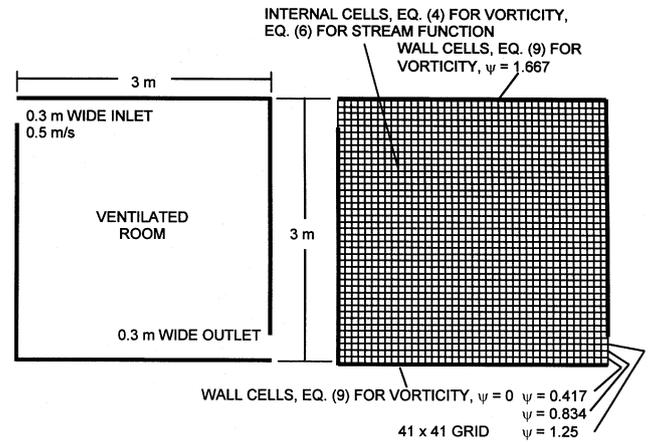

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = \frac{1}{\rho} X - \frac{1}{\rho} \frac{\partial p}{\partial x} + \nu \left( \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \right) \quad (1)$$

$$\frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} = \frac{1}{\rho} X - \frac{1}{\rho} \frac{\partial p}{\partial y} + \nu \left( \frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} \right) \quad (2)$$

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \quad (3)$$

Because these equations are complex, only a few exact solutions have been obtained for very simple flow conditions. The typical ventilation system is well beyond the realm of an exact solution. Forms of the Navier-Stokes equations have been developed using numerical methods that divide the flow field into finite volumes or elements. The elements typically assume uniform properties throughout and exchange pressure, momentum, and viscous dissipation information with one another.

The solution is obtained iteratively either by time step or by a steady flow updating of each element. The new value of pressure or velocity of an element at each iteration may be incorporated into the overall solution gradually using relaxation methods, which help sta-

**Fig. 1 Example Two-Dimensional Model**

bilize the solution, giving time for information to travel between the elements and allowing each to assert its influence on the entire flow field. An example of this method is the finite difference approximation of the **stream function-vorticity formulation** of the Navier-Stokes equations in two dimensions:

**Example.** A two-dimensional model of a ventilated room (Figure 1) is modeled using the stream function-vorticity formulation of the Navier-Stokes equations. The room is 3 m by 3 m. Air enters at 0.5 m/s through a 0.3 m wide opening on the left wall near the ceiling and leaves through a 0.3 m wide opening near the floor. The grid representing the room consists of 41 × 41 elements.

### Solution:

The stream function-vorticity formulation of the Navier-Stokes equations begins with the **vorticity transport** equation:

$$u \frac{\partial \omega}{\partial x} + v \frac{\partial \omega}{\partial y} = \nu \left( \frac{\partial^2 \omega}{\partial x^2} + \frac{\partial^2 \omega}{\partial y^2} \right) \quad (4)$$

The **stream function** is related to the velocity:

$$u = \frac{\partial \Psi}{\partial y}, \quad v = -\frac{\partial \Psi}{\partial x} \quad (5)$$

Vorticity is analogous to rotation of the fluid:

$$\omega = \left( \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \right) = -\nabla^2 \Psi \quad (6)$$

Most CFD models have some sort of turbulence model to account for eddy viscosity when the Reynolds number exceeds about 2000. The simplest of the turbulence models uses the Prandtl mixing length:

$$v_t = \kappa L C_\mu^{1/4} K^{1/2} \quad (7)$$

The preparation of this chapter is assigned to TC 4.10, Indoor Environmental Modeling.

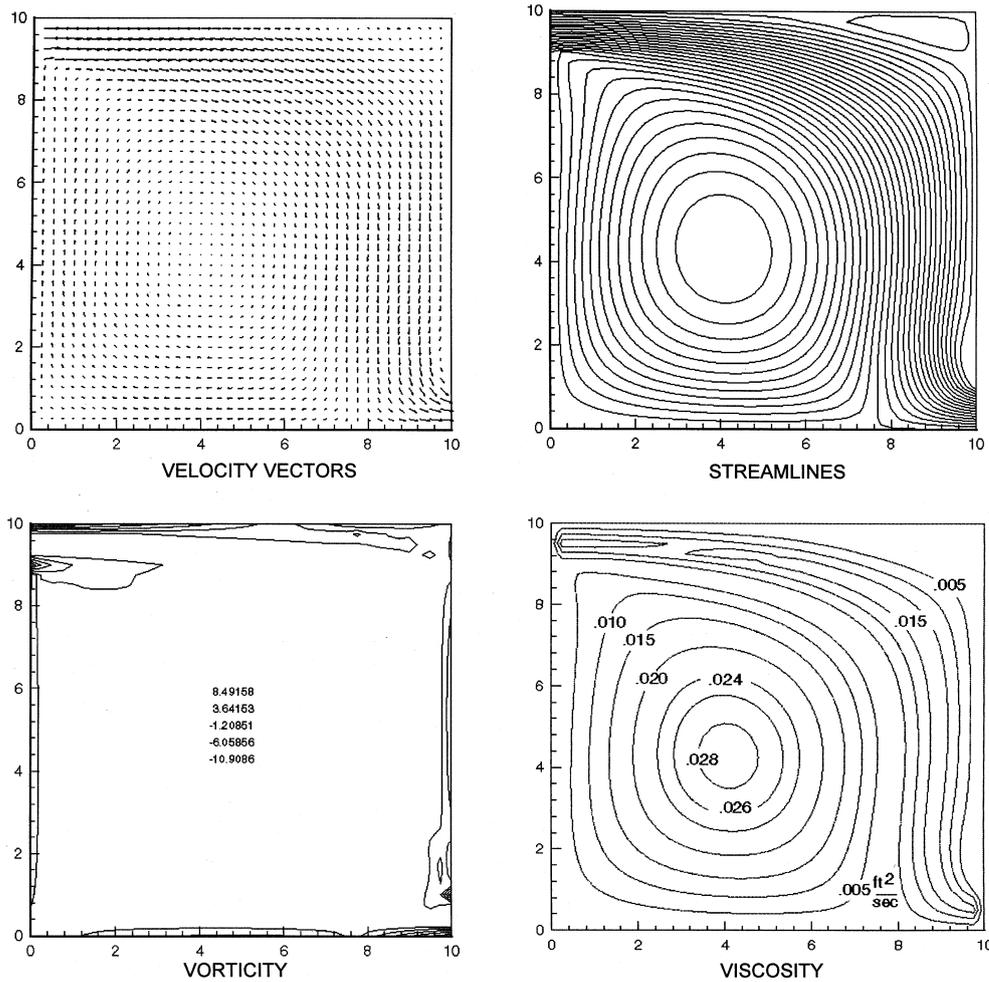

Fig. 2 Stream Function-Vorticity Solution for Ventilated Room (50 000 Iterations)

In recirculating flows, the length to the wall is difficult to measure and is flow-dependent. Equation (5) defines the length scale by the position of streamlines relative to the two boundary values of the stream function:

$$L = \left| \frac{\Psi}{V} \right| \quad \text{or} \quad L = \frac{|\Psi - \Psi_B|}{|V|} \quad \text{whichever is smaller} \quad (8)$$

The turbulent kinetic energy  $K$  is a function of  $V'$ , the magnitude of the fluctuating component of the velocity due to turbulence.  $V'$  can be assumed to be about 10% of  $V$ , the local average velocity, for typical room air models:

$$K = \frac{3}{2}(V')^2 = \frac{3}{2}(0.1V)^2 \quad (9)$$

Equations (7), (8), and (9) are combined to give a simple turbulence model based on the stream function alone:

$$v_t = \kappa |\Psi| C_\mu^{1/4} \sqrt{\frac{3}{2}} (0.1)$$

$$\text{or } v_t = \kappa |\Psi - \Psi_B| C_\mu^{1/4} \sqrt{\frac{3}{2}} (0.1) \quad \text{whichever is smaller} \quad (10)$$

Finite difference equations of the following form are used to approximate Equations (4) and (6):

$$\frac{\partial f}{\partial s} \approx \frac{f_{n+1} - f_{n-1}}{2\Delta s} \quad (11)$$

$$\frac{\partial^2 f}{\partial s^2} \approx \frac{f_{n+1} - 2f_n + f_{n-1}}{\Delta s^2} \quad (12)$$

The equations are rearranged so that the current value of the center cell or element is based on that of the surrounding cells. In addition, the vorticity transport Equation (4) is expanded for second-order accuracy as done by Dennis and Hudson (1978):

$$\omega_{i,j} = \frac{\left(1 - \frac{\Delta x u_{i+1,j}}{2v_{i,j}} + \frac{\Delta x^2 u_{i+1,j}^2}{8v_{i,j}^2}\right)\omega_{i+1,j} + \left(1 + \frac{\Delta x u_{i-1,j}}{2v_{i,j}} + \frac{\Delta x^2 u_{i-1,j}^2}{8v_{i,j}^2}\right)\omega_{i-1,j} + \dots + \left(1 - \frac{\Delta x v_{i,j+1}}{2v_{i,j}} + \frac{\Delta x^2 v_{i,j+1}^2}{8v_{i,j}^2}\right)\omega_{i,j+1} + \left(1 + \frac{\Delta x v_{i,j-1}}{2v_{i,j}} + \frac{\Delta x^2 v_{i,j-1}^2}{8v_{i,j}^2}\right)\omega_{i,j-1}}{\left(4 + \frac{\Delta x^2 (u_{i,j}^2 + v_{i,j}^2)}{4v_{i,j}^2}\right)} \quad (13)$$

$$\Psi_{i,j} = \frac{\Psi_{i+1,j} + \Psi_{i-1,j} + \Psi_{i,j+1} + \Psi_{i,j-1} + \Delta x^2 \omega_{i,j}}{4} \quad (14)$$

The subscripted velocities shown in Equation (13) are obtained from Equation (5) in the form of Equation (11). For example, the  $v$  velocity at location  $i, j - 1$  is

$$v_{i,j-1} = \frac{(\Psi_{i+1,j-1}) - (\Psi_{i-1,j-1})}{2\Delta x}$$

or

$$v_{i,j} = \frac{(\Psi_{i+1,j}) - (\Psi_{i-1,j})}{2\Delta x} \quad (15)$$

Boundary conditions for vorticity are defined by the apparent rotation rate of the nearby fluid passing by:

$$\omega_{i,j}(\text{wall}) = \frac{\Psi_{adj} - \Psi_{i,j}(\text{wall})}{\Delta x^2} \quad (16)$$

Relaxation parameters are applied to the vorticity and to the viscosity. The parameter  $\delta$  for the vorticity is typically equal to 0.03, so that 3% of the new value and 97% of the old value is used. The viscosity is unstable, so a smaller relaxation parameter is required; 0.01 was used in this example. To illustrate this procedure, a new value of vorticity is calculated using Equation (13) or (16) (depending on the node type). The current value of vorticity is obtained by adding most of the old value to a fraction of the new value:

$$\omega_{i,j}(\text{current}) = \delta\omega_{i,j}(\text{new}) + (1 - \delta)\omega_{i,j}(\text{old}) \quad (17)$$

The inlets and outlets have a fixed, uniform velocity. The stream function is set at each of the three nodes between the walls. Since the wall below the inlet has  $\psi = 0$  and the wall above has  $\psi = 1.667$ , the stream function is divided evenly between the inlet nodes:  $\psi_{1,38} = 0.25(1.667) = 0.417$ ;  $\psi_{1,39} = 0.5(1.667) = 0.834$ ;  $\psi_{1,40} = 0.75(1.667) = 1.25$ . The same distribution is applied to the outlet nodes as shown in Figure 1. In a real room, the velocity would not be uniform across the outlet, but for an illustrative example, this simplification is appropriate.

The results of this analysis method are shown in Figure 2.

These results show the overall flow pattern of the room. Ventilation air travels along the ceiling, then attaches to the right wall before exiting. This generates a clockwise rotational flow where the eddy viscosity approaches two hundred times the molecular viscosity. At this point, the engineer would make a finer grid and run the model again to see if the solution has reached grid independence.

### Finite Volume Formulations

Commercially available CFD programs are generally used to solve specific applications. Code development requires frequent validation and benchmarking and is best done by companies that specialize in that task. Most commercially available codes are based on finite volume formulations such as the SIMPLE algorithm (Patankar 1988). The finite volume method is distinguished from the finite element method in that the properties and flow conditions of the fluid are assumed uniform throughout the elemental volume and the exchange of momentum, energy, and pressure occurs at the faces.

### Finite Element Formulations

Less common than the finite volume formulations, finite element formulations are usually available when the flow solver is packaged commercially with a stress analysis code. The finite element method may be differentiated from the finite volume method in the way the properties and flow conditions are point values and information travels between nodes, through the elements (Baker 1983). Until recently, the finite element method had the advantage of geometry adaptability.

### Preprocessors

The first step in the CFD process is building the grid that mathematically represents the physical model. The preprocessor constructs the grid from such data as room dimensions, diffuser and duct dimensions, and internal features such as furniture or partitions

that may affect flow. The preprocessor usually includes a computer aided design (CAD) package to allow the analyst to construct the required geometry. A good preprocessor usually includes a translator to other CAD packages so that geometry data is interchangeable.

The grid has an exact correspondence to the geometry; open areas, walls, diffusers, etc., are represented by the elements or volumes of computational fluid, boundaries, and blocked elements. The grid may be structured, where the element index or location is described by coordinates of  $i(x)$ ,  $j(y)$ , and  $k(z)$ . Or, the grid may be unstructured, in which the elements are arbitrarily arranged and defined by associative identification.

### Post Processors

After the flow solver has converged on the solution, the data is presented through the post processor. The typical post processor displays contour diagrams of equation variables such as pressure, temperature, velocity, turbulence, and contaminant concentration. Post processors are available that provide elaborate three-dimensional contour and vector plots with color scaling and animated output for time-dependent solutions.

### Energy Equation

When the CFD application involves the exchange of heat, the energy equation is used. The energy equation is similar in structure to the Navier-Stokes equation:

$$\rho c \left( u \frac{\partial T}{\partial x} + v \frac{\partial T}{\partial y} \right) = k \left( \frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} \right) \quad (18)$$

The energy equation accommodates several HVAC situations. For example, heat in a room may be lost or gained through walls, windows, heaters, air conditioners, or occupants. Natural convection may dominate the flow pattern during heating or cooling and affect the comfort of the occupants, causing drafts or reduced air change effectiveness.

The energy equation is also important in compressible flow (high velocity). When the Mach number exceeds 0.2, the effects of compressibility begin to appear. The fluid density and velocity are determined in part by the energy equation. The CFD applications that require these high velocities are usually components (valves, ducting, ejectors, etc.).

A special class of problems requires the solution of the **conduction equation** (Laplace's equation). This type of analysis is called **conjugate heat transfer**. An example would be a room with an insulated wall of known thermal conductivity, where the solver determines both the temperature profile across the wall and the flow in the room.

### Multispecies Flows

Often, a system with a mixture of gases must be evaluated. For example, a vent hood in a laboratory may be used to evacuate toxic gases from the room. A CFD model can provide an accurate assessment of the hood performance under a wide range of conditions and help to optimize the design for energy consumption.

If the concentration of the second gas is low, its viscous and momentum effects may be ignored. These types of problems may be solved using the single-species equation with the second species being convected along. The diffusion term is handled separately. If the concentration of the second gas is high enough to affect the properties of the mixture, such as density or viscosity, then the fully coupled form of the transport equations must be used.

Another class of multispecies flow problems involves the change of phase of one or more components. The humidity of a room with an evaporative water source would be an example of this.

Chemically reacting flows are often analyzed with CFD. Combustion models have been used extensively. These flows are complicated by the interaction of the various species, the phase changes, and the changes in properties and heat of formation of the combustion products.

### Viscosity Models

In the classical Navier-Stokes equations, the viscosity is assumed constant. For low Reynolds numbers (i.e.,  $Re < 2500$ ), the laminar form is used. When higher Reynolds numbers are encountered, a means to adjust the viscosity (the **eddy viscosity**) is required. These types of equations are frequently called **turbulence models** because the basis for eddy viscosity is the turbulence level. Several turbulence models are available, but the most accepted and benchmarked model is the  $k$ - $\epsilon$  model. Chen (1995) provides some background for the  $k$ - $\epsilon$  application to room airflow. The standard  $k$ - $\epsilon$  model is a two-equation model. The first equation describes the turbulent kinetic energy transport and generation rate:

$$\begin{aligned} \rho u \frac{\partial k}{\partial x} + \rho v \frac{\partial k}{\partial y} &= \frac{\partial}{\partial x} \left[ \left( \mu + \frac{\mu_t}{\sigma_k} \right) \frac{\partial k}{\partial x} \right] + \frac{\partial}{\partial y} \left[ \left( \mu + \frac{\mu_t}{\sigma_k} \right) \frac{\partial k}{\partial y} \right] \\ &+ \mu_t \left[ 2 \left( \frac{\partial u}{\partial x} \right)^2 + 2 \left( \frac{\partial v}{\partial y} \right)^2 + \left( \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right)^2 \right] \\ &- \rho \epsilon - 2\mu \left[ \left( \frac{\partial \sqrt{k}}{\partial x} \right)^2 + \left( \frac{\partial \sqrt{k}}{\partial y} \right)^2 \right] \end{aligned} \quad (19)$$

Turbulent kinetic energy [Equation (9)] represents the fluctuating component of velocity.

The second equation in the  $k$ - $\epsilon$  model is the dissipation rate:

$$\begin{aligned} \rho u \frac{\partial \epsilon}{\partial x} + \rho v \frac{\partial \epsilon}{\partial y} &= \frac{\partial}{\partial x} \left[ \left( \mu + \frac{\mu_t}{\sigma_\epsilon} \right) \frac{\partial \epsilon}{\partial x} \right] + \frac{\partial}{\partial y} \left[ \left( \mu + \frac{\mu_t}{\sigma_\epsilon} \right) \frac{\partial \epsilon}{\partial y} \right] \\ &+ C_{\epsilon 1} \mu_t \frac{\epsilon}{k} \left[ 2 \left( \frac{\partial u}{\partial x} \right)^2 + 2 \left( \frac{\partial v}{\partial y} \right)^2 + \left( \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right)^2 \right] \\ &- C_{\epsilon 2} f_2 \rho \frac{\epsilon^2}{k} + E \end{aligned} \quad (20)$$

where

$$E \equiv 2 \frac{\mu_t}{\rho} \left[ \left( \frac{\partial^2 u}{\partial x^2} \right)^2 + \left( \frac{\partial^2 v}{\partial x^2} \right)^2 \right]$$

Equation (20) is solved in conjunction with the Equation (19) to obtain the local eddy viscosity:

$$\mu_t = C_{\mu f} \mu \rho \frac{k^2}{\epsilon} \quad (21)$$

This two-equation model has a counterpart for high Reynolds number flows, but most room air motion studies use a lower Reynolds number model.

The near wall conditions for the turbulence model are often defined with wall functions that are based on the classical turbulent boundary layer. They may have two layers (the laminar sublayer and the turbulent layer) or they may have three layers (a laminar sublayer, a buffer layer, and a fully turbulent outer layer). The two-layer wall function is shown as follows:

$$\frac{u}{u_\tau} = y^+ \quad \text{for} \quad 0 < y^+ \leq 30 \quad (22)$$

$$\frac{u}{u_\tau} = \frac{1}{\kappa} \ln(Ey^+) \quad \text{for} \quad 30 < y^+ \leq 300 \quad (23)$$

where

$$y^+ = \frac{\rho u_\tau y}{\mu}$$

and

$$\mu \left. \frac{\partial u}{\partial y} \right|_{\text{wall}} = \tau_w = \rho u_\tau^2 \quad (24)$$

**Direct numerical simulation (DNS)** is an active area of study of turbulence modeling. The basis for DNS turbulence modeling is that there is actually no turbulence model at all. Rather, the motion of the individual eddies within the bulk flow are modeled themselves. This model requires an extremely small grid size in which an eddy cannot exist due to molecular viscosity. Due to the huge demand on computing resources; only small flow fields, about shoe box size at the most, have been simulated using DNS.

Since DNS is really not yet practical for room air simulations, a compromise between it and conventional turbulence models has been developed. This method, **large eddy simulation (LES)**, uses an eddy viscosity for the subgrid scale turbulence, but fully captures the time-dependent behavior of the larger energy bearing eddies. The application to room airflow is just beginning (Emmerich and McGrattan 1998).

### CFD Applications

Currently, CFD has been applied to room air motion. The room might represent an auditorium, an aircraft cabin, or an automobile interior. Useful parameters such as velocity and temperature distribution, air change effectiveness, and humidity are predicted for the comfort of the occupant.

External flow models have used CFD to predict building infiltration, heat transfer rates for heating and cooling loads, and wind loads for structural design.

Finally, CFD is a useful tool for other internal flows, especially when nonstandard components are analyzed. Complex manifolds can be flow-balanced in one step, and important data such as pressure drop, aero/hydrodynamic loads, and heat transfer rates are available with the currently obtainable tools.

### SYMBOLS

- $adj$  = subscript denoting adjacent node
- $c$  = specific heat, J/(kg·K) based on units of  $p$
- $C_{\epsilon 1}$  = constant = 1.45
- $C_{\epsilon 2}$  = constant = 1.92
- $C_\mu$  = constant = 0.09
- $f$  = field variable such as velocity
- $f_2$  = coefficient =  $1 - 0.3 \exp(-Re_f^2)$ , where  $Re_f$  is local Reynolds number =  $\rho K^2 / \mu \epsilon$
- $f_\mu$  = coefficient =  $\exp[-3.4 / (1 + Re_f / 50)^2]$
- $i$  = subscript index in  $x$  direction
- $j$  = subscript index in  $y$  direction
- $k$  = thermal conductivity, W/(m·K)
- $K$  = kinetic energy of turbulence,  $m^2/s^2$
- $L$  = turbulence length scale, m
- $n$  = general subscript index
- $P$  = pressure, Pa
- $s$  = distance, m
- $T$  = temperature, K
- $u$  = fluid velocity in  $x$  direction, m/s
- $u_\tau$  = friction velocity, m/s
- $v$  = fluid velocity in  $y$  direction, m/s
- $V$  = local velocity magnitude, m/s
- $V'$  = turbulent velocity fluctuation, m/s
- $x$  = horizontal distance, m
- $\Delta x$  = node spacing, m
- $y$  = vertical distance, m

$y^+$  = distance from wall in the universal velocity profile, m  
 $t$  = time, s  
 $\delta$  = relaxation parameter  
 $\epsilon$  = dissipation,  $\text{m}^2/\text{s}^3$   
 $\kappa$  = von Karman constant = 0.41  
 $\mu$  = dynamic viscosity,  $\text{kg}/(\text{m}\cdot\text{s})$   
 $\mu_e$  = effective viscosity,  $\text{kg}/(\text{m}\cdot\text{s})$   
 $\nu$  = kinematic viscosity,  $\text{m}^2/\text{s}$   
 $\nu_e$  = effective viscosity,  $\text{m}^2/\text{s}$   
 $\rho$  = density,  $\text{kg}/\text{m}^3$   
 $\sigma_k$  = constant = 1.0  
 $\sigma_\epsilon$  = constant = 1.3  
 $\psi$  = stream function,  $\text{m}^2/\text{s}$   
 $\psi_B$  = boundary stream function,  $\text{m}^2/\text{s}$   
 $\omega$  = vorticity,  $1/\text{s}$

--	---

**C**OMMERCIAL, industrial, and residential air duct system design must consider (1) space availability, (2) space air diffusion, (3) noise levels, (4) duct leakage, (5) duct heat gains and losses, (6) balancing, (7) fire and smoke control, (8) initial investment cost, and (9) system operating cost.

Deficiencies in duct design can result in systems that operate incorrectly or are expensive to own and operate. Poor air distribution can cause discomfort, loss of productivity and even adverse health effects; lack of sound attenuators may permit objectionable noise levels. Poorly designed ductwork can result in unbalanced systems. Faulty duct construction or lack of duct sealing produces inadequate airflow rates at the terminals. Proper duct insulation eliminates the problem caused by excessive heat gain or loss.

In this chapter, system design and the calculation of a system's frictional and dynamic resistance to airflow are considered. Chapter 16 of the 2000 *ASHRAE Handbook—Systems and Equipment* examines duct construction and presents construction standards for residential, commercial, and industrial heating, ventilating, air-conditioning, and exhaust systems.

### BERNOULLI EQUATION

The Bernoulli equation can be developed by equating the forces on an element of a stream tube in a frictionless fluid flow to the rate of momentum change. On integrating this relationship for steady flow, the following expression (Osborne 1966) results:

$$\frac{v^2}{2} + \int \frac{dP}{\rho} + gz = \text{constant, N} \cdot \text{m/kg} \quad (1)$$

where

- $v$  = streamline (local) velocity, m/s
- $P$  = absolute pressure, Pa (N/m<sup>2</sup>)
- $\rho$  = density, kg/m<sup>3</sup>
- $g$  = acceleration due to gravity, m/s<sup>2</sup>
- $z$  = elevation, m

Assuming constant fluid density within the system, Equation (1) reduces to

$$\frac{v^2}{2} + \frac{P}{\rho} + gz = \text{constant, N} \cdot \text{m/kg} \quad (2)$$

Although Equation (2) was derived for steady, ideal frictionless flow along a stream tube, it can be extended to analyze flow through ducts in real systems. In terms of pressure, the relationship for fluid resistance between two sections is

$$\frac{\rho_1 V_1^2}{2} + P_1 + g\rho_1 z_1 = \frac{\rho_2 V_2^2}{2} + P_2 + g\rho_2 z_2 + \Delta p_{t,1-2} \quad (3)$$

where

$V$  = average duct velocity, m/s

$\Delta p_{t,1-2}$  = total pressure loss due to friction and dynamic losses between sections 1 and 2, Pa

In Equation (3),  $V$  (section average velocity) replaces  $v$  (streamline velocity) because experimentally determined loss coefficients allow for errors in calculating  $\rho v^2/2$  (velocity pressure) across streamlines.

On the left side of Equation (3), add and subtract  $p_{z1}$ ; on the right side, add and subtract  $p_{z2}$ , where  $p_{z1}$  and  $p_{z2}$  are the values of atmospheric air at heights  $z_1$  and  $z_2$ . Thus,

$$\begin{aligned} & \frac{\rho_1 V_1^2}{2} + P_1 + (p_{z1} - p_{z1}) + g\rho_1 z_1 \\ &= \frac{\rho_2 V_2^2}{2} + P_2 + (p_{z2} - p_{z2}) + g\rho_2 z_2 + \Delta p_{t,1-2} \end{aligned} \quad (4)$$

The atmospheric pressure at any elevation ( $p_{z1}$  and  $p_{z2}$ ) expressed in terms of the atmospheric pressure  $p_a$  at the same datum elevation is given by

$$p_{z1} = p_a - g\rho_a z_1 \quad (5)$$

$$p_{z2} = p_a - g\rho_a z_2 \quad (6)$$

Substituting Equations (5) and (6) into Equation (4) and simplifying yields the total pressure change between sections 1 and 2. Assume no change in temperature between sections 1 and 2 (no heat exchanger within the section); therefore,  $\rho_1 = \rho_2$ . When a heat exchanger is located within the section, the average of the inlet and outlet temperatures is generally used. Let  $\rho = \rho_1 = \rho_2$ ,  $(P_1 - p_{z1})$  and  $(P_2 - p_{z2})$  are gage pressures at elevations  $z_1$  and  $z_2$ .

$$\begin{aligned} \Delta p_{t,1-2} &= \left( p_{s,1} + \frac{\rho V_1^2}{2} \right) - \left( p_{s,2} + \frac{\rho V_2^2}{2} \right) \\ &+ g(\rho_a - \rho)(z_2 - z_1) \end{aligned} \quad (7a)$$

$$\Delta p_{t,1-2} = \Delta p_t + \Delta p_{se} \quad (7b)$$

The preparation of this chapter is assigned to TC 5.2, Duct Design.

$$\Delta p_t = \Delta p_{t,1-2} - \Delta p_{se} \quad (7c)$$

where

- $p_{s,1}$  = static pressure, gage at elevation  $z_1$ , Pa
- $p_{s,2}$  = static pressure, gage at elevation  $z_2$ , Pa
- $V_1$  = average velocity at section 1, m/s
- $V_2$  = average velocity at section 2, m/s
- $\rho_a$  = density of ambient air, kg/m<sup>3</sup>
- $\rho$  = density of air or gas within duct, kg/m<sup>3</sup>
- $\Delta p_{se}$  = thermal gravity effect, Pa
- $\Delta p_t$  = total pressure change between sections 1 and 2, Pa
- $\Delta p_{t,1-2}$  = total pressure loss due to friction and dynamic losses between sections 1 and 2, Pa

### HEAD AND PRESSURE

The terms **head** and **pressure** are often used interchangeably; however, head is the height of a fluid column supported by fluid flow, while pressure is the normal force per unit area. For liquids, it is convenient to measure the head in terms of the flowing fluid. With a gas or air, however, it is customary to measure pressure on a column of liquid.

#### Static Pressure

The term  $p/\rho g$  is static head;  $p$  is static pressure.

#### Velocity Pressure

The term  $V^2/2g$  refers to velocity head, and the term  $\rho V^2/2$  refers to velocity pressure. Although velocity head is independent of fluid density, velocity pressure, calculated by Equation (8), is not.

$$p_v = \rho V^2/2 \quad (8)$$

where

- $p_v$  = velocity pressure, Pa
- $V$  = fluid mean velocity, m/s

For air at standard conditions (1.204 kg/m<sup>3</sup>), Equation (8) becomes

$$p_v = 0.602V^2 \quad (9)$$

Velocity is calculated by Equation (10) or (11).

$$V = 1000Q/A \quad (10)$$

where

- $Q$  = airflow rate, L/s
- $A$  = cross-sectional area of duct, mm<sup>2</sup>

$$V = 0.001Q/A \quad (11)$$

where  $A$  = cross-sectional area of duct, m<sup>2</sup>.

#### Total Pressure

Total pressure is the sum of static pressure and velocity pressure:

$$p_t = p_s + \rho V^2/2 \quad (12)$$

or

$$p_t = p_s + p_v \quad (13)$$

where

- $p_t$  = total pressure, Pa
- $p_s$  = static pressure, Pa

### Pressure Measurement

The range, precision, and limitations of instruments for measuring pressure and velocity are discussed in Chapter 14. The manometer is a simple and useful means for measuring partial vacuum and low pressure. Static, velocity, and total pressures in a duct system relative to atmospheric pressure are measured with a pitot tube connected to a manometer. Pitot tube construction and locations for traversing round and rectangular ducts are presented in Chapter 14.

### SYSTEM ANALYSIS

The total pressure change due to friction, fittings, equipment, and net **thermal gravity effect (stack effect)** for each section of a duct system is calculated by the following equation:

$$\Delta p_{t_i} = \Delta p_{f_i} + \sum_{j=1}^m \Delta p_{ij} + \sum_{k=1}^n \Delta p_{ik} - \sum_{r=1}^{\lambda} \Delta p_{se_{ir}} \quad (14)$$

$$\text{for } i = 1, 2, \dots, n_{up} + n_{dn}$$

where

- $\Delta p_{t_i}$  = net total pressure change for  $i$ -section, Pa
- $\Delta p_{f_i}$  = pressure loss due to friction for  $i$ -section, Pa
- $\Delta p_{ij}$  = total pressure loss due to  $j$ -fittings, including fan system effect (FSE), for  $i$ -section, Pa
- $\Delta p_{ik}$  = pressure loss due to  $k$ -equipment for  $i$ -section, Pa
- $\Delta p_{se_{ir}}$  = thermal gravity effect due to  $r$ -stacks for  $i$ -section, Pa
- $m$  = number of fittings within  $i$ -section
- $n$  = number of equipment within  $i$ -section
- $\lambda$  = number of stacks within  $i$ -section
- $n_{up}$  = number of duct sections upstream of fan (exhaust/return air subsystems)
- $n_{dn}$  = number of duct sections downstream of fan (supply air subsystems)

From Equation (7), the thermal gravity effect for each nonhorizontal duct with a density other than that of ambient air is determined by the following equation:

$$\Delta p_{se} = 9.81(\rho_a - \rho)(z_2 - z_1) \quad (15)$$

where

- $\Delta p_{se}$  = thermal gravity effect, Pa
- $z_1$  and  $z_2$  = elevation from datum in direction of airflow (Figure 1), m
- $\rho_a$  = density of ambient air, kg/m<sup>3</sup>
- $\rho$  = density of air or gas within duct, kg/m<sup>3</sup>

**Example 1.** For Figure 1, calculate the thermal gravity effect for two cases: (a) air cooled to  $-34^\circ\text{C}$ , and (b) air heated to  $540^\circ\text{C}$ . The density of air at  $-34^\circ\text{C}$  and  $540^\circ\text{C}$  is  $1.477 \text{ kg/m}^3$  and  $0.434 \text{ kg/m}^3$ , respectively. The density of the ambient air is  $1.204 \text{ kg/m}^3$ . Stack height is 15 m.

**Solution:**

$$\Delta p_{se} = 9.81(\rho_a - \rho)z$$

(a) For  $\rho > \rho_a$  (Figure 1A),

$$\begin{aligned} \Delta p_{se} &= 9.81(1.204 - 1.477)15 \\ &= -40 \text{ Pa} \end{aligned}$$

(b) For  $\rho < \rho_a$  (Figure 1B),

$$\begin{aligned} \Delta p_{se} &= 9.81(1.204 - 0.434)15 \\ &= +113 \text{ Pa} \end{aligned}$$

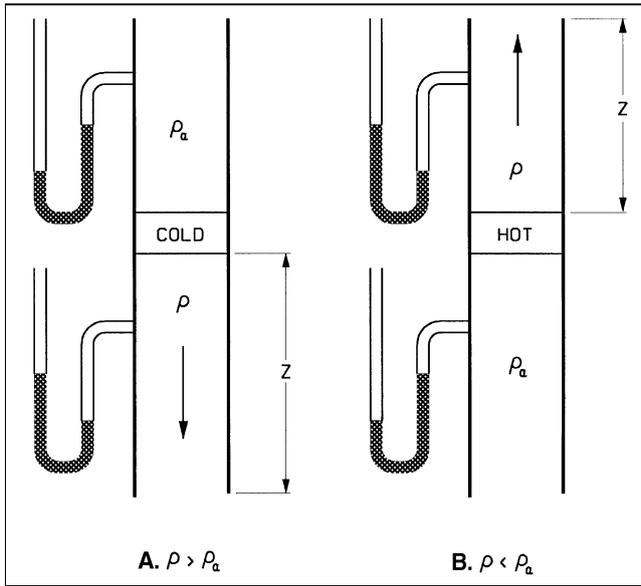

Fig. 1 Thermal Gravity Effect for Example 1

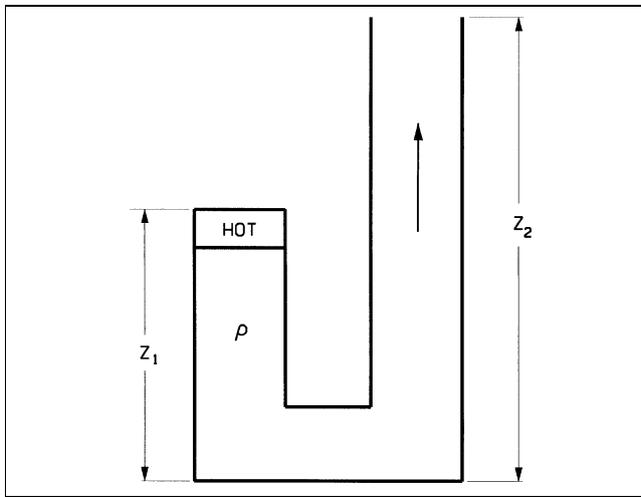

Fig. 2 Multiple Stacks for Example 2

**Example 2.** Calculate the thermal gravity effect for the two-stack system shown in Figure 2, where the air is 120°C and the stack heights are 15 and 30 m. The density of 120°C air is 0.898 kg/m<sup>3</sup>; ambient air is 1.204 kg/m<sup>3</sup>.

**Solution:**

$$\begin{aligned} \Delta p_{se} &= 9.81(\rho_a - \rho)(z_2 - z_1) \\ &= 9.81(1.204 - 0.898)(30 - 15) \\ &= 45 \text{ Pa} \end{aligned}$$

For the system shown in Figure 3, the direction of air movement created by the thermal gravity effect depends on the initiating force. The initiating force could be fans, wind, opening and closing doors, and turning equipment on and off. If for any reason air starts to enter the left stack (Figure 3A), it creates a buoyancy effect in the right stack. On the other hand, if flow starts to enter the right stack (Figure 3B), it creates a buoyancy effect in the left stack. In both cases the produced thermal gravity effect is stable and depends on the stack height and magnitude of heating. The starting direction of flow is important when using natural convection for ventilation.

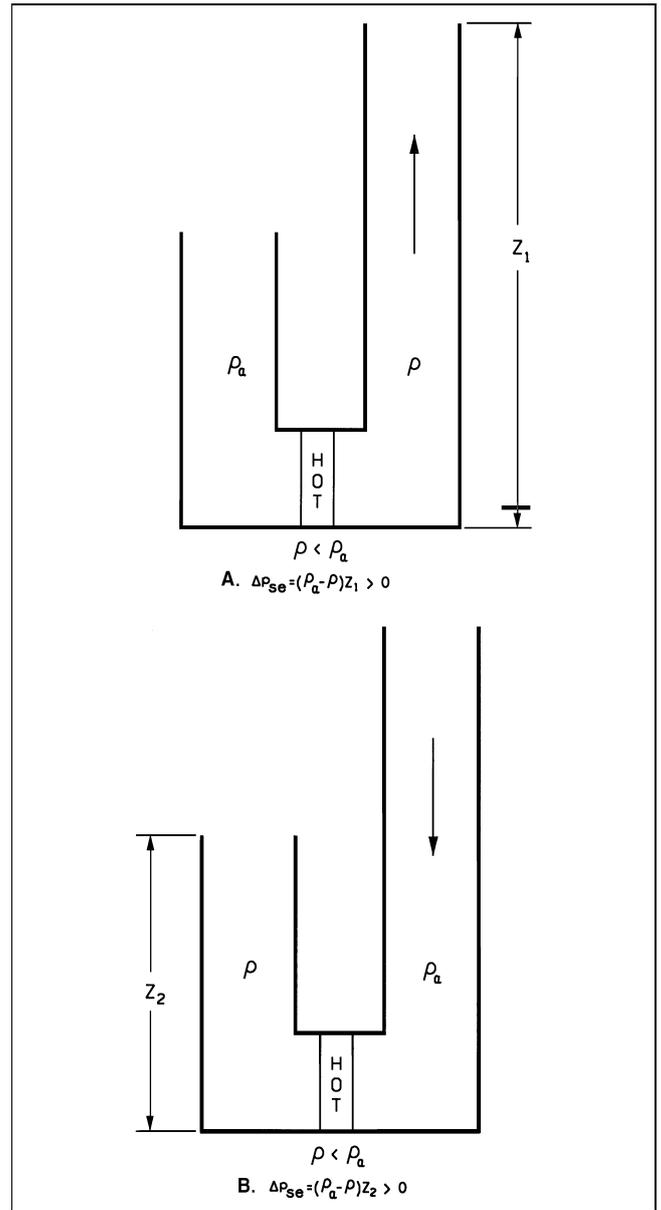

Fig. 3 Multiple Stack Analysis

To determine the fan total pressure requirement for a system, use the following equation:

$$P_t = \sum_{i \in F_{up}} \Delta p_{t_i} + \sum_{i \in F_{dn}} \Delta p_{t_i} \quad \text{for } i = 1, 2, \dots, n_{up} + n_{dn} \quad (16)$$

where

- $F_{up}$  and  $F_{dn}$  = sets of duct sections upstream and downstream of a fan
- $P_t$  = fan total pressure, Pa
- $\epsilon$  = symbol that ties duct sections into system paths from the exhaust/return air terminals to the supply terminals

Figure 4 illustrates the use of Equation (16). This system has three supply and two return terminals consisting of nine sections connected in six paths: 1-3-4-9-7-5, 1-3-4-9-7-6, 1-3-4-9-8, 2-4-9-7-5, 2-4-9-7-6, and 2-4-9-8. Sections 1 and 3 are unequal area; thus, they are assigned separate numbers in accordance with the rules for

identifying sections (see Step 4 in the section on HVAC Duct Design Procedures). To determine the fan pressure requirement, the following six equations, derived from Equation (16), are applied. These equations must be satisfied to attain pressure balancing for

design airflow. Relying entirely on dampers is not economical and may create objectionable flow-generated noise.

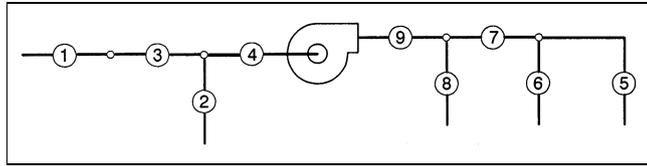

Fig. 4 Illustrative 6-Path, 9-Section System

$$\begin{cases}
 P_t = \Delta p_1 + \Delta p_3 + \Delta p_4 + \Delta p_9 + \Delta p_7 + \Delta p_5 \\
 P_t = \Delta p_1 + \Delta p_3 + \Delta p_4 + \Delta p_9 + \Delta p_7 + \Delta p_6 \\
 P_t = \Delta p_1 + \Delta p_3 + \Delta p_4 + \Delta p_9 + \Delta p_8 \\
 P_t = \Delta p_2 + \Delta p_4 + \Delta p_9 + \Delta p_7 + \Delta p_5 \\
 P_t = \Delta p_2 + \Delta p_4 + \Delta p_9 + \Delta p_7 + \Delta p_6 \\
 P_t = \Delta p_2 + \Delta p_4 + \Delta p_9 + \Delta p_8
 \end{cases}
 \tag{17}$$

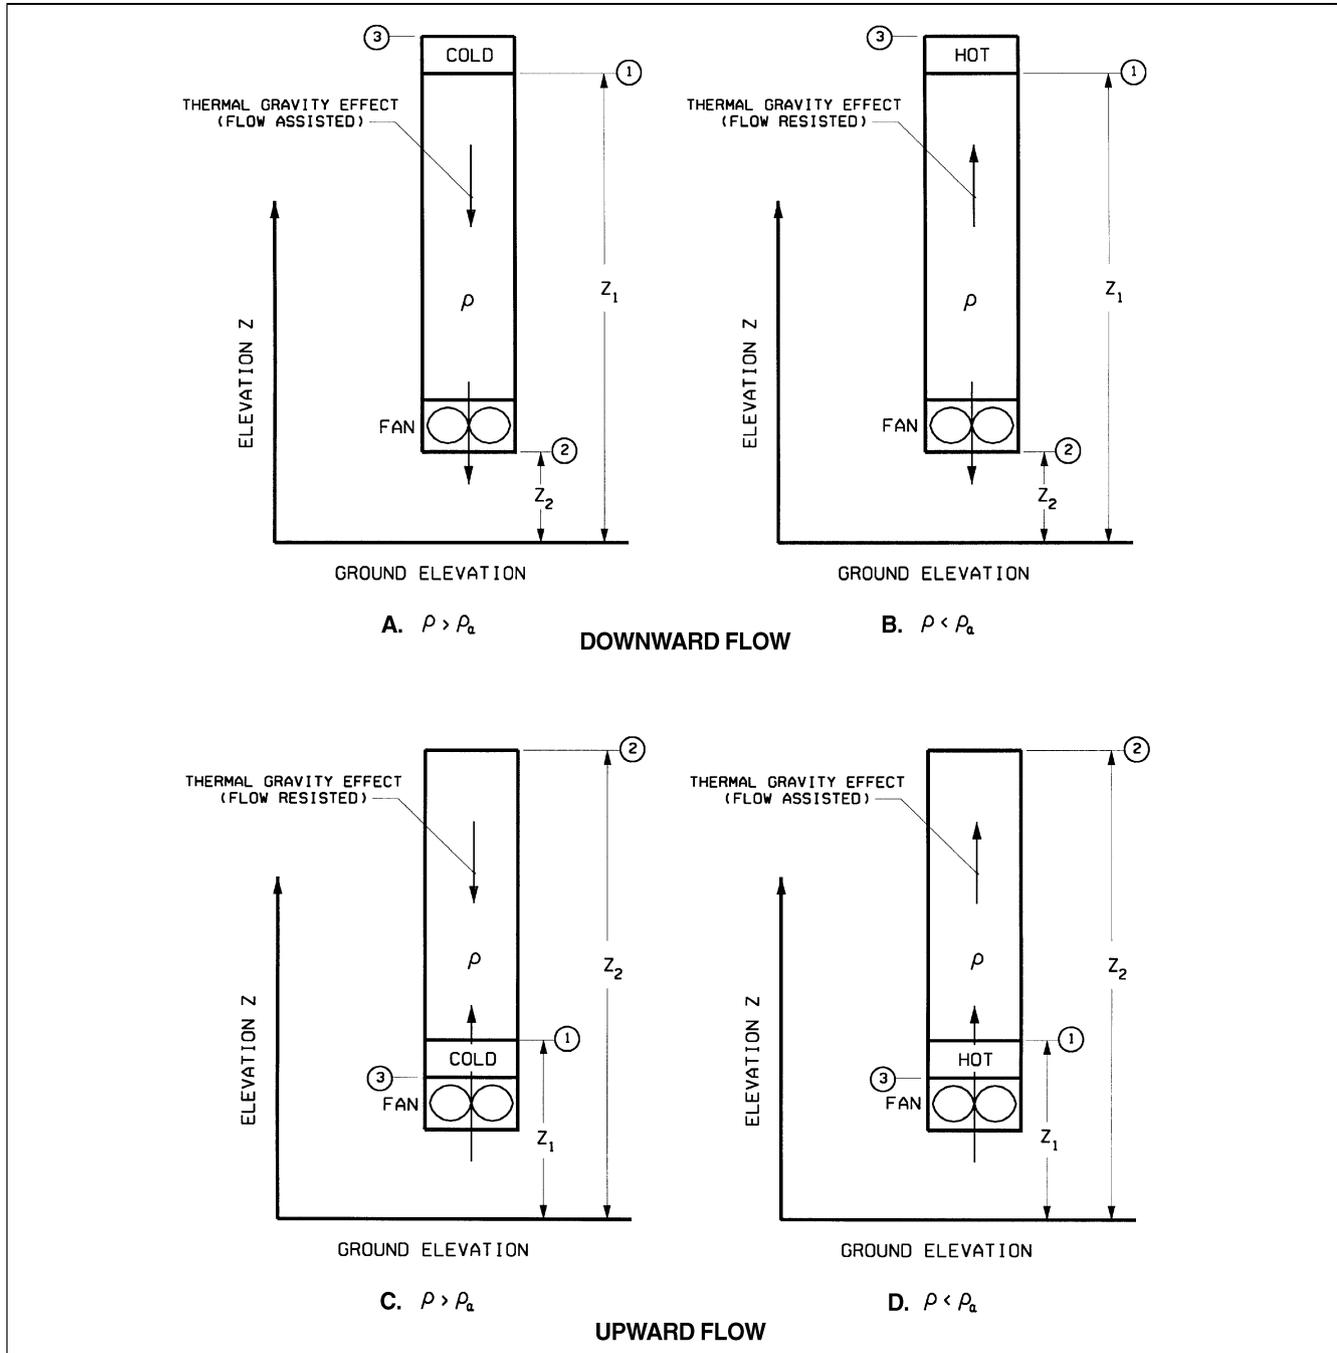

Fig. 5 Single Stack with Fan for Examples 3 and 4

**Example 3.** For Figures 5A and 5C, calculate the thermal gravity effect and fan total pressure required when the air is cooled to  $-34^{\circ}\text{C}$ . The heat exchanger and ductwork (section 1 to 2) total pressure losses are 170 and 70 Pa respectively. The density of  $-34^{\circ}\text{C}$  air is  $1.477\text{ kg/m}^3$ ; ambient air is  $1.204\text{ kg/m}^3$ . Elevations are 21 m and 3 m as noted in the solutions below.

**Solution.**

(a) For Figure 5A (downward flow),

$$\begin{aligned} \Delta p_{se} &= 9.81(\rho_a - \rho)(z_2 - z_1) \\ &= 9.81(1.204 - 1.477)(3 - 21) \\ &= 48\text{ Pa} \end{aligned}$$

$$\begin{aligned} P_t &= \Delta p_{t,3-2} - \Delta p_{se} \\ &= (170 + 70) - (48) \\ &= 192\text{ Pa} \end{aligned}$$

(b) For Figure 5C (upward flow),

$$\begin{aligned} \Delta p_{se} &= 9.81(\rho_a - \rho)(z_2 - z_1) \\ &= 9.81(1.204 - 1.477)(21 - 3) \\ &= -48\text{ Pa} \end{aligned}$$

$$\begin{aligned} P_t &= \Delta p_{t,3-2} - \Delta p_{se} \\ &= (170 + 70) - (-48) \\ &= 288\text{ Pa} \end{aligned}$$

**Example 4.** For Figures 5B and 5D, calculate the thermal gravity effect and fan total pressure required when the air is heated to  $120^{\circ}\text{C}$ . The heat exchanger and ductwork (section 1 to 2) total pressure losses are

170 and 70 Pa respectively. The density of  $120^{\circ}\text{C}$  air is  $0.898\text{ kg/m}^3$ ; ambient air is  $1.204\text{ kg/m}^3$ . Elevations are 21 m and 3 m as noted in the solutions below.

**Solution:**

(a) For Figure 5B (downward flow),

$$\begin{aligned} \Delta p_{se} &= 9.81(\rho_a - \rho)(z_2 - z_1) \\ &= 9.81(1.204 - 0.898)(3 - 21) \\ &= -54\text{ Pa} \end{aligned}$$

$$\begin{aligned} P_t &= \Delta p_{t,3-2} - \Delta p_{se} \\ &= (170 + 70) - (-54) \\ &= 294\text{ Pa} \end{aligned}$$

(b) For Figure 5D (upward flow),

$$\begin{aligned} \Delta p_{se} &= 9.81(\rho_a - \rho)(z_2 - z_1) \\ &= 9.81(1.204 - 0.898)(21 - 3) \\ &= 54\text{ Pa} \end{aligned}$$

$$\begin{aligned} P_t &= \Delta p_{t,3-2} - \Delta p_{se} \\ &= (170 + 70) - (54) \\ &= 186\text{ Pa} \end{aligned}$$

**Example 5.** Calculate the thermal gravity effect for each section of the system shown in Figure 6 and the net thermal gravity effect of the system. The density of ambient air is  $1.204\text{ kg/m}^3$ , and the lengths are as follows:  $z_1 = 15\text{ m}$ ,  $z_2 = 27\text{ m}$ ,  $z_4 = 30\text{ m}$ ,  $z_5 = 8\text{ m}$ , and  $z_9 = 60\text{ m}$ . The pressure required at section 3 is  $-25\text{ Pa}$  ( $-2.7\text{ mm}$  of water). Write the equation to determine the fan total pressure requirement.

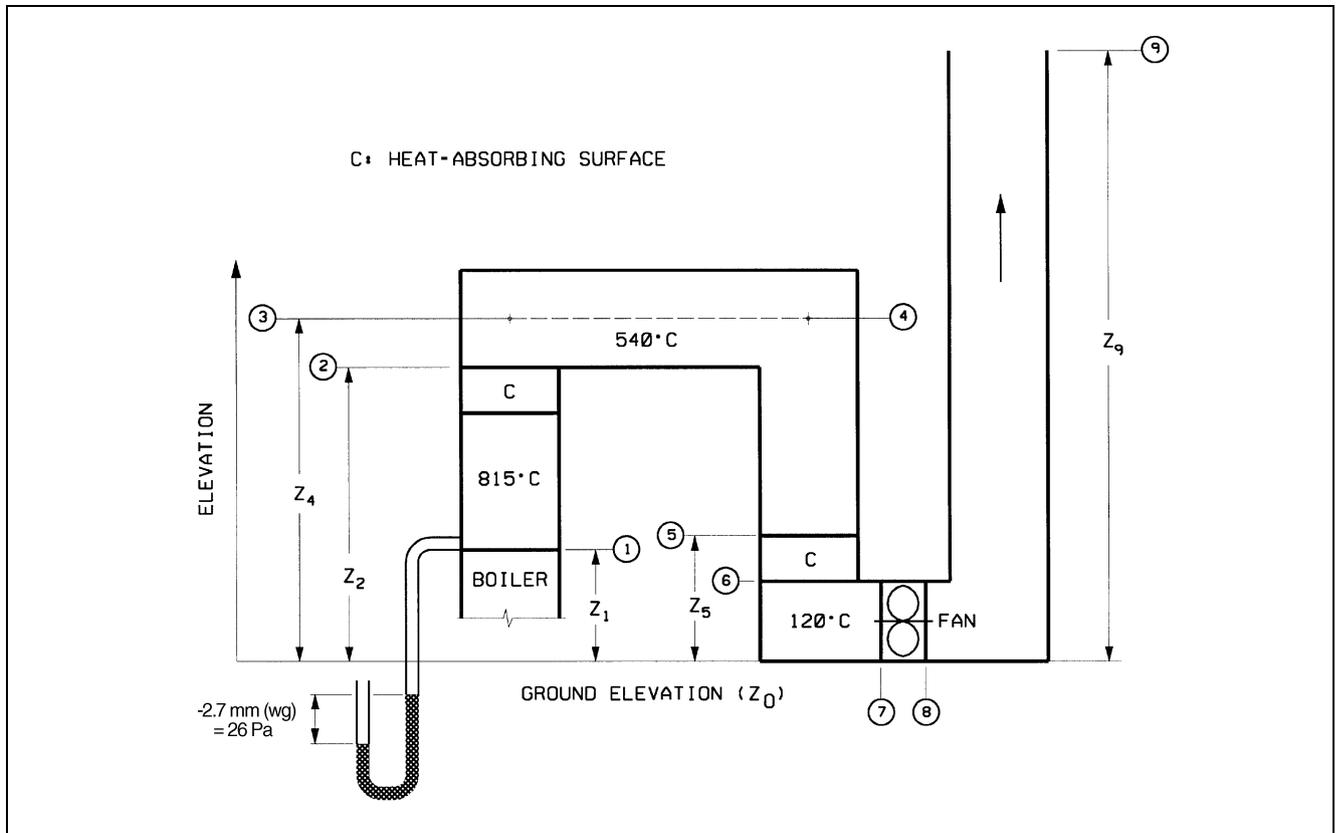

Fig. 6 Triple Stack System for Example 5

**Solution:** The following table summarizes the thermal gravity effect for each section of the system as calculated by Equation (15). The net thermal gravity effect for the system is 118 Pa. To select a fan, use the following equation:

$$P_t = 25 + \Delta p_{t,1-7} + \Delta p_{t,8-9} - \Delta p_{se}$$

$$= 25 + \Delta p_{t,1-7} + \Delta p_{t,8-9} - 118$$

$$= \Delta p_{t,1-7} + \Delta p_{t,8-9} - 93$$

Path (x-x')	Temp., °C	$\rho$ , kg/m <sup>3</sup>	$\Delta z$ (z <sub>x'</sub> - z <sub>x</sub> ), m	$\Delta\rho$ ( $\rho_a - \rho_{x-x'}$ ), kg/m <sup>3</sup>	$\Delta p_{se}$ , Pa [Eq. (15)]
1-2	815	0.324	(27 - 15)	+0.880	+104
3-4	540	0.434	0	+0.770	0
4-5	540	0.434	(8 - 30)	+0.770	-166
6-7	120	0.898	0	+0.306	0
8-9	120	0.898	(60 - 0)	+0.306	+180
Net Thermal Gravity Effect					118

**PRESSURE CHANGES IN SYSTEM**

Figure 7 shows total and static pressure changes in a fan/duct system consisting of a fan with both supply and return air ductwork. Also shown are the total and static pressure gradients referenced to atmospheric pressure.

For all constant-area sections, the total and static pressure losses are equal. At the diverging transitions, velocity pressure decreases, absolute total pressure decreases, and absolute static pressure can increase. The static pressure increase at these sections is known as **static gain**.

At the converging transitions, velocity pressure increases in the direction of airflow, and the absolute total and absolute static pressures decrease.

At the exit, the total pressure loss depends on the shape of the fitting and the flow characteristics. Exit loss coefficients  $C_o$  can be greater than, less than, or equal to one. The total and static pressure grade lines for the various coefficients are shown in Figure 3. Note that for a loss coefficient less than one, static pressure upstream of the exit is less than atmospheric pressure (negative). The static pressure just upstream of the discharge fitting can be calculated by subtracting the upstream velocity pressure from the upstream total pressure.

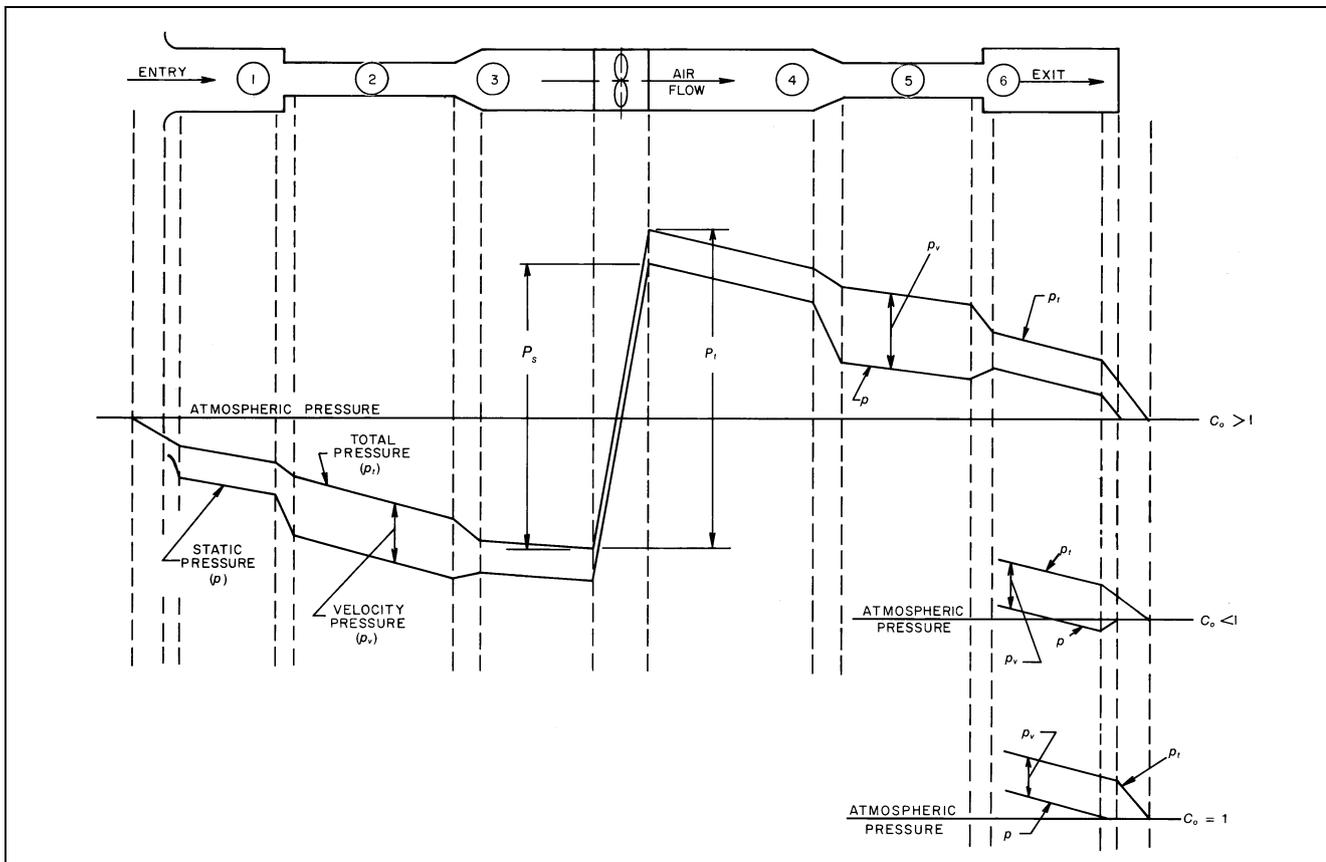

At section 1, the total pressure loss depends on the shape of the entry. The total pressure immediately downstream of the entrance equals the difference between the upstream pressure, which is zero (atmospheric pressure), and the loss through the fitting. The static pressure of the ambient air is zero; several diameters downstream, static pressure is negative, equal to the sum of the total pressure (negative) and the velocity pressure (always positive).

System resistance to airflow is noted by the total pressure grade line in Figure 7. Sections 3 and 4 include fan system effect pressure losses. To obtain the fan static pressure requirement for fan selection where the fan total pressure is known, use

$$P_s = P_t - p_{v,o} \tag{18}$$

where

- $P_s$  = fan static pressure, Pa
- $P_t$  = fan total pressure, Pa
- $p_{v,o}$  = fan outlet velocity pressure, Pa

**Fig. 7 Pressure Changes During Flow in Ducts**

## FLUID RESISTANCE

Duct system losses are the irreversible transformation of mechanical energy into heat. The two types of losses are (1) friction losses and (2) dynamic losses.

### FRICITION LOSSES

Friction losses are due to fluid viscosity and are a result of momentum exchange between molecules in laminar flow and between individual particles of adjacent fluid layers moving at different velocities in turbulent flow. Friction losses occur along the entire duct length.

### Darcy, Colebrook, and Altshul-Tsal Equations

For fluid flow in conduits, friction loss can be calculated by the Darcy equation:

$$\Delta p_f = \frac{1000fL}{D_h} \frac{\rho V^2}{2} \quad (19)$$

where

- $\Delta p_f$  = friction losses in terms of total pressure, Pa
- $f$  = friction factor, dimensionless
- $L$  = duct length, m
- $D_h$  = hydraulic diameter [Equation (24)], mm
- $V$  = velocity, m/s
- $\rho$  = density, kg/m<sup>3</sup>

Within the region of laminar flow (Reynolds numbers less than 2000), the friction factor is a function of Reynolds number only.

For completely turbulent flow, the friction factor depends on Reynolds number, duct surface roughness, and internal protuberances such as joints. Between the bounding limits of hydraulically smooth behavior and fully rough behavior, is a transitional roughness zone where the friction factor depends on both roughness and Reynolds number. In this transitionally rough, turbulent zone the friction factor  $f$  is calculated by Colebrook's equation (Colebrook 1938-39). Colebrook's transition curve merges asymptotically into the curves representing laminar and completely turbulent flow. Because Colebrook's equation cannot be solved explicitly for  $f$ , use iterative techniques (Behls 1971).

$$\frac{1}{\sqrt{f}} = -2 \log \left( \frac{\epsilon}{3.7D_h} + \frac{2.51}{Re\sqrt{f}} \right) \quad (20)$$

where

- $\epsilon$  = material absolute roughness factor, mm
- Re = Reynolds number

A simplified formula for calculating friction factor, developed by Altshul (Altshul et al. 1975) and modified by Tsal, is

$$f' = 0.11 \left( \frac{\epsilon}{D_h} + \frac{68}{Re} \right)^{0.25} \quad (21)$$

If  $f' \geq 0.018$ :  $f = f'$   
 If  $f' < 0.018$ :  $f = 0.85f' + 0.0028$

Friction factors obtained from the Altshul-Tsal equation are within 1.6% of those obtained by Colebrook's equation.

Reynolds number (Re) may be calculated by using the following equation.

$$Re = \frac{D_h V}{1000\nu} \quad (22)$$

where  $\nu$  = kinematic viscosity, m<sup>2</sup>/s.

For standard air, Re can be calculated by

$$Re = 66.4D_h V \quad (23)$$

### Roughness Factors

The roughness factors  $\epsilon$  listed in Table 1 are recommended for use with the Colebrook or Altshul-Tsal equation [Equations (20) and (21), respectively]. These values include not only material, but also duct construction, joint type, and joint spacing (Griggs and Khodabakhsh-Sharifabad 1992). Roughness factors for other materials are presented in Idelchik et al. (1994). Idelchik summarizes roughness factors for 80 materials including metal tubes; conduits made from concrete and cement; and wood, plywood, and glass tubes.

Swim (1978) conducted tests on duct liners of varying densities, surface treatments, transverse joints (workmanship), and methods of attachment to sheet metal ducts. As a result of these tests, Swim recommends for design 4.6 mm for spray-coated liners and 1.5 mm for liners with a facing material cemented onto the air side. In both cases, the roughness factor includes the resistance offered by mechanical fasteners and assumes good joints. Liners cut too short result in (1) loss of thermal performance, (2) possible condensation problems, (3) potential damage to the liner (erosion of the blanket or tearing away from the duct surface), and (4) the collection of dirt and debris and the initiation of biological problems. Liner density does not significantly influence flow resistance.

Manufacturers' data indicate that the absolute roughness for fully extended nonmetallic flexible ducts ranges from 1.1 to 4.6 mm. For fully extended flexible metallic ducts, absolute roughness ranges from 0.1 to 2.1 mm. This range covers flexible duct with the supporting wire exposed to flow or covered by the material. Figure 8 provides a pressure drop correction factor for straight flexible duct when less than fully extended.

Table 1 Duct Roughness Factors

Duct Material	Roughness Category	Absolute Roughness $\epsilon$ , mm
Uncoated carbon steel, clean (Moody 1944) (0.05 mm)	Smooth	0.03
PVC plastic pipe (Swim 1982) (0.01 to 0.05 mm)		
Aluminum (Hutchinson 1953) (0.04 to 0.06 mm)		
Galvanized steel, longitudinal seams, 1200 mm joints (Griggs et al. 1987) (0.05 to 0.10 mm)	Medium smooth	0.09
Galvanized steel, continuously rolled, spiral seams, 3000 mm joints (Jones 1979) (0.06 to 0.12 mm)		
Galvanized steel, spiral seam with 1, 2, and 3 ribs, 3600 mm joints (Griggs et al. 1987) (0.09 to 0.12 mm)		
Galvanized steel, longitudinal seams, 760 mm joints (Wright 1945) (0.15 mm)	Average	0.15
Fibrous glass duct, rigid	Medium rough	0.9
Fibrous glass duct liner, air side with facing material (Swim 1978) (1.5 mm)		
Fibrous glass duct liner, air side spray coated (Swim 1978) (4.5 mm)	Rough	3.0
Flexible duct, metallic (1.2 to 2.1 mm when fully extended)		
Flexible duct, all types of fabric and wire (1.0 to 4.6 mm when fully extended)		
Concrete (Moody 1944) (1.3 to 3.0 mm)		

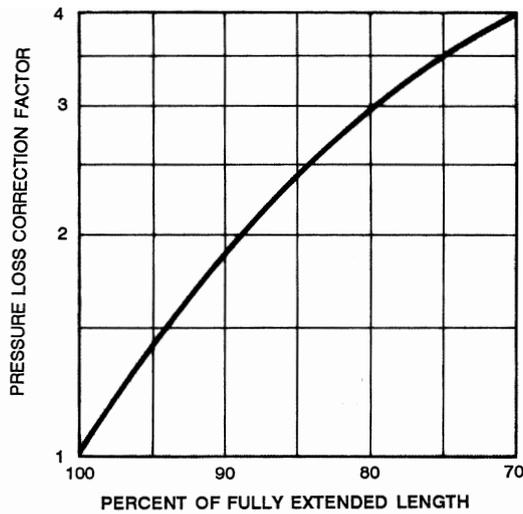

Fig. 8 Correction Factor for Unextended Flexible Duct

### Friction Chart

Fluid resistance caused by friction in round ducts can be determined by the friction chart (Figure 9). This chart is based on standard air flowing through round galvanized ducts with beaded slip couplings on 1220 mm centers, equivalent to an absolute roughness of 0.09 mm.

Changes in barometric pressure, temperature, and humidity affect air density, air viscosity, and Reynolds number. No corrections to Figure 9 are needed for (1) duct materials with a medium smooth roughness factor, (2) temperature variations in the order of  $\pm 15$  K from 20°C, (3) elevations to 500 m, and (4) duct pressures from  $-5$  to  $+5$  kPa relative to the ambient pressure. These individual variations in temperature, elevation, and duct pressure result in duct losses within  $\pm 5\%$  of the standard air friction chart.

For duct materials other than those categorized as medium smooth in Table 1, and for variations in temperature, barometric pressure (elevation), and duct pressures (outside the range listed), calculate the friction loss in a duct by the Altshul-Tsal and Darcy equations [Equations (21) and (19), respectively].

### Noncircular Ducts

A momentum analysis can relate average wall shear stress to pressure drop per unit length for fully developed turbulent flow in a passage of arbitrary shape but uniform longitudinal cross-sectional area. This analysis leads to the definition of **hydraulic diameter**:

$$D_h = 4A/P \quad (24)$$

where

- $D_h$  = hydraulic diameter, mm
- $A$  = duct area, mm<sup>2</sup>
- $P$  = perimeter of cross section, mm

While the hydraulic diameter is often used to correlate noncircular data, exact solutions for laminar flow in noncircular passages show that such practice causes some inconsistencies. No exact solutions exist for turbulent flow. Tests over a limited range of turbulent flow indicated that fluid resistance is the same for equal lengths of duct for equal mean velocities of flow if the ducts have the same ratio of cross-sectional area to perimeter. From a series of experiments using round, square, and rectangular ducts having essentially the same hydraulic diameter, Huebscher (1948) found that each, for most purposes, had the same flow resistance at equal mean velocities. Tests by Griggs and Khodabakhsh-Sharifabad (1992) also indicated that experimental rectangular duct data for airflow over the

range typical of HVAC systems can be correlated satisfactorily using Equation (20) together with hydraulic diameter, particularly when a realistic experimental uncertainty is accepted. These tests support using hydraulic diameter to correlate noncircular duct data.

**Rectangular Ducts.** Huebscher (1948) developed the relationship between rectangular and round ducts that is used to determine size equivalency based on equal flow, resistance, and length. This relationship, Equation (25), is the basis for Table 2.

$$D_e = \frac{1.30(ab)^{0.625}}{(a+b)^{0.250}} \quad (25)$$

where

- $D_e$  = circular equivalent of rectangular duct for equal length, fluid resistance, and airflow, mm
- $a$  = length one side of duct, mm
- $b$  = length adjacent side of duct, mm

To determine equivalent round duct diameter, use Table 2. Equations (21) or (20) and (19) must be used to determine pressure loss.

**Flat Oval Ducts.** To convert round ducts to spiral flat oval sizes, use Table 3. Table 3 is based on Equation (26) (Heyt and Diaz 1975), the circular equivalent of a flat oval duct for equal airflow, resistance, and length. Equations (21) or (20) and (19) must be used to determine friction loss.

$$D_e = \frac{1.55AR^{0.625}}{P^{0.250}} \quad (26)$$

where  $AR$  is the cross-sectional area of flat oval duct defined as

$$AR = (\pi a^2/4) + a(A - a) \quad (27)$$

and the perimeter  $P$  is calculated by

$$P = \pi a + 2(A - a) \quad (28)$$

where

- $P$  = perimeter of flat oval duct, mm
- $A$  = major axis of flat oval duct, mm
- $a$  = minor axis of flat oval duct, mm

### DYNAMIC LOSSES

Dynamic losses result from flow disturbances caused by duct-mounted equipment and fittings that change the airflow path's direction and/or area. These fittings include entries, exits, elbows, transitions, and junctions. Idelchik et al. (1994) discuss parameters affecting fluid resistance of fittings and presents local loss coefficients in three forms: tables, curves, and equations.

#### Local Loss Coefficients

The dimensionless coefficient  $C$  is used for fluid resistance, because this coefficient has the same value in dynamically similar streams (i.e., streams with geometrically similar stretches, equal Reynolds numbers, and equal values of other criteria necessary for dynamic similarity). The fluid resistance coefficient represents the ratio of total pressure loss to velocity pressure at the referenced cross section:

$$C = \frac{\Delta p_j}{(\rho V^2/2)} = \frac{\Delta p_j}{p_v} \quad (29)$$

where

- $C$  = local loss coefficient, dimensionless
- $\Delta p_j$  = total pressure loss, Pa
- $\rho$  = density, kg/m<sup>3</sup>
- $V$  = velocity, m/s
- $p_v$  = velocity pressure, Pa

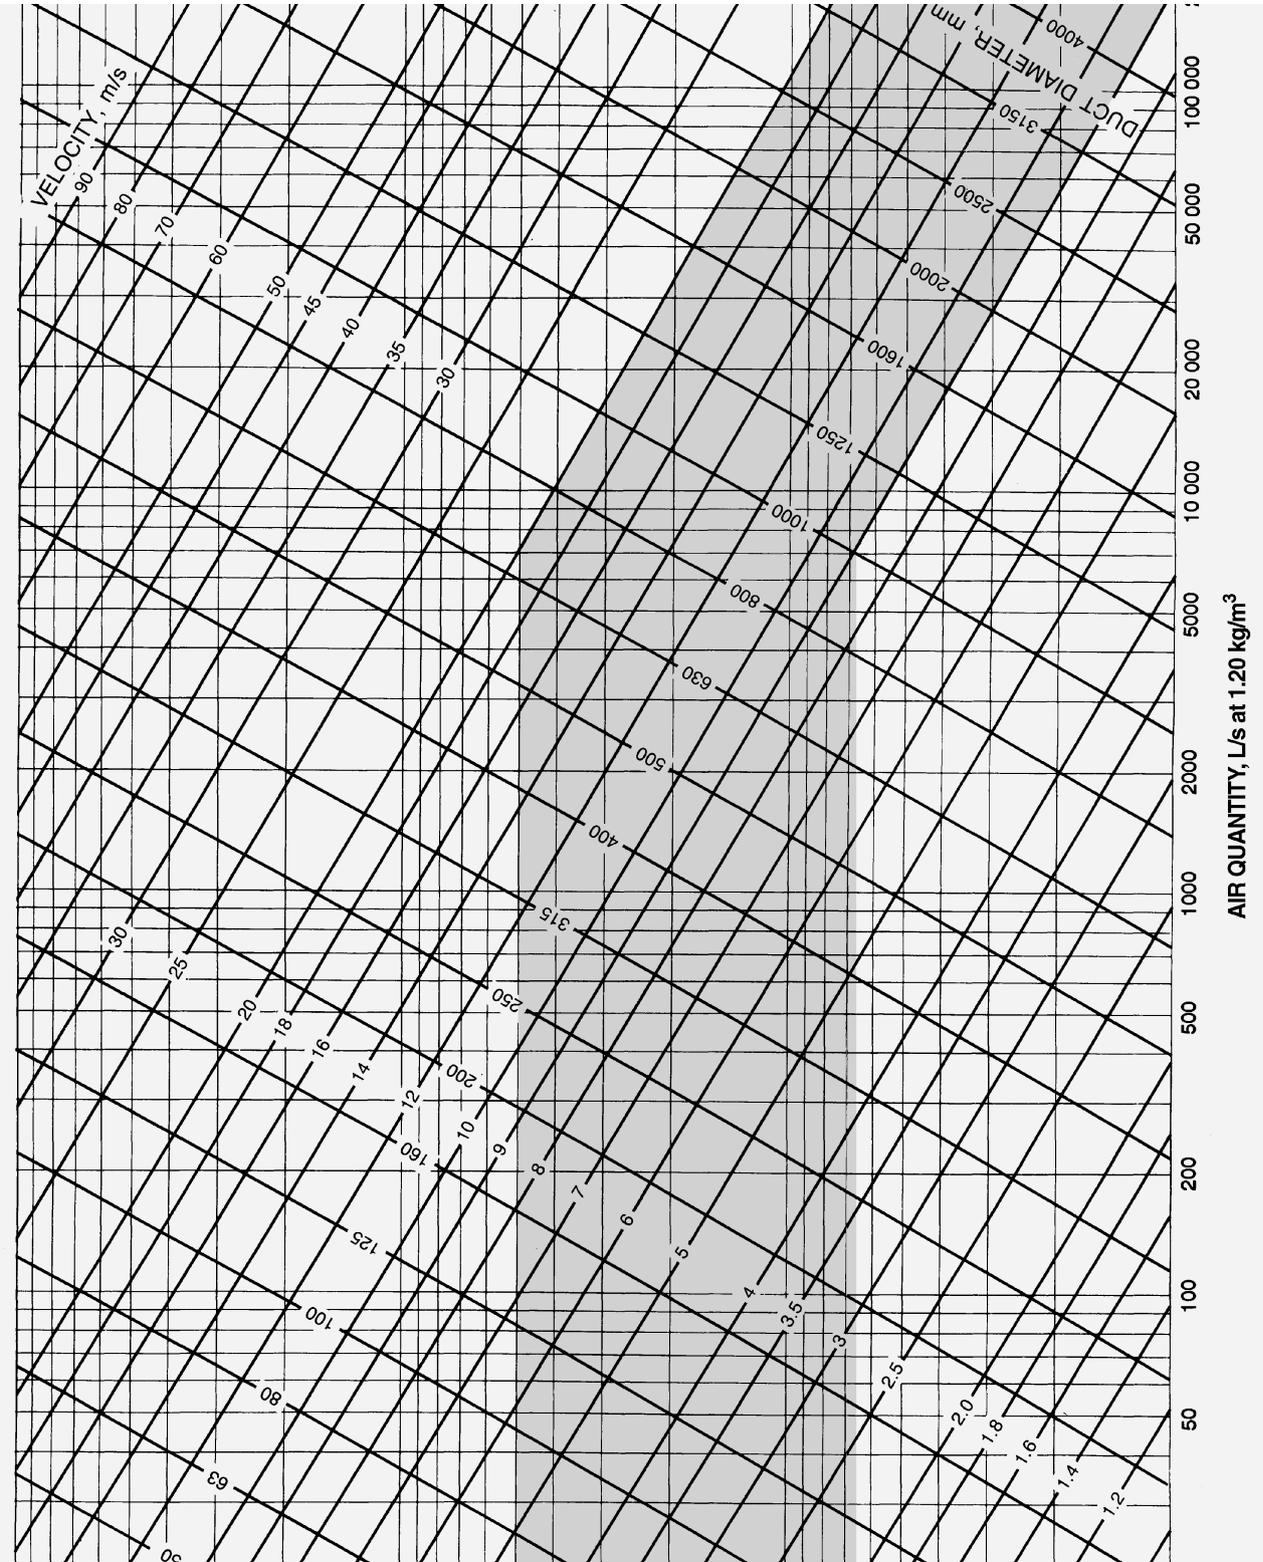

Fig. 9 Friction Chart for Round Duct ( $\rho = 1.20 \text{ kg/m}^3$  and  $\epsilon = 0.09 \text{ mm}$ )

Dynamic losses occur along a duct length and cannot be separated from friction losses. For ease of calculation, dynamic losses are assumed to be concentrated at a section (local) and to exclude friction. Frictional losses must be considered only for relatively long fittings. Generally, fitting friction losses are accounted for by measuring duct lengths from the centerline of one fitting to that of the next fitting. For fittings closely coupled (less than six hydraulic diameters apart), the flow pattern entering subsequent fittings differs from the flow pattern used to determine loss coefficients. Adequate data for these situations are unavailable.

For all fittings, except junctions, calculate the total pressure loss  $\Delta p_j$  at a section by

$$\Delta p_j = C_o p_{v,o} \tag{30}$$

where the subscript *o* is the cross section at which the velocity pressure is referenced. The dynamic loss is based on the actual velocity in the duct, not the velocity in an equivalent noncircular duct. For the cross section to reference a fitting loss coefficient, refer to Step 4 in the section on HVAC Duct Design Procedures. Where necessary (unequal area fittings), convert a loss coefficient from section *o* to section *i* using Equation (31), where *V* is the velocity at the respective sections.

$$C_i = \frac{C_o}{(V_i/V_o)^2} \tag{31}$$

For converging and diverging flow junctions, total pressure losses through the straight (main) section are calculated as

$$\Delta p_j = C_{c,s} p_{v,c} \tag{32}$$

For total pressure losses through the branch section,

$$\Delta p_j = C_{c,b} p_{v,c} \tag{33}$$

where  $p_{v,c}$  is the velocity pressure at the common section *c*, and  $C_{c,s}$  and  $C_{c,b}$  are losses for the straight (main) and branch flow paths, respectively, each referenced to the velocity pressure at section *c*. To convert junction local loss coefficients referenced to straight and branch velocity pressures, use the following equation:

$$C_i = \frac{C_{c,i}}{(V_i/V_c)^2} \tag{34}$$

where

- $C_i$  = local loss coefficient referenced to section being calculated (see subscripts), dimensionless
- $C_{c,i}$  = straight ( $C_{c,s}$ ) or branch ( $C_{c,b}$ ) local loss coefficient referenced to dynamic pressure at common section, dimensionless
- $V_i$  = velocity at section to which  $C_i$  is being referenced, m/s
- $V_c$  = velocity at common section, m/s

Subscripts:

- b* = branch
- s* = straight (main) section
- c* = common section

The junction of two parallel streams moving at different velocities is characterized by turbulent mixing of the streams, accompanied by pressure losses. In the course of this mixing, an exchange of momentum takes place between the particles moving at different velocities, finally resulting in the equalization of the velocity distributions in the common stream. The jet with higher velocity loses a part of its kinetic energy by transmitting it to the slower moving jet. The loss in total pressure before and after mixing is always large and positive for the higher velocity jet and increases with an increase in the amount of energy transmitted to the lower velocity jet. Consequently, the local loss coefficient, defined by Equation (29), will always be positive. The energy stored in the lower velocity jet increases as a result of mixing. The loss in total pressure and the local loss coefficient can, therefore, also have negative values for the lower velocity jet (Idelchik et al. 1994).

**Table 4 Duct Fitting Codes**

Fitting Function	Geometry	Category	Sequential Number
S: Supply	D: round (Diameter)	1. Entries 2. Exits	1,2,3...n
E: Exhaust/Return	R: Rectangular	3. Elbows 4. Transitions	
C: Common (supply and return)	F: Flat oval	5. Junctions 6. Obstructions 7. Fan and system interactions 8. Duct-mounted equipment 9. Dampers 10. Hoods	

**Duct Fitting Database**

A duct fitting database, developed by ASHRAE (1994), which includes 228 round and rectangular fittings with the provision to include flat oval fittings, is available from ASHRAE in electronic form with the capability to be linked to duct design programs.

The fittings are numbered (coded) as shown in Table 4. Entries and converging junctions are only in the exhaust/return portion of systems. Exits and diverging junctions are only in supply systems. Equal-area elbows, obstructions, and duct-mounted equipment are common to both supply and exhaust systems. Transitions and unequal-area elbows can be either supply or exhaust fittings. Fitting ED5-1 (see the section on Fitting Loss Coefficients) is an Exhaust fitting with a round shape (**D**iameter). The number 5 indicates that the fitting is a junction, and 1 is its sequential number. Fittings SR3-1 and ER3-1 are Supply and Exhaust fittings, respectively. The R indicates that the fitting is **R**ectangular, and the 3 identifies the fitting as an elbow. Note that the cross-sectional areas at sections 0 and 1 are not equal (see the section on Fitting Loss Coefficients). Otherwise, the elbow would be a Common fitting such as CR3-6. Additional fittings are reproduced in the section on Fitting Loss Coefficients to support the example design problems (see Table 12 for Example 8; see Table 14 for Example 9).

**DUCTWORK SECTIONAL LOSSES**

**Darcy-Weisbach Equation**

Total pressure loss in a duct section is calculated by combining Equations (19) and (29) in terms of  $\Delta p$ , where  $\Sigma C$  is the summation of local loss coefficients within the duct section. Each fitting loss coefficient must be referenced to that section's velocity pressure.

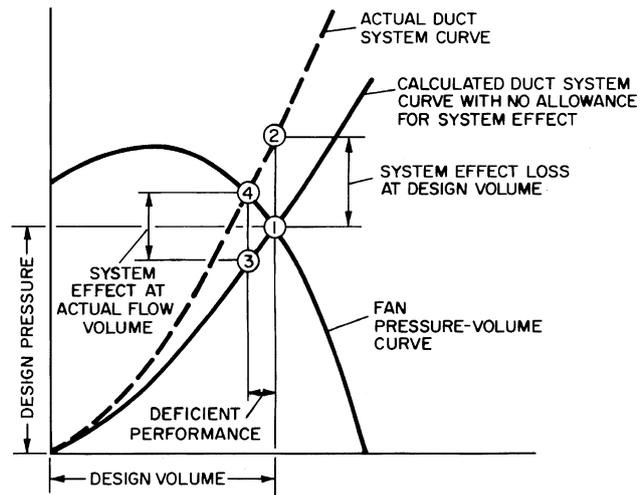

$$\Delta p = \left( \frac{1000fL}{D_h} + \Sigma C \right) \left( \frac{\rho V^2}{2} \right) \tag{35}$$

**FAN-SYSTEM INTERFACE**

**Fan Inlet and Outlet Conditions**

Fan performance data measured in the field may show lower performance capacity than manufacturers' ratings. The most common causes of deficient performance of the fan/system combination are improper outlet connections, nonuniform inlet flow, and swirl at the fan inlet. These conditions alter the aerodynamic characteristics of the fan so that its full flow potential is not realized. One bad connection can reduce fan performance far below its rating. No data have been published that account for the effects of fan inlet and outlet flexible vibration connectors.

Normally, a fan is tested with open inlets and a section of straight duct attached to the outlet (ASHRAE Standard 51). This setup results in uniform flow into the fan and efficient static pressure

**Fig. 10 Deficient System Performance with System Effect Ignored**

recovery on the fan outlet. If good inlet and outlet conditions are not provided in the actual installation, the performance of the fan suffers. To select and apply the fan properly, these effects must be considered, and the pressure requirements of the fan, as calculated by standard duct design procedures, must be increased.

Figure 10 illustrates deficient fan/system performance. The system pressure losses have been determined accurately, and a fan has been selected for operation at Point 1. However, no allowance has been made for the effect of system connections to the fan on fan performance. To compensate, a fan system effect must be added to the calculated system pressure losses to determine the actual system curve. The point of intersection between the fan performance curve and the actual system curve is Point 4. The actual flow volume is, therefore, deficient by the difference from 1 to 4. To achieve design flow volume, a fan system effect pressure loss equal to the pressure difference between Points 1 and 2 should be added to the calculated system pressure losses, and the fan should be selected to operate at Point 2.

**Fan System Effect Coefficients**

The system effect concept was formulated by Farquhar (1973) and Meyer (1973); the magnitudes of the system effect, called **system effect factors**, were determined experimentally in the laboratory of the Air Movement and Control Association (AMCA) (Brown 1973, Clarke et al. 1978) and published in their *Publication 201* (AMCA 1990a). The system effect factors, converted to local loss coefficients, are in the *Duct Fitting Database* (ASHRAE 1994) for both centrifugal and axial fans. Fan system effect coefficients are only an approximation. Fans of different types and even fans of the same type, but supplied by different manufacturers, do not necessarily react to a system in the same way. Therefore, judgment based on experience must be applied to any design.

**Fan Outlet Conditions.** Fans intended primarily for duct systems are usually tested with an outlet duct in place (ASHRAE Standard 51). Figure 11 shows the changes in velocity profiles at various distances from the fan outlet. For 100% recovery, the duct, including transition, must meet the requirements for 100% effective duct length [ $L_e$  (Figure 11)], which is calculated as follows:

For  $V_o > 13$  m/s,

$$L_e = \frac{V_o \sqrt{A_o}}{4500} \tag{36}$$

For  $V_o \leq 13$  m/s,

$$L_e = \frac{\sqrt{A_o}}{350} \quad (37)$$

where

- $V_o$  = duct velocity, m/s
- $L_e$  = effective duct length, m
- $A_o$  = duct area, mm<sup>2</sup>

As illustrated by Fitting SR7-1 in the section on Fitting Loss Coefficients, centrifugal fans should not abruptly discharge to the atmosphere. A diffuser design should be selected from Fitting SR7-2 (see the section on Fitting Loss Coefficients) or SR7-3 (see ASHRAE 1994).

**Fan Inlet Conditions.** For rated performance, air must enter the fan uniformly over the inlet area in an axial direction without pre-rotation. Nonuniform flow into the inlet is the most common cause of reduced fan performance. Such inlet conditions are not equivalent to a simple increase in the system resistance; therefore, they cannot be treated as a percentage decrease in the flow and pressure from the fan. A poor inlet condition results in an entirely new fan performance. An elbow at the fan inlet, for example Fitting ED7-2 (see the section on Fitting Loss Coefficients), causes turbulence and uneven flow into the fan impeller. The losses due to the fan system effect can be eliminated by including an adequate length of straight duct between the elbow and the fan inlet.

The ideal inlet condition allows air to enter axially and uniformly without spin. A spin in the same direction as the impeller rotation reduces the pressure-volume curve by an amount dependent on the

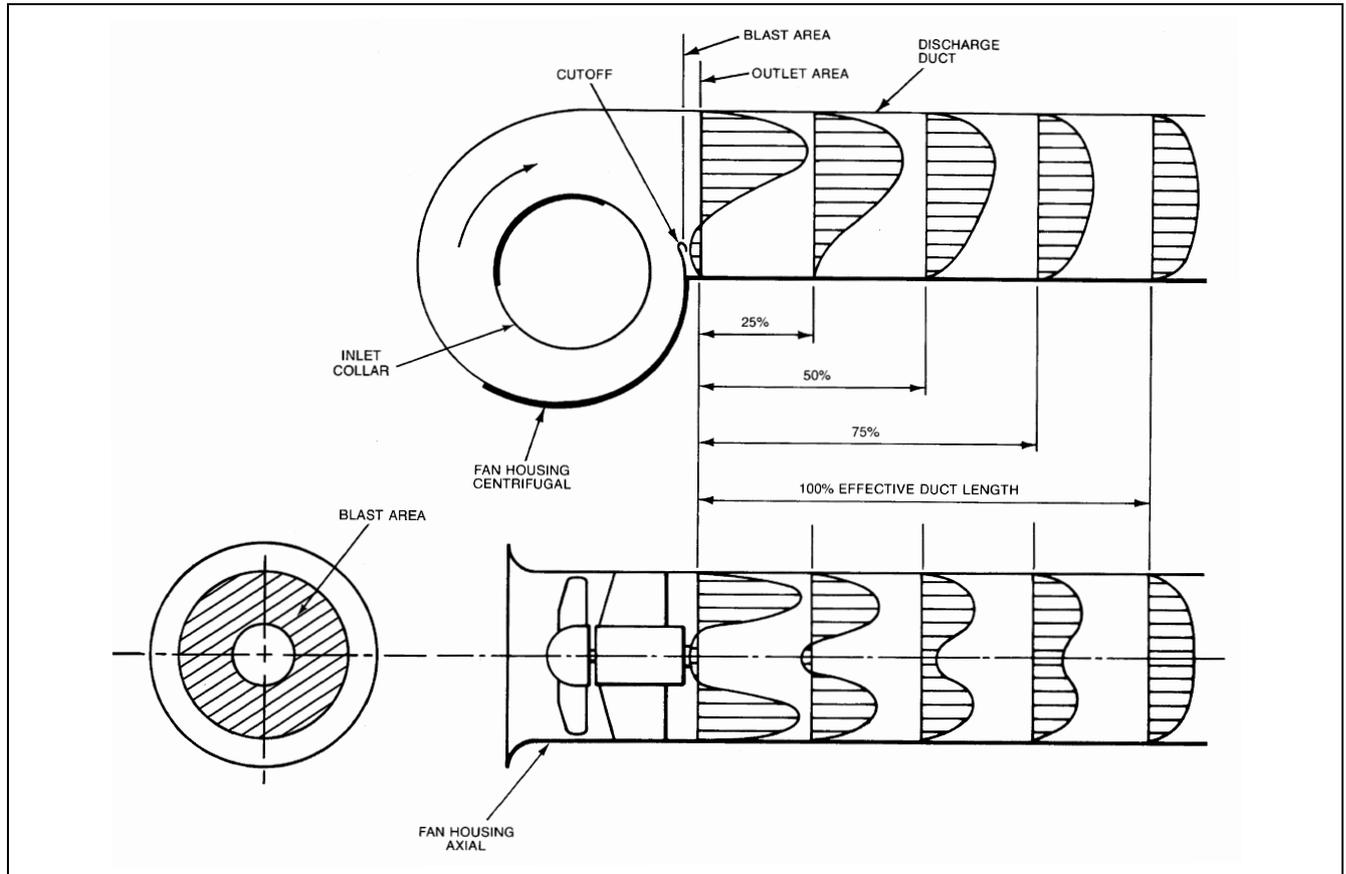

intensity of the vortex. A counterrotating vortex at the inlet slightly increases the pressure-volume curve, but the power is increased substantially.

Inlet spin may arise from a great variety of approach conditions, and sometimes the cause is not obvious. Inlet spin can be avoided by providing an adequate length of straight duct between the elbow and the fan inlet. Figure 12 illustrates some common duct connections that cause inlet spin and includes recommendations for correcting spin.

Fans within plenums and cabinets or next to walls should be located so that air may flow unobstructed into the inlets. Fan performance is reduced if the space between the fan inlet and the enclosure is too restrictive. The system effect coefficients for fans in an enclosure or adjacent to walls are listed under Fitting ED7-1 (see the section on Fitting Loss Coefficients). The manner in which the airstream enters an enclosure in relation to the fan inlets also affects fan performance. Plenum or enclosure inlets or walls that are not symmetrical with the fan inlets cause uneven flow and/or inlet spin.

**Testing, Adjusting, and Balancing Considerations**

Fan system effects (FSEs) are not only to be used in conjunction with the system resistance characteristics in the fan selection process, but are also applied in the calculations of the results of testing, adjusting, and balancing (TAB) field tests to allow direct comparison to design calculations and/or fan performance data. Fan inlet swirl and the effect on system performance of poor fan inlet and outlet ductwork connections cannot be measured directly. Poor inlet flow patterns affect fan performance within the impeller wheel

## DUCT SYSTEM DESIGN

### DESIGN CONSIDERATIONS

#### Space Pressure Relationships

Space pressure is determined by fan location and duct system arrangement. For example, a supply fan that pumps air into a space increases space pressure; an exhaust fan reduces space pressure. If both supply and exhaust fans are used, space pressure depends on the relative capacity of the fans. Space pressure is positive if supply exceeds exhaust and negative if exhaust exceeds supply (Osborne 1966). System pressure variations due to wind can be minimized or eliminated by careful selection of intake air and exhaust vent locations (Chapter 16).

#### Fire and Smoke Management

Because duct systems can convey smoke, hot gases, and fire from one area to another and can accelerate a fire within the system, fire protection is an essential part of air-conditioning and ventilation system design. Generally, fire safety codes require compliance with the standards of national organizations. NFPA *Standard 90A* examines fire safety requirements for (1) ducts, connectors, and appurtenances; (2) plenums and corridors; (3) air outlets, air inlets, and fresh air intakes; (4) air filters; (5) fans; (6) electric wiring and equipment; (7) air-cooling and -heating equipment; (8) building construction, including protection of penetrations; and (9) controls, including smoke control.

Fire safety codes often refer to the testing and labeling practices of nationally recognized laboratories, such as Factory Mutual and Underwriters Laboratories (UL). The *Building Materials Directory* compiled by UL lists fire and smoke dampers that have been tested and meet the requirements of UL *Standards 555* and *555S*. This directory also summarizes maximum allowable sizes for individual dampers and assemblies of these dampers. Fire dampers are 1.5 h or 3 h fire-rated. Smoke dampers are classified by (1) temperature degradation [ambient air or high temperature (120°C minimum)] and (2) leakage at 250 Pa and 1000 Pa pressure difference (2 kPa and 3 kPa classification optional). Smoke dampers are tested under conditions of maximum airflow. UL's *Fire Resistance Directory* lists the fire resistance of floor/roof and ceiling assemblies with and without ceiling fire dampers.

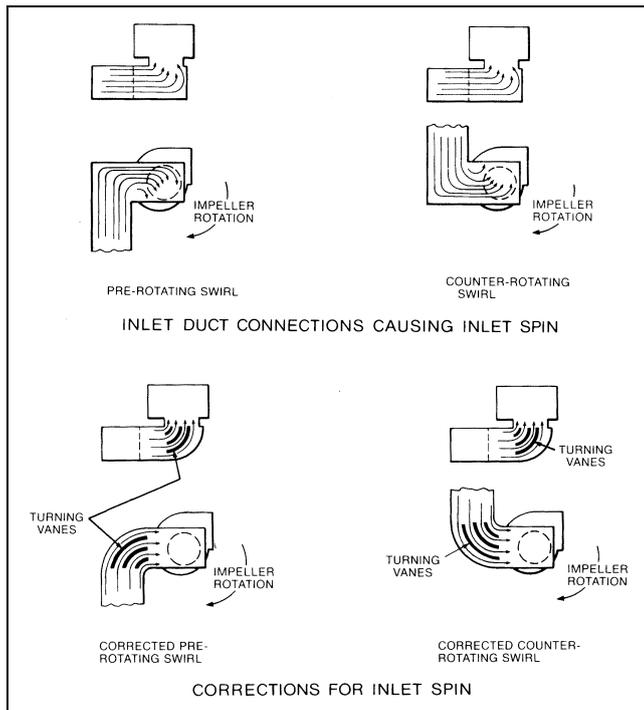

For a more detailed presentation of fire protection, see Chapter 51 of the 1999 *ASHRAE Handbook—Applications* and the NFPA *Fire Protection Handbook*.

#### Duct Insulation

In all new construction (except low-rise residential buildings), air-handling ducts and plenums installed as part of an HVAC air distribution system should be thermally insulated in accordance with Section 6.2.4.2 of *ASHRAE Standard 90.1*. Duct insulation for new low-rise residential buildings should be in compliance with *ASHRAE Standard 90.2*. Existing buildings should meet the requirements of *ASHRAE Standard 100*. The insulation thicknesses in these standards are minimum values. Economic and thermal considerations may justify higher insulation levels. Additional insulation, vapor retarders, or both may be required to limit vapor transmission and condensation.

Duct heat gains or losses must be known for the calculation of supply air quantities, supply air temperatures, and coil loads (see Chapter 29 of this volume and Chapter 2 of the 2000 *ASHRAE Handbook—Systems and Equipment*). To estimate duct heat transfer and entering or leaving air temperatures, use the following equations:

$$q_l = \frac{UPL}{1000} \left[ \left( \frac{t_e + t_l}{2} \right) - t_a \right] \quad (39)$$

**Fig. 12 Inlet Duct Connections Causing Inlet Spin and Corrections for Inlet Spin**

(Adapted by permission from AMCA *Publication 201*)

(centrifugal fan) or wheel rotor impeller (axial fan), while the fan outlet system effect is flow instability and turbulence within the fan discharge ductwork.

The static pressure at the fan inlet and the static pressure at the fan outlet may be measured directly in some systems. In most cases, static pressure measurements for use in determining fan total (or static) pressure will not be made directly at the fan inlet and outlet, but at locations a relatively short distance from the fan inlet and downstream from the fan outlet. To calculate fan total pressure for this case from field measurements, use Equation (38), where  $\Delta p_{x-y}$  is the summation of calculated total pressure losses between the fan inlet and outlet sections noted. Plane 3 is used to determine airflow rate. If necessary, use Equation (18) to calculate fan static pressure knowing fan total pressure. For locating measurement planes and calculation procedures, consult AMCA *Publication 203* (AMCA 1990b).

$$P_t = (p_{s,5} + p_{v,5}) + \Delta p_{2-5} + \text{FSE}_2 + (p_{s,4} + p_{v,4}) + \Delta p_{4-1} + \text{FSE}_1 + \text{FSE}_{1,sw} \quad (38)$$

where

- $P_t$  = fan total pressure, Pa
- $p_s$  = static pressure, Pa
- $p_v$  = velocity pressure, Pa
- FSE = fan system effect, Pa
- $\Delta p_{x-y}$  = summarization of total pressure losses between planes  $x$  and  $y$ , Pa

Subscripts (numerical subscripts same as used by AMCA *Publication 203*):

- 1 = fan inlet
- 2 = fan outlet
- 3 = plane of airflow measurement
- 4 = plane of static pressure measurement upstream of fan
- 5 = plane of static pressure measurement downstream of fan
- sw = swirl

$$t_e = \frac{t_l(y + 1) - 2t_a}{(y - 1)} \quad (40)$$

$$t_l = \frac{t_e(y - 1) + 2t_a}{(y + 1)} \quad (41)$$

where

- $q_l$  = heat loss/gain through duct walls, W (negative for heat gain)
- $U$  = overall heat transfer coefficient of duct wall, W/(m<sup>2</sup>·K)
- $P$  = perimeter of bare or insulated duct, mm
- $L$  = duct length, m
- $t_e$  = temperature of air entering duct, °C
- $t_l$  = temperature of air leaving duct, °C
- $t_a$  = temperature of air surrounding duct, °C
- $y = 2.0AV\rho c_p/ULP$  for rectangular ducts
- $= 0.5DV\rho c_p/UL$  for round ducts
- $A$  = cross-sectional area of duct, mm<sup>2</sup>
- $V$  = average velocity, m/s
- $\rho$  = density of air, kg/m<sup>3</sup>
- $c_p$  = specific heat of air, kJ/(kg·K)
- $D$  = diameter of duct, mm

Use Figure 13A to determine U-factors for insulated and uninsulated ducts. Lauvray (1978) has shown the effects of (1) compressing insulation wrapped externally on sheet metal ducts and (2) insulated flexible ducts with air-porous liners. For a 50 mm thick, 12 kg/m<sup>3</sup> fibrous glass blanket compressed 50% during installation, the heat transfer rate increases approximately 20% (see Figure 13A). Pervious flexible duct liners also influence heat transfer significantly (see Figure 13B). At 12.7 m/s, the pervious liner U-factor is 1.87 W/(m<sup>2</sup>·K); for an impervious liner,  $U = 1.08$  W/(m<sup>2</sup>·K).

**Example 6.** A 20 m length of 600 mm by 900 mm uninsulated sheet metal duct, freely suspended, conveys heated air through a space maintained above freezing at 5°C. Based on heat loss calculations for the heated zone, 8100 L/s of standard air [ $c_p = 1.006$  kJ/(kg·K)] at a supply air temperature of 50°C is required. The duct is connected directly to the heated zone. Determine the temperature of the air entering the duct and the duct heat loss.

**Solution:** Calculate duct velocity using Equation (10):

$$V = \frac{1000 \times 8100 \text{ L/s}}{600 \text{ mm} \times 900 \text{ mm}} = 15 \text{ m/s}$$

Calculate entering air temperature using Equation (40):

$$U = 4.16 \text{ W/(m}^2 \cdot \text{K)} \text{ (from Figure 13A)}$$

$$P = 2(600 + 900) = 3000 \text{ mm}$$

$$y = \frac{2.0(600 \text{ mm})(900 \text{ mm})(15 \text{ m/s})(1.204 \text{ kg/m}^3)(1.006)}{4.16 \text{ W/(m}^2 \cdot \text{K)} \times 3000 \text{ mm} \times 20 \text{ m}} = 78.6$$

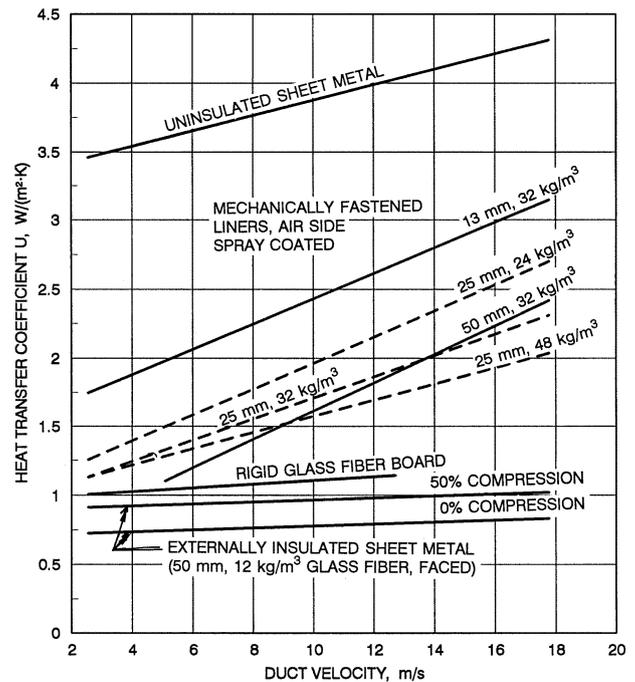

$$t_e = \frac{50^\circ\text{C}(78.6 + 1) - (2 \times 5^\circ\text{C})}{(78.6 - 1)} = 51.2^\circ\text{C}$$

Calculate duct heat loss using Equation (39):

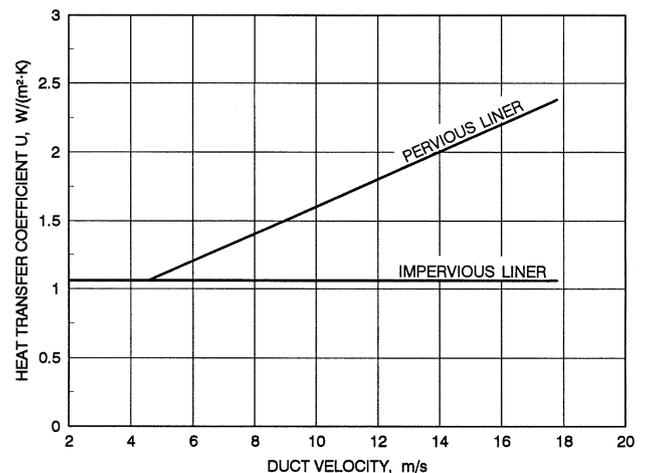

$$q_l = \frac{4.16 \text{ W/(m}^2 \cdot \text{K)} \times 3000 \text{ mm} \times 20 \text{ m}}{1000} \times \left[ \frac{51.2^\circ\text{C} + 50^\circ\text{C}}{2} - 5^\circ\text{C} \right] = 11400 \text{ W}$$

**Example 7.** Same as Example 6, except the duct is insulated externally with 50 mm thick fibrous glass with a density of 12 kg/m<sup>3</sup>. The insulation is wrapped with 0% compression.

**Solution:** All values except  $U$  remain the same as in Example 6. From Figure 13A,  $U = 0.83$  W/(m<sup>2</sup>·K) at 15 m/s. Therefore,

A. RIGID DUCTS

B. INSULATED FLEXIBLE DUCTS

**Fig. 13 Duct Heat Transfer Coefficients**

$$y = 394$$

$$t_e = 50.2^\circ\text{C}$$

$$q_l = 2250 \text{ W}$$

Insulating this duct reduces heat loss to 20% of the uninsulated value.

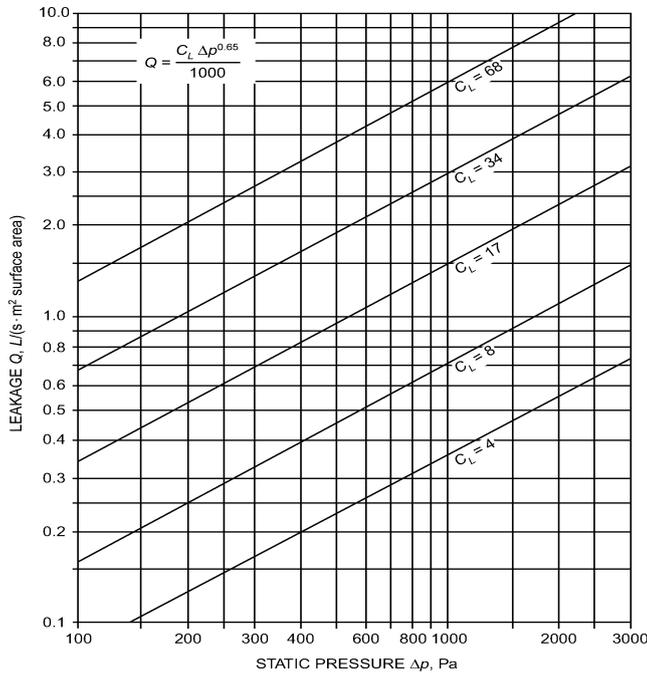

### Duct System Leakage

Leakage in all unsealed ducts varies considerably with the fabricating machinery used, the methods for assembly, and installation workmanship. For sealed ducts, a wide variety of sealing methods and products exists. Sealed and unsealed duct leakage tests (AISI/SMACNA 1972, ASHRAE/SMACNA/TIMA 1985, Swim and Griggs 1995) have confirmed that longitudinal seam, transverse joint, and assembled duct leakage can be represented by Equation (42) and that for the same construction, leakage is not significantly different in the negative and positive modes. A range of leakage rates

**Table 5 Unsealed Longitudinal Seam Leakage, Metal Ducts**

Type of Duct/Seam	Leakage, L/s per metre Seam Length <sup>a</sup>	
	Range	Average
Rectangular		
Pittsburgh lock	0.015 to 0.87	0.25
Button punch snaplock	0.015 to 0.25	0.10
Round		
Snaplock	0.06 to 0.22	0.17
Grooved	0.17 to 0.28	0.19

<sup>a</sup>Leakage rate is at 250 Pa static pressure.

**Fig. 14 Duct Leakage Classifications**

for longitudinal seams commonly used in the construction of metal ducts is presented in Table 5. Longitudinal seam leakage for unsealed or unwelded metal ducts is about 10 to 15% of total duct leakage.

$$Q = C \Delta p_s^N \quad (42)$$

where

- Q = duct leakage rate, L/s per m<sup>2</sup>
- C = constant reflecting area characteristics of leakage path
- Δp<sub>s</sub> = static pressure differential from duct interior to exterior, Pa
- N = exponent relating turbulent or laminar flow in leakage path

Analysis of the AISI/ASHRAE/SMACNA/TIMA data resulted in the categorization of duct systems into **leakage classes** C<sub>L</sub> based on Equation (43), where the exponent N is assumed to be 0.65. A selected series of leakage classes based on Equation (43) is shown in Figure 14.

$$C_L = \frac{1000Q}{\Delta p_s^{0.65}} \quad (43)$$

where

- Q = leakage rate, L/s per m<sup>2</sup> (surface area)
- C<sub>L</sub> = leakage class, mL/s·m<sup>2</sup> at 1 Pa

**Table 6 Duct Leakage Classification<sup>a</sup>**

Duct Type	Sealed <sup>b,c</sup>		Unsealed <sup>c</sup>	
	Predicted Leakage Class C <sub>L</sub>	Leakage Rate, L/(s·m <sup>2</sup> ) at 250 Pa	Predicted Leakage Class C <sub>L</sub>	Leakage Rate, L/(s·m <sup>2</sup> ) at 250 Pa
Metal (flexible excluded)				
Round and flat oval	4	0.14	42 (8 to 99)	1.5 (0.3 to 3.6)
Rectangular				
≤ 500 Pa (both positive and negative pressures)	17	0.62	68 (17 to 155)	2.5 (0.6 to 5.6)
> 500 and ≤ 2500 Pa (both positive and negative pressures)	8	0.29	68 (17 to 155)	2.5 (0.6 to 5.6)
Flexible				
Metal, Aluminum	11	0.40	42 (17 to 76)	1.5 (0.6 to 2.8)
Nonmetal	17	0.62	30 (6 to 76)	1.5 (0.2 to 2.8)
Fibrous glass				
Round	4	0.14	na	na
Rectangular	8	0.29	na	na

<sup>a</sup>The leakage classes listed in this table are averages based on tests conducted by AISI/SMACNA (1972), ASHRAE/SMACNA/TIMA (1985), and Swim and Griggs (1995).

<sup>b</sup>The leakage classes listed in the sealed category are based on the assumptions that for metal ducts, all transverse joints, seams, and openings in the duct wall are sealed at pressures over 750 Pa, that transverse joints and longitudinal seams are sealed at 500 and 750 Pa, and that transverse joints are sealed below 500 Pa. Lower leakage classes are obtained by careful selection of joints and sealing methods.

<sup>c</sup>Leakage classes assigned anticipate about 0.82 joints per metre of duct. For systems with a high fitting to straight duct ratio, greater leakage occurs in both the sealed and unsealed conditions.

Table 6 is a forecast of the leakage class attainable for commonly used duct construction and sealing practices. Connections of ducts to grilles, diffusers, and registers are not represented in the test data. Leakage classes listed are for a specific duct type, not a system with a variety of duct types, access doors, and other duct-mounted equipment. The designer is responsible for assigning acceptable system leakage rates. It is recommended that this be accomplished by using Table 7 as a guideline to specify a ductwork leakage class or by specifying a duct seal level as recommended by Table 8. The designer should take into account attainable leakage rates by duct type and the fact that casings of volume-controlling air terminal units may leak 1 to 2% of their maximum flow. The effects of such leakage should be anticipated, if allowed, and the ductwork should not be expected to compensate for equipment leakage. When a system leakage class is specified by a designer, it is a performance specification that should not be compromised by prescriptive sealing. A portion of a system may exceed its leakage class if the aggregate system leakage meets the allowable rate. Table 9 can be used to estimate the system percent leakage based on the system design leakage class and system duct surface area. Table 9 is predicated on assessment at an average of upstream and downstream pressures because use of the highest pressure alone could indicate an artificially high rate. When several duct pressure classifications occur in a system, ductwork in each pressure class should be evaluated independently to arrive at an aggregate leakage for the system.

Leakage tests should be conducted in compliance with SMACNA's *HVAC Air Duct Leakage Test Manual* (1985) to verify the intent of the designer and the workmanship of the the installing contractor. Leakage tests used to confirm leakage class should be conducted at the pressure class for which the duct is constructed. Leakage testing is also addressed in ASHRAE *Standard* 90.1.

Limited performance standards for metal duct sealants and tapes exist. For guidance in their selection and use refer to SMACNA's *HVAC Duct Construction Standards* (1995). Fibrous glass ducts and their closure systems are covered by UL *Standards* 181 and 181A.

**Table 7 Recommended Ductwork Leakage Class by Duct Type**

Duct Type	Leakage Class	Leakage Rate, L/(s·m <sup>2</sup> ) at 250 Pa
Metal		
Round	4	0.14
Flat oval	4	0.14
Rectangular	8	0.29
Flexible	8	0.29
Fibrous glass		
Round	4	0.14
Rectangular	8	0.29

**Table 8A Recommended Duct Seal Levels<sup>a</sup>**

Duct Location	Duct Type			
	Supply		Exhaust	Return
	≤ 500 Pa	> 500 Pa		
Outdoors	A	A	A	A
Unconditioned spaces	B	A	B	B
Conditioned spaces (concealed ductwork)	C	B	B	C
Conditioned spaces (exposed ductwork)	A	A	B	B

<sup>a</sup>See Table 8B for definition of seal level.

**Table 8B Duct Seal Levels**

Seal Level	Sealing Requirements <sup>a</sup>
A	All transverse joints, longitudinal seams, and duct wall penetrations
B	All transverse joints and longitudinal seams
C	Transverse joints only

<sup>a</sup>Transverse joints are connections of two duct or fitting elements oriented perpendicular to flow. Longitudinal seams are joints oriented in the direction of airflow. Duct wall penetrations are openings made by screws, non-self-sealing fasteners, pipe, tubing, rods, and wire. Round and flat oval spiral lock seams need not be sealed prior to assembly, but may be coated after assembly to reduce leakage. All other connections are considered transverse joints, including but not limited to spin-ins, taps and other branch connections, access door frames, and duct connections to equipment.

For fibrous glass duct construction standards consult NAIMA (1997) and SMACNA (1992). Flexible duct performance and installation standards are covered by UL 181, UL 181B and ADC (1996). Soldered or welded duct construction is necessary where sealants are not suitable. Sealants used on exterior ducts must be resistant to weather, temperature cycles, sunlight, and ozone.

Shaft and compartment pressure changes affect duct leakage and are important to health and safety in the design and operation of contaminant and smoke control systems. Shafts should not be used for supply, return, and/or exhaust air without accounting for their leakage rates. Airflow around buildings, building component leakage, and the distribution of inside and outside pressures over the height of a building, including shafts, are discussed in Chapters 16 and 26. Smoke management system design is covered in Chapter 51 of the 1999 *ASHRAE Handbook—Applications* and in Klote and Milke (1992).

**System Component Design Velocities**

Table 10 summarizes face velocities for HVAC components in built-up systems. In most cases, the values are abstracted from pertinent chapters in the 2000 *ASHRAE Handbook—Systems and Equipment*; final selection of the components should be based on data in these chapters or from manufacturers.

**Table 9 Leakage as Percentage of Airflow<sup>a,b</sup>**

Leakage Class	System L/s per m <sup>2</sup> Duct Surface <sup>c</sup>	Static Pressure, Pa						
		125	250	500	750	1000	1500

<sup>a</sup>Adapted with permission from HVAC *Air Duct Leakage Test Manual* (SMACNA 1985, Appendix A).

<sup>b</sup>Percentage applies to the airflow entering a section of duct operating at an assumed pressure equal to the average of the upstream and downstream pressures.

<sup>c</sup>The ratios in this column are typical of fan volumetric flow rate divided by total system surface. Portions of the systems may vary from these averages.

Louvers require special treatment since the blade shapes, angles, and spacing cause significant variations in louver-free area and performance (pressure drop and water penetration). Selection and analysis should be based on test data obtained in accordance with AMCA *Standard 500-L* (1999). This standard presents both pressure drop and water penetration test procedures and a uniform method for calculating the free area of a louver. Tests are conducted on a 1220 mm square louver with the frame mounted flush in the wall. For the water penetration tests, the rainfall is 100 mm/h, no wind, and the water flow down the wall is 0.05 L/s per linear metre of louver width.

Use Figure 15 for preliminary sizing of air intake and exhaust louvers. For air quantities greater than 3300 L/s per louver, the air intake gross louver openings are based on 2 m/s; for exhaust louvers, 2.5 m/s is used for air quantities of 2400 L/s per louver and greater. For air quantities less than these, refer to Figure 15. These criteria are presented on a per louver basis (i.e., each louver in a bank of louvers) to include each louver frame. Representative production-run louvers were used in establishing Figure 15, and all data used in that analysis are based on AMCA standard tests. For louvers larger than 1.5 m<sup>2</sup>, the free areas are greater than 45%, while for louvers less than 1.5 m<sup>2</sup>, the free areas are less than 45%. Unless specific louver data are analyzed, no louver should have a face area less than 0.4 m<sup>2</sup>. If debris collection on the screen of an intake louver is possible, or if louvers are located at grade with adjacent pedestrian traffic, louver face velocity should not exceed 0.5 m/s.

**System and Duct Noise**

The major sources of noise from air-conditioning systems are diffusers, grilles, fans, ducts, fittings, and vibrations. Chapter 46 of the 1999 *ASHRAE Handbook—Applications* discusses sound control for each of these sources. Sound control for terminal devices

**Table 10 Typical Design Velocities for HVAC Components**

<sup>e</sup>Abstracted from Chapter 19, 2000 ASHRAE Handbook—Systems and Equipment.

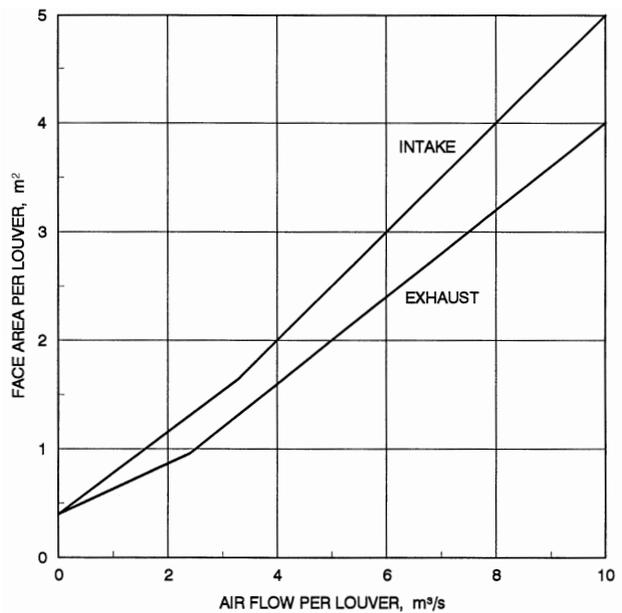

consists of selecting devices that meet the design goal under all operating conditions and installing them properly so that no additional sound is generated. The sound power output of a fan is determined by the type of fan, airflow, and pressure. Sound control in the duct system requires proper duct layout, sizing, and provision for installing duct attenuators, if required. The noise generated by a system increases with both duct velocity and system pressure. Chapter 46 of the 1999 ASHRAE Handbook—Applications presents methods for calculating required sound attenuation.

**Testing and Balancing**

Each air duct system should be tested, adjusted, and balanced. Detailed procedures are given in Chapter 36 of the 1999 ASHRAE Handbook—Applications. To properly determine fan total (or static) pressure from field measurements taking into account fan system effect, refer to the section on Fan-System Interface. Equation (38) allows direct comparison of system resistance to design calculations and/or fan performance data. It is important that the system effect magnitudes be known prior to testing. If necessary, use Equation (18) to calculate fan static pressure knowing fan total pressure [Equation (38)]. For TAB calculation procedures of numerous fan/system configurations encountered in the field, refer to AMCA Publication 203 (AMCA 1990b).

**DUCT DESIGN METHODS**

Duct design methods for HVAC systems and for exhaust systems conveying vapors, gases, and smoke are the equal friction method,

Parameters Used to Establish Figure	Intake Louver	Exhaust Louver
Minimum free area (1220 mm square test section), %	45	45
Water penetration, $\mu\text{L}/(\text{m}^2 \cdot \text{s})$	Negligible (less than 0.6)	na
Maximum static pressure drop, Pa	35	60

**Fig. 15 Criteria for Louver Sizing**

the static regain method, and the T-method. The section on Industrial Exhaust System Duct Design presents the design criteria and procedures for exhaust systems conveying particulates. Equal friction and static regain are nonoptimizing methods, while the T-method is a practical optimization method introduced by Tsai et al. (1988).

To ensure that system designs are acoustically acceptable, noise generation should be analyzed and sound attenuators and/or acoustically lined duct provided where necessary. Dampers must be installed throughout systems designed by equal friction, static regain, and the T-method because inaccuracies are introduced into these design methods by duct size round-off and the effect of close-coupled fittings on the total pressure loss calculations.

**Equal Friction Method**

In the equal friction method, ducts are sized for a constant pressure loss per unit length. The shaded area of the friction chart (Figure 9) is the suggested range of friction rate and air velocity. When energy cost is high and installed ductwork cost is low, a low friction rate design is more economical. For low energy cost and high duct cost, a higher friction rate is more economical. After initial sizing, calculate the total pressure loss for all duct sections, and then resize sections to balance pressure losses at each junction.

**Static Regain Method**

The objective of the static regain method is to obtain the same static pressure at diverging flow junctions by changing downstream duct sizes. This design objective can be developed by rearranging Equation (7a) and setting  $p_{s,2}$  equal to  $p_{s,1}$  (neglecting thermal gravity effect term). Thus,

$$p_{s,1} - p_{s,2} = \Delta p_{t,1-2} - \left[ \frac{\rho V_1^2}{2} - \frac{\rho V_2^2}{2} \right] \quad (44)$$

and

$$\Delta p_{t,1-2} = \frac{\rho V_1^2}{2} - \frac{\rho V_2^2}{2} \quad (45)$$

where  $\Delta p_{t,1-2}$  is the total pressure loss from upstream of junction 1 to upstream of junction 2, or the terminal of section 2. The immediate downstream duct size that satisfies Equation (45) is determined by iteration.

To start the design of a system, a maximum velocity is selected for the root section (duct section upstream and/or downstream of a fan). In Figure 17, section 6 is the root for the return air subsystem. Section 19 is the root for the supply air subsystem. The shaded area on the friction chart (Figure 9) is the suggested range of air velocity. When energy cost is high and installed ductwork cost is low, a lower initial velocity is more economical. For low energy cost and high duct cost, a higher velocity is more economical. All other sections, except terminal sections, are sized iteratively by Equation (45). In Figure 17, terminal sections are 1, 2, 4, 7, 8, 11, 12, 15, and 16. Knowing the terminal static pressure requirements, Equation (45) is used to calculate the duct size of terminal sections. If the terminal is an exit fitting rather than a register, diffuser, or terminal box, the static pressure at the exit of the terminal section is zero.

The classical static regain method (Carrier Corporation 1960, Chun-Lun 1983) is based on Equation (46), where  $R$  is the static pressure regain factor, and  $\Delta p_r$  is the static pressure regain between junctions.

$$\Delta p_r = R \left( \frac{\rho V_1^2}{2} - \frac{\rho V_2^2}{2} \right) \quad (46)$$

Typically  $R$ -values ranging from 0.5 to 0.95 have been used. Tsal and Behls (1988) show that this uncertainty exists because the splitting of mass at junctions and the dynamic (fitting) losses between junctions are ignored. The classical static regain method using an  $R$ -value should not be used because  $R$  is not predictable.

### T-Method Optimization

T-method optimization (Tsal et al. 1988) is a dynamic programming procedure based on the tee-staging idea used by Bellman (1957), except that phase level vector tracing is eliminated by optimizing locally at each stage. This modification reduces the number of calculations but requires iteration.

**Optimization Basis.** The objective function, Equation (47), includes both initial system cost and the present worth of energy. Hours of operation, annual escalation and interest rates, and amortization period are also required for optimization.

$$E = E_p(\text{PWEF}) + E_s \quad (47)$$

where

- $E$  = present worth owning and operating cost
- $E_p$  = first year energy cost
- $E_s$  = initial cost

PWEF = present worth escalation factor (Smith 1968), dimensionless

Energy cost is determined by

$$E_p = Q_f \left[ \frac{(E_d + E_c T)}{10^6 \eta_f \eta_e} \right] P_t \quad (48)$$

where

- $Q_f$  = fan airflow rate, L/s
- $E_c$  = unit energy cost, cost/kWh
- $E_d$  = energy demand cost, cost/kWh
- $T$  = system operating time, h/year
- $P_t$  = fan total pressure, Pa
- $\eta_f$  = fan total efficiency, decimal
- $\eta_e$  = motor-drive efficiency, decimal

Energy cost depends on both applicable energy rates  $E_c$  and demand cost  $E_d$ . Since the difference in fan pressure between an optimized and a nonoptimized system is a small part of demand, it is usually neglected. Initial cost includes ducts and HVAC equipment, which is primarily the central handling unit. The cost of duct systems is given by the following equations:

$$\text{Round} \quad E_s = S_d \pi D L / 1000 \quad (49)$$

$$\text{Rectangular} \quad E_s = 2 S_d (H + W) L / 1000 \quad (50)$$

where

- $S_d$  = unit ductwork cost/m<sup>2</sup> (including material and labor)
- $H$  = duct height, mm
- $W$  = duct width, mm
- $L$  = duct length, m

The cost of space required by ducts and equipment is another important factor of duct optimization. Including this cost reduces the size of ducts, thereby increasing energy consumption. Because the space available for ductwork is usually not used for anything else, its cost is ignored.

Both electrical energy rates and ductwork costs vary widely, by a factor of up to eight times for industrial users (DOE). Black iron rectangular ductwork can cost about 3.9 times that of spiral ductwork (Wendes 1989). Combining these ratios yields a factor of 30 to 1 based on locale and type of ductwork. Therefore, a great potential exists for reducing duct system life-cycle cost due to energy and ductwork cost variations.

The following constraints are necessary for duct optimization (Tsal and Adler 1987):

- *Continuity.* For each node, the flow in equals the flow out.
- *Pressure balancing.* The total pressure loss in each path must equal the fan total pressure; or, in effect, at any junction, the total pressure loss for all paths is the same.
- *Nominal duct size.* Ducts are constructed in discrete, nominal sizes. Each diameter of a round duct or height and width of a rectangular duct is rounded to the nearest increment, usually 25 or 50 mm. If a lower nominal size is selected, the initial cost decreases, but the pressure loss increases and may exceed the fan pressure. If the higher nominal size is selected, the opposite is true—the initial cost increases, but the section pressure loss decreases. However, this lower pressure at one section may allow smaller ducts to be selected for sections that follow. Therefore, optimization must consider size rounding.
- *Air velocity restriction.* The maximum allowable velocity is an acoustic limitation (ductwork regenerated noise).
- *Construction restriction.* Architectural limits may restrict duct sizes. If air velocity or construction constraints are violated during an iteration, a duct size must be calculated. The pressure loss calculated for this preselected duct size is considered a fixed loss.

**Calculation Procedure.** The T-method comprises the following major procedures:

- *System condensing.* This procedure condenses a multiple-section duct system into a single imaginary duct section with identical hydraulic characteristics and the same owning cost as the entire system. By Equation (1.41) in Tsal et al. (1988), two or more converging or diverging sections and the common section at a junction can be replaced by one condensed section. By applying this equation from junction to junction in the direction to the root section (fan), the entire supply and return systems can be condensed into one section (a single resistance).
- *Fan selection.* From the condensed system, the ideal optimum fan total pressure  $P_t^{opt}$  is calculated and used to select a fan. If a fan with a different pressure is selected, its pressure  $P^{opt}$  is considered optimum.
- *System expansion.* The expansion process distributes the available fan pressure  $P^{opt}$  throughout the system. Unlike the condensing procedure, the expansion procedure starts at the root section and continues in the direction of the terminals.

**Economic Analysis.** Tsal et al. (1988) describe the calculation procedure and include an economic analysis of the T-method.

### T-Method Simulation

T-method simulation, also developed by Tsal et al. (1990), determines the flow in each duct section of an existing system with a known operating fan performance curve. The simulation version of the T-method converges very efficiently. Usually three iterations are sufficient to obtain a solution with a high degree of accuracy.

**Calculation procedure.** The simulation version of the T-method includes the following major procedures:

- *System condensing.* This procedure condenses a branched tee system into a single imaginary duct section with identical hydraulic characteristics. Two or more converging or diverging sections and the common section at a junction can be replaced by one condensed section [by Equation (18) in Tsal et al. (1990)]. By applying this equation from junction to junction in the direction to the root section (fan), the entire system, including supply and return subsystems, can be condensed into one imaginary section (a single resistance).
- *Fan operating point.* This step determines the system flow and pressure by locating the intersection of the fan performance and system curves, where the system curve is represented by the imaginary section from the last step.
- *System expansion.* Knowing system flow and pressure, the previously condensed imaginary duct section is expanded into the original system with flow distributed in accordance with the ratio of pressure losses calculated in the system condensing step.

**Simulation Applications.** The need for duct system simulation appears in many HVAC problems. In addition to the following concerns that can be clarified by simulation, the T-method is an excellent design tool for simulating the flow distribution within a system with various modes of operation.

- Flow distribution in a variable air volume (VAV) system due to terminal box flow diversity
- Airflow redistribution due to HVAC system additions and/or modifications
- System airflow analysis for partially occupied buildings
- Necessity to replace fans and/or motors when retrofitting an air distribution system
- Multiple-fan system operating condition when one or more fans shut down
- Pressure differences between adjacent confined spaces within a nuclear facility when a design basis accident (DBA) occurs (Farajian et al. 1992)
- Smoke management system performance during a fire, when certain fire/smoke dampers close and others remain open

### HVAC DUCT DESIGN PROCEDURES

The general procedure for HVAC system duct design is as follows:

1. Study the building plans, and arrange the supply and return outlets to provide proper distribution of air within each space. Adjust calculated air quantities for duct heat gains or losses and duct leakage. Also, adjust the supply, return, and/or exhaust air quantities to meet space pressurization requirements.
2. Select outlet sizes from manufacturers' data (see Chapter 32).
3. Sketch the duct system, connecting supply outlets and return intakes with the air-handling units/air conditioners. Space allocated for supply and return ducts often dictates system layout and ductwork shape. Use round ducts whenever feasible and avoid close-coupled fittings.
4. Divide the system into sections and number each section. A duct system should be divided at all points where flow, size, or shape changes. Assign fittings to the section toward the supply and return (or exhaust) terminals. The following examples are for the fittings identified for Example 6 (Figure 16), and system section numbers assigned (Figure 17). For converging flow fitting 3, assign the straight-through flow to section 1 (toward terminal 1), and the branch to section 2 (toward terminal 4). For diverging flow fitting 24, assign the straight-through flow to section 13 (toward terminals 26 and 29) and the branch to section 10 (toward terminals 43 and 44). For transition fitting 11, assign the fitting to upstream section 4 [toward terminal 9 (intake louver)]. For fitting 20, assign the unequal area elbow to downstream section 9 (toward diffusers 43 and 44). The fan outlet diffuser, fitting 42, is assigned to section 19 (again, toward the supply duct terminals).
5. Size ducts by the selected design method. Calculate system total pressure loss; then select the fan (refer to Chapter 18 of the 2000 *ASHRAE Handbook—Systems and Equipment*).
6. Lay out the system in detail. If duct routing and fittings vary significantly from the original design, recalculate the pressure losses. Reselect the fan if necessary.
7. Resize duct sections to approximately balance pressures at each junction.
8. Analyze the design for objectionable noise levels, and specify sound attenuators as necessary. Refer to the section on System and Duct Noise.

**Example 8.** For the system illustrated by Figures 16 and 17, size the ductwork by the equal friction method, and pressure balance the system by changing duct sizes (use 10 mm increments). Determine the system resistance and total pressure unbalance at the junctions. The airflow quantities are actual values adjusted for heat gains or losses, and ductwork is sealed (assume no leakage), galvanized steel ducts with transverse joints on 1200 mm centers ( $\epsilon = 0.09$  mm). Air is at 1.204 kg/m<sup>3</sup> density.

Because the primary purpose of Figure 16 is to illustrate calculation procedures, its duct layout is not typical of any real duct system. The layout includes fittings from the local loss coefficient tables, with emphasis on converging and diverging tees and various types of entries and discharges. The supply system is constructed of rectangular ductwork; the return system, round ductwork.

**Solution:** See Figure 17 for section numbers assigned to the system. The duct sections are sized within the suggested range of friction rate shown on the friction chart (Figure 9). Tables 11 and 12 give the total pressure loss calculations and the supporting summary of loss coefficients by sections. The straight duct friction factor and pressure loss were calculated by Equations (19) and (20). The fitting loss coefficients are from the *Duct Fitting Database* (ASHRAE 1994). Loss coefficients were calculated automatically by the database program (not by manual interpolation). The pressure loss values in Table 11 for the diffusers (fittings 43 and 44), the louver (fitting 9), and the air-measuring station (fitting 46) are manufacturers' data.

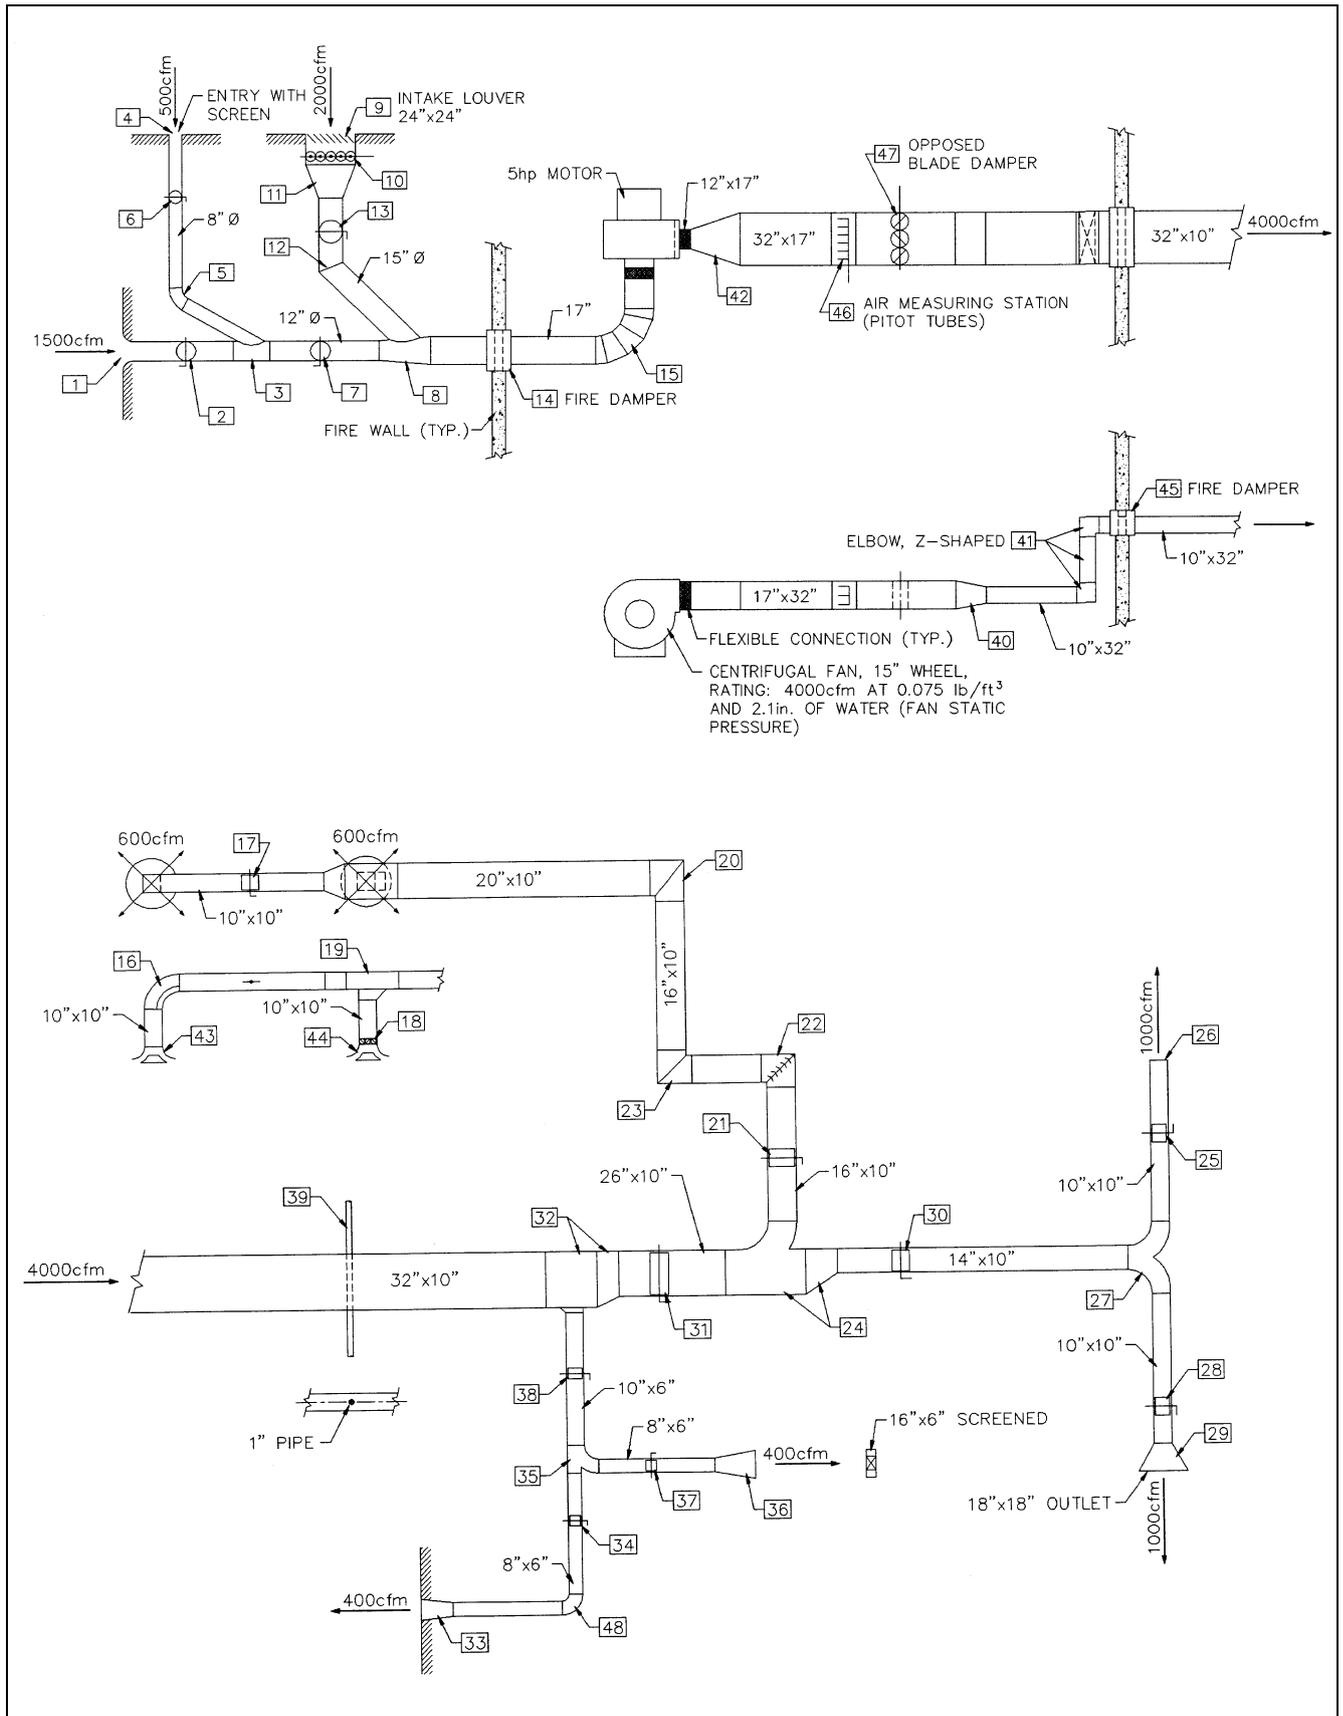

Fig. 16 Schematic for Example 8

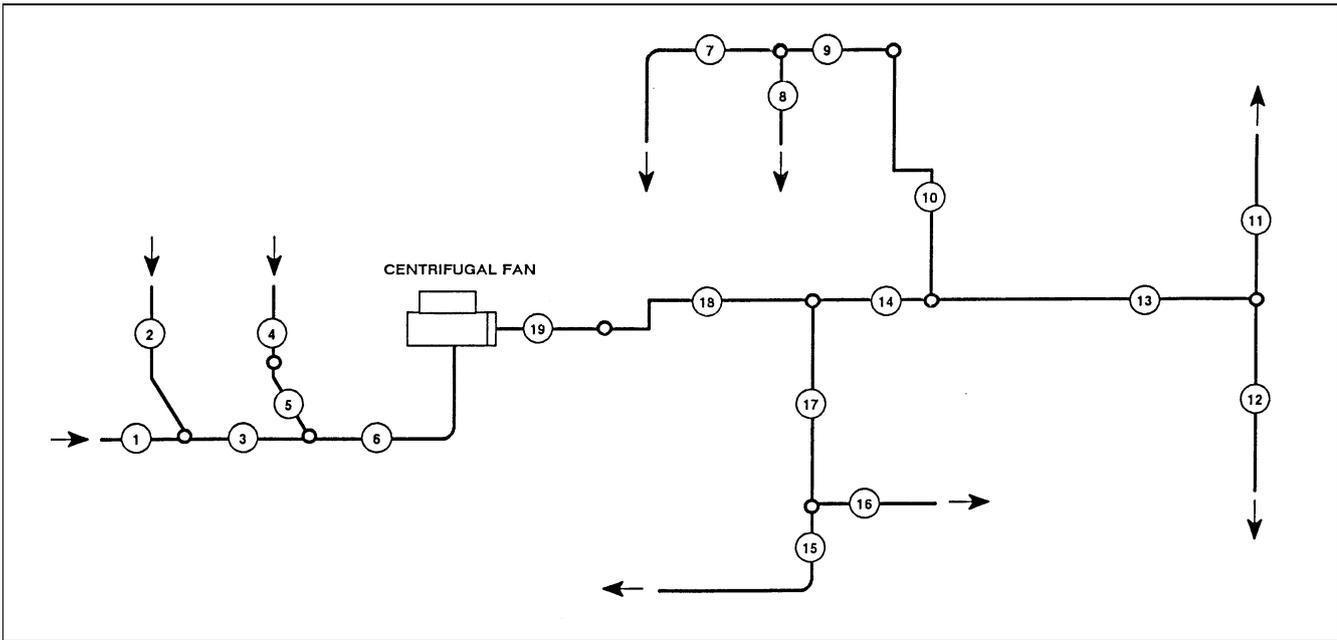

Fig. 17 System Schematic with Section Numbers for Example 8

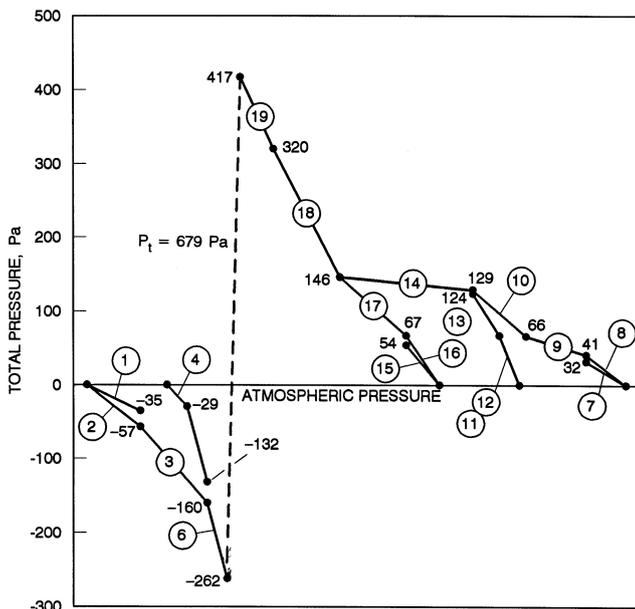

Fig. 18 Total Pressure Grade Line for Example 8

The pressure unbalance at the junctions may be noted by referring to Figure 18, the total pressure grade line for the system. The system resistance  $P_t$  is 679 Pa. Noise levels and the need for duct silencers were not evaluated. To calculate the fan static pressure, use Equation (18):

$$P_s = 679 - 119 = 560 \text{ Pa}$$

where 119 Pa is the fan outlet velocity pressure.

### INDUSTRIAL EXHAUST SYSTEM DUCT DESIGN

Chapter 29 of the 1999 ASHRAE Handbook—Applications discusses design criteria, including hood design, for industrial exhaust

systems. Exhaust systems conveying vapors, gases, and smoke can be designed by equal friction, or T-method. Systems conveying particulates are designed by the constant velocity method at duct velocities adequate to convey particles to the system air cleaner. For contaminant transport velocities, see Table 5 in Chapter 29 of the 1999 ASHRAE Handbook—Applications.

Two pressure-balancing methods can be considered when designing industrial exhaust systems. One method uses balancing devices (e.g., dampers, blast gates) to obtain design airflow through each hood. The other approach balances systems by adding resistance to ductwork sections (i.e., changing duct size, selecting different fittings, and increasing airflow). This self-balancing method is preferred, especially for systems conveying abrasive materials. Where potentially explosive or radioactive materials are conveyed, the prebalanced system is mandatory because contaminants could accumulate at the balancing devices. To balance systems by increasing airflow, use Equation (51), which assumes that all ductwork has the same diameter and that fitting loss coefficients, including main and branch tee coefficients, are constant.

$$Q_c = Q_d(P_h/P_l)^{0.5} \tag{51}$$

where

- $Q_c$  = airflow rate required to increase  $P_l$  to  $P_h$ , L/s
- $Q_d$  = total airflow rate through low-resistance duct run, L/s
- $P_h$  = absolute value of pressure loss in high-resistance ductwork section(s), Pa
- $P_l$  = absolute value of pressure loss in low-resistance ductwork section(s), Pa

For systems conveying particulates, use elbows with a large centerline radius-to-diameter ratio ( $r/D$ ), greater than 1.5 whenever possible. If  $r/D$  is 1.5 or less, abrasion in dust-handling systems can reduce the life of elbows. Elbows are often made of seven or more gores, especially in large diameters. For converging flow fittings, a 30° entry angle is recommended to minimize energy losses and abrasion in dust-handling systems. For the entry loss coefficients of hoods and equipment for specific operations, refer to Chapter 29 of the 1999 ASHRAE Handbook—Applications and to ACGIH (1998).

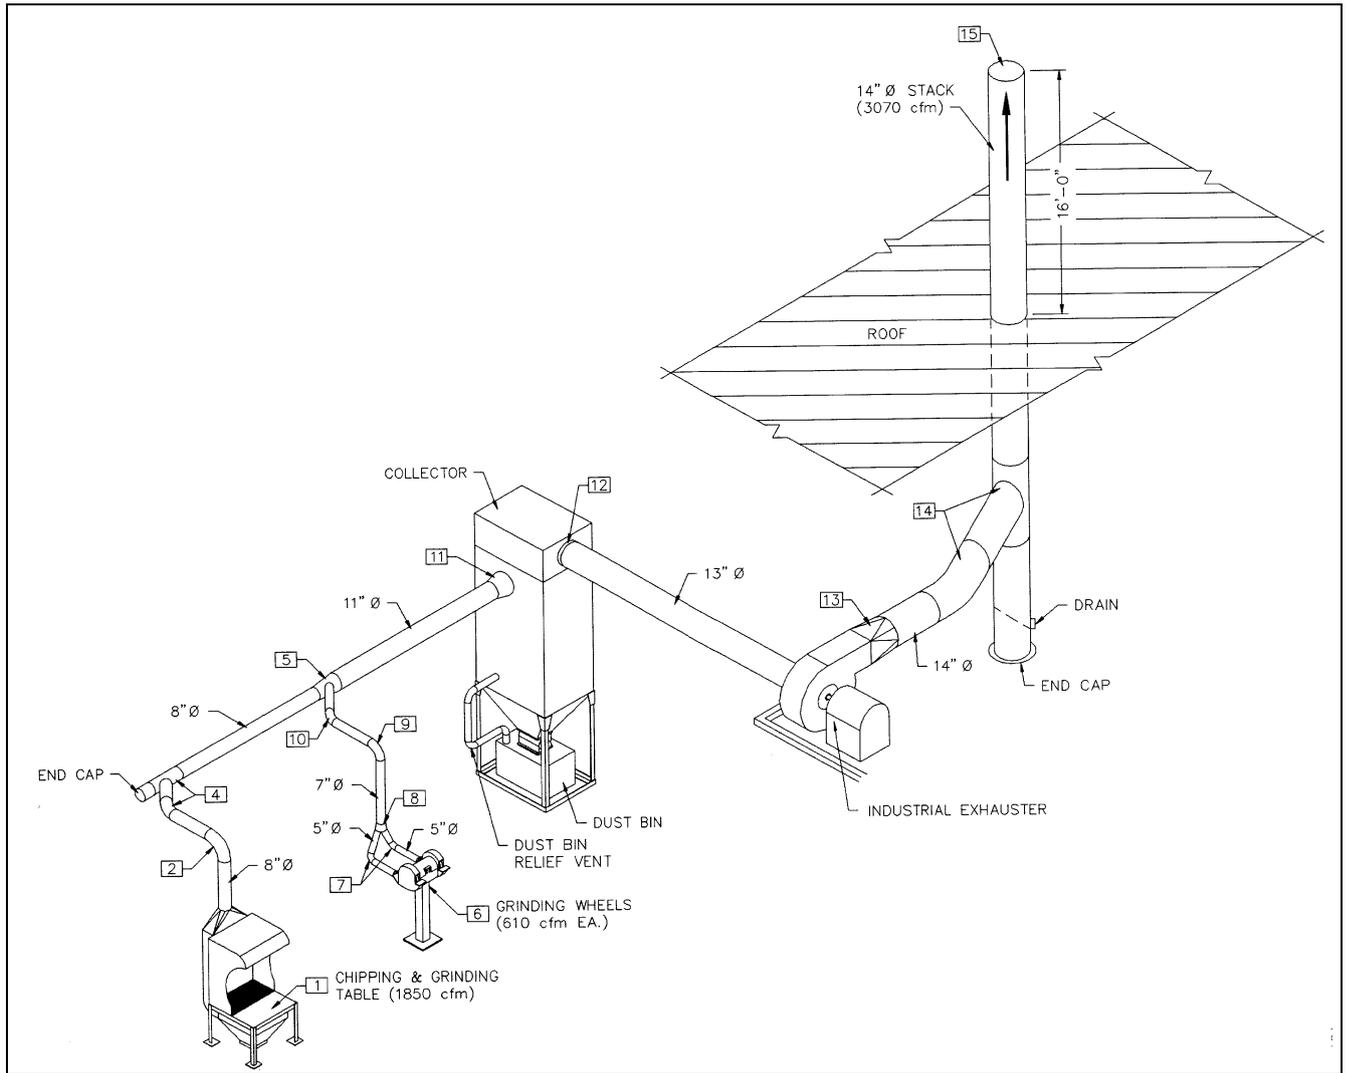

Fig. 19 Metalworking Exhaust System for Example 9

**Example 9.** For the metalworking exhaust system in Figures 19 and 20, size the ductwork and calculate the fan static pressure requirement for an industrial exhaust designed to convey granular materials. Pressure balance the system by changing duct sizes and adjusting airflow rates. The minimum particulate transport velocity for the chipping and grinding table ducts (sections 1 and 5, Figure 20) is 20 m/s. For the ducts associated with the grinder wheels (sections 2, 3, 4, and 5), the minimum duct velocity is 23 m/s. Ductwork is galvanized steel, with the absolute roughness being 0.09 mm. Assume standard air and use ISO diameter sizes, given in the following table:

Standard Circular Duct Diameters (ISO 1983)		
63	180	500
71	200	560
80	224	630
90	250	710
100	280	800
112	315	900
125	355	1000
140	400	1120
160	450	1250

Note: Dimensions listed are in millimetres.

The building is one story, and the design wind velocity is 9 m/s. For the stack, use Design J shown in Figure 13 in Chapter 16 for complete

<sup>a</sup>Duct Fitting Database (ASHRAE 1994) data for fittings reprinted in the section on Fitting Loss Coefficients.

rain protection. The stack height, determined by calculations from Chapter 16, is 4.9 m above the roof. This stack height is based on minimized stack downwash; therefore, the stack discharge velocity must exceed 1.5 times the design wind velocity.

**Solution:** For the contaminated ducts upstream of the collector, initial duct sizes and transport velocities are summarized below. The 22.8 m/s velocity in section 4 is acceptable because the transport velocity is not significantly lower than 23 m/s. For the next available duct size (160 mm diameter), the duct velocity is 28.8 m/s, significantly higher than 23 m/s.

Duct Section	Design Airflow, L/s	Transport Velocity, m/s	Duct Diameter, mm	Duct Velocity, m/s
1	850	20	224	21.6
2,3	290 each	23	125	23.6
4	580	23	180	22.8
5	1430	23	280	23.2

The following tabulation summarizes design calculations up through the junction after sections 1 and 4.

Design No.	D <sub>1</sub> , mm	Δp <sub>1</sub> , Pa	Δp <sub>2+4</sub> , Pa	Imbalance, Δp <sub>1</sub> - Δp <sub>2+4</sub>
1	224	411	794	-383
2	200	762	850	-88
3	180	1320	712	+609

- Q<sub>1</sub> = 850 L/s
- Q<sub>2</sub> = 290 L/s; D<sub>2</sub> = 125 mm dia.
- Q<sub>3</sub> = 290 L/s; D<sub>3</sub> = 125 mm dia.
- Q<sub>4</sub> = 850 L/s; D<sub>4</sub> = 180 mm dia.

For the initial design, Design 1, the imbalance between section 1 and section 2 (or 3) is 383 Pa, with section 1 requiring additional resistance. Decreasing section 1 duct diameter by ISO sizes results in the least imbalance, 88 Pa, when the duct diameter is 200 mm (Design 3). Because section 1 requires additional resistance, estimate the new airflow rate using Equation (51):

$$Q_{c,1} = 850(850/762)^{0.5} = 900 \text{ L/s}$$

At 900 L/s flow in section 1, 130 Pa imbalance remains at the junction of sections 1 and 4. By trial-and-error solution, balance is attained when the flow in section 1 is 860 L/s. The duct between the collector and the fan inlet is 355 mm round to match the fan inlet (340 mm diameter). To minimize downwash, the stack discharge velocity must exceed 13.5 m/s, 1.5 times the design wind velocity (9 m/s) as stated in the problem definition. Therefore, the stack is 355 mm round, and the stack discharge velocity is 14.5 m/s.

<sup>a</sup>See Figure 20.

<sup>b</sup>Duct lengths are to fitting centerlines.

<sup>c</sup>See Table 14.

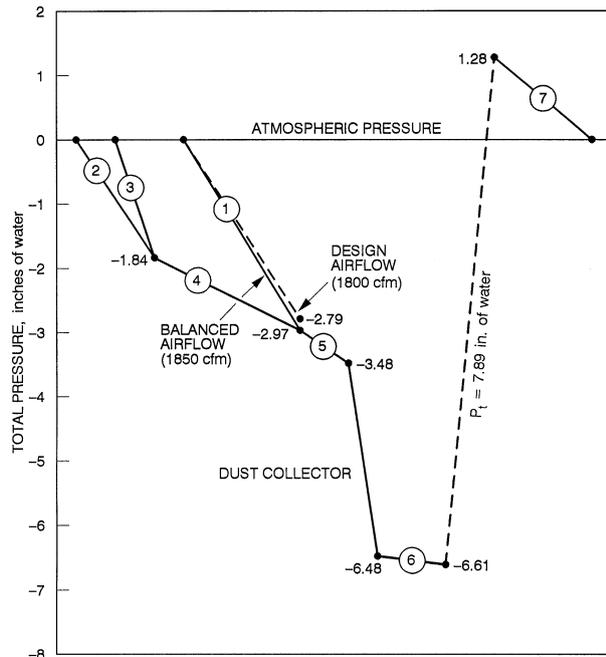

<sup>d</sup>Duct pressure based on a 0.09 mm absolute roughness factor.

Table 13 summarizes the system losses by sections. The straight duct friction factor and pressure loss were calculated by Equations (19) and (20). Table 14 lists fitting loss coefficients and input parameters necessary to determine the loss coefficients. The fitting loss coefficients are from the *Duct Fitting Database* (ASHRAE 1994). The fitting loss coefficient tables are included in the section on Fitting Loss Coefficients for illustration but can not be obtained exactly by manual interpolation since the coefficients were calculated by the duct fitting database algorithms (more significant figures). For a pressure grade line of the system, see Figure 21. The fan total pressure, calculated by Equation (16), is 1992 Pa. To calculate the fan static pressure, use Equation (18):

$$P_s = 1992 - 192 = 1800 \text{ Pa}$$

where 192 Pa is the fan outlet velocity pressure. The fan airflow rate is 1440 L/s, and its outlet area is 0.081 m<sup>2</sup> (260 mm by 310 mm). Therefore, the fan outlet velocity is 17.9 m/s.

The hood suction for the chipping and grinding table hood is 560 Pa, calculated by Equation (18) from Chapter 29 of the 1999 *ASHRAE Handbook—Applications* [ $HS = (1 + 0.25)(451) = 560 \text{ Pa}$ , where 0.25 is the

**Fig. 21 Total Pressure Grade Line for Example 9**

<sup>e</sup>Collector manufacturers set the fabric bag cleaning mechanism to actuate at a pressure difference of 750 Pa between the inlet and outlet plenums. The pressure difference across the clean media is approximately 400 Pa.

**T**HIS CHAPTER includes tables and charts to size piping for various fluid flow systems. Further details on specific piping systems can be found in appropriate chapters of the ASHRAE Handbook series.

Two related but distinct concerns emerge when designing a fluid flow system: sizing the pipe and determining the flow-pressure relationship. The two are often confused because they can use the same equations and design tools. Nevertheless, they should be determined separately.

The emphasis in this chapter is on the problem of sizing the pipe, and to this end design charts and tables for specific fluids are presented in addition to the equations that describe the flow of fluids in pipes. Once a system has been sized, it should be analyzed with more detailed methods of calculation to determine the pump pressure required to achieve the desired flow. Computerized methods are well suited to handling the details of calculating losses around an extensive system.

### PRESSURE DROP EQUATIONS

#### Darcy-Weisbach Equation

Pressure drop caused by fluid friction in fully developed flows of all “well-behaved” (Newtonian) fluids is described by the Darcy-Weisbach equation:

$$\Delta p = f \left( \frac{L}{D} \right) \left( \frac{\rho V^2}{2} \right) \quad (1)$$

where

- $\Delta p$  = pressure drop, Pa
- $f$  = friction factor, dimensionless (from Moody chart, Figure 13 in Chapter 2)
- $L$  = length of pipe, m
- $D$  = internal diameter of pipe, m
- $\rho$  = fluid density at mean temperature, kg/m<sup>3</sup>
- $V$  = average velocity, m/s

This equation is often presented in specific energy form as

$$\Delta h = \frac{\Delta p}{\rho g} = f \left( \frac{L}{D} \right) \left( \frac{V^2}{2g} \right) \quad (2)$$

where

- $\Delta h$  = energy loss, m
- $g$  = acceleration of gravity, m/s<sup>2</sup>

In this form, the density of the fluid does not appear explicitly (although it is in the Reynolds number, which influences  $f$ ).

---

The preparation of this chapter is assigned to TC 6.1, Hydronic and Steam Equipment and Systems.

The friction factor  $f$  is a function of pipe roughness  $\epsilon$ , inside diameter  $D$ , and parameter  $Re$ , the Reynolds number:

$$Re = DV\rho/\mu \quad (3)$$

where

- $Re$  = Reynolds number, dimensionless
- $\epsilon$  = absolute roughness of pipe wall, m
- $\mu$  = dynamic viscosity of fluid, Pa·s

The friction factor is frequently presented on a Moody chart (Figure 13 in Chapter 2) giving  $f$  as a function of  $Re$  with  $\epsilon/D$  as a parameter.

A useful fit of smooth and rough pipe data for the usual turbulent flow regime is the **Colebrook equation**:

$$\frac{1}{\sqrt{f}} = 1.74 - 2 \log \left( \frac{2\epsilon}{D} + \frac{18.7}{Re\sqrt{f}} \right) \quad (4)$$

Another form of Equation (4) appears in Chapter 2, but the two are equivalent. Equation (4) is more useful in showing behavior at limiting cases—as  $\epsilon/D$  approaches 0 (smooth limit), the  $18.7/Re\sqrt{f}$  term dominates; at high  $\epsilon/D$  and  $Re$  (fully rough limit), the  $2\epsilon/D$  term dominates.

Equation (4) is implicit in  $f$ ; that is,  $f$  appears on both sides, so a value for  $f$  is usually obtained iteratively.

#### Hazen-Williams Equation

A less widely used alternative to the Darcy-Weisbach formulation for calculating pressure drop is the Hazen-Williams equation, which is expressed as

$$\Delta p = 6.819L \left( \frac{V}{C} \right)^{1.852} \left( \frac{1}{D} \right)^{1.167} (\rho g) \quad (5)$$

or

$$\Delta h = 6.819L \left( \frac{V}{C} \right)^{1.852} \left( \frac{1}{D} \right)^{1.167} \quad (6)$$

where  $C$  = roughness factor.

Typical values of  $C$  are 150 for plastic pipe and copper tubing, 140 for new steel pipe, down to 100 and below for badly corroded or very rough pipe.

#### Valve and Fitting Losses

Valves and fittings cause pressure losses greater than those caused by the pipe alone. One formulation expresses losses as

$$\Delta p = K\rho \left( \frac{V^2}{2} \right) \quad \text{or} \quad \Delta h = K \left( \frac{V^2}{2g} \right) \quad (7)$$

where  $K$  = geometry- and size-dependent loss coefficient (Tables 1 through 5).

<sup>a</sup> Previous references are Freeman (1941), Crane Co. (1976), and Hydraulic Institute (1979). Numbers in ( ) are from Table 1 and Table 2, above.

**Example 1.** Determine the pressure drop for 15°C water flowing at 1 m/s through a nominal 25 mm, 90° threaded elbow.

**Solution:** From Table 1, the *K* for a 25 mm, 90° threaded elbow is 1.5.

$$\Delta p = 1.5 \times 1^2/2 = 750 \text{ Pa}$$

The loss coefficient for valves appears in another form as *A<sub>v</sub>*, a dimensional coefficient expressing the flow through a valve at a specified pressure drop.

$$Q = A_v \sqrt{\Delta p / \rho} \tag{8}$$

where

- Q* = volumetric flow, m<sup>3</sup>/s
- A<sub>v</sub>* = valve coefficient, m<sup>3</sup>/s at Δ*p* = 1 Pa
- Δ*p* = pressure drop, Pa
- ρ = density of fluid ≈ 1000 kg/m<sup>3</sup> for water at temperatures below 120°C

**Example 2.** Determine the volumetric flow through a valve with *A<sub>v</sub>* = 0.00024 for an allowable pressure drop of 35 kPa.

**Solution:**

$$Q = 0.00024 \sqrt{35\,000/1000} = 0.0014 \text{ m}^3/\text{s} = 1.4 \text{ L/s}$$

Alternative formulations express fitting losses in terms of equivalent lengths of straight pipe (Table 6, Table 7, and Figure 4). Pressure loss data for fittings are also presented in Idelchik (1986).

Equation (7) and the data in Table 1 and Table 2 are based on the assumption that separated flow in the fitting causes the *K* factors to be independent of Reynolds number. In reality, the *K* factor for most pipe fittings varies with Reynolds number. Tests by Rahmeyer (1999a,b) (sponsored as ASHRAE *Research Project 968*) on 50 mm threaded and 100 mm welded fittings demonstrate the variation and are shown in Table 4 and Table 5. The study also presents *K* factors of diverting and mixing flows that range between full through flow and full branch flow. It also examined the variation in *K* factors caused by variations in geometry among manufacturers and by surface defects in individual fittings.

Hegberg (1995) and Rahmeyer (1999a,b) discuss the origins of the data shown in Table 4 and Table 5. The Hydraulic Institute (1979) data appear to have come from Freeman (1941), work that was actually performed in 1895. The work of Giesecke (1926) and Giesecke and Badgett (1931, 1932a,b) may not be representative of present-day fittings.

### Calculating Pressure Losses

The most common engineering design flow loss calculation selects a pipe size for the desired total flow rate and available or allowable pressure drop.

Because either formulation of fitting losses requires a known diameter, pipe size must be selected before calculating the detailed influence of fittings. A frequently used rule of thumb assumes that the design length of pipe is 50 to 100% longer than actual to account for fitting losses. After a pipe diameter has been selected on this basis, the influence of each fitting can be evaluated.

## WATER PIPING

### FLOW RATE LIMITATIONS

Stewart and Dona (1987) surveyed the literature relating to water flow rate limitations. Noise, erosion, and installation and operating costs all limit the maximum and minimum velocities in piping systems. If piping sizes are too small, noise levels, erosion levels, and pumping costs can be unfavorable; if piping sizes are too large, installation costs are excessive. Therefore, pipe sizes are chosen to minimize initial cost while avoiding the undesirable effects of high velocities.

**Table 6 Water Velocities Based on Type of Service**

Type of Service	Velocity, fps	Reference
General service	1.2 to 3.0	a, b, c
City water	0.9 to 2.1	a, b
	0.6 to 1.5	c
Boiler feed	1.8 to 4.6	a, c
Pump suction and drain lines	1.2 to 2.1	a, b

<sup>a</sup>Crane Co. (1976).

<sup>b</sup>Carrier (1960).

<sup>c</sup>Grinnell Company (1951).

**Table 7 Maximum Water Velocity to Minimize Erosion**

Normal Operation, h/yr	Water Velocity, m/s
1500	4.6
2000	4.4
3000	4.0
4000	3.7
6000	3.0

Source: Carrier (1960).

A variety of upper limits of water velocity and/or pressure drop in piping and piping systems is used. One recommendation places a velocity limit of 1.2 m/s for 50 mm pipe and smaller, and a pressure drop limit of 400 Pa/m for piping over 50 mm. Other guidelines are based on the type of service (Table 6) or the annual operating hours (Table 7). These limitations are imposed either to control the levels of pipe and valve noise, erosion, and water hammer pressure or for economic reasons. Carrier (1960) recommends that the velocity not exceed 4.6 m/s in any case.

### Noise Generation

Velocity-dependent noise in piping and piping systems results from any or all of four sources: turbulence, cavitation, release of entrained air, and water hammer. In investigations of flow-related noise, Marseille (1965), Ball and Webster (1976), and Rogers (1953, 1954, 1956) reported that velocities on the order of 3 to 5 m/s lie within the range of allowable noise levels for residential and commercial buildings. The experiments showed considerable variation in the noise levels obtained for a specified velocity. Generally, systems with longer pipe and with more numerous fittings and valves were noisier. In addition, sound measurements were taken under widely differing conditions; for example, some tests used plastic-covered pipe, while others did not. Thus, no detailed correlations relating sound level to flow velocity in generalized systems are available.

The noise generated by fluid flow in a pipe increases sharply if cavitation or the release of entrained air occurs. Usually the combination of a high water velocity with a change in flow direction or a decrease in the cross section of a pipe causing a sudden pressure drop is necessary to cause cavitation. Ball and Webster (1976) found that at their maximum velocity of 13 m/s, cavitation did not occur in straight pipe; using the apparatus with two elbows, cold water velocities up to 6.5 m/s caused no cavitation. Cavitation did occur in orifices of 1:8 area ratio (orifice flow area is one-eighth of pipe flow area) at 1.5 m/s and in 1:4 area ratio orifices at 3 m/s (Rogers 1954).

Some data are available for predicting hydrodynamic (liquid) noise generated by control valves. The International Society for Measurement and Control compiled prediction correlations in an effort to develop control valves for reduced noise levels (ISA 1985). The correlation to predict hydrodynamic noise from control valves is

$$SL = 10 \log A_v + 20 \log \Delta p - 30 \log t + 76.6 \quad (9)$$

where

- SL = sound level, dB
- $A_v$  = valve coefficient,  $m^3/(s \cdot \sqrt{Pa})$
- $Q$  = flow rate,  $m^3/s$
- $\Delta p$  = pressure drop across valve, Pa
- $t$  = downstream pipe wall thickness, mm

Air entrained in water usually has a higher partial pressure than the water. Even when flow rates are small enough to avoid cavitation, the release of entrained air may create noise. Every effort should be made to vent the piping system or otherwise remove entrained air.

### Erosion

Erosion in piping systems is caused by water bubbles, sand, or other solid matter impinging on the inner surface of the pipe. Generally, at velocities lower than 30 m/s, erosion is not significant as long as there is no cavitation. When solid matter is entrained in the fluid at high velocities, erosion occurs rapidly, especially in bends. Thus, high velocities should not be used in systems where sand or other solids are present or where slurries are transported.

### Allowances for Aging

With age, the internal surfaces of pipes become increasingly rough, which reduces the available flow with a fixed pressure supply. However, designing with excessive age allowances may result in oversized piping. Age-related decreases in capacity depend on the type of water, type of pipe material, temperature of water, and type of system (open or closed) and include

- Sliming (biological growth or deposited soil on the pipe walls), which occurs mainly in unchlorinated, raw water systems.
- Caking of calcareous salts, which occurs in hard water (i.e., water bearing calcium salts) and increases with water temperature.
- Corrosion (incrustations of ferrous and ferric hydroxide on the pipe walls), which occurs in metal pipe in soft water. Because oxygen is necessary for corrosion to take place, significantly more corrosion takes place in open systems.

Allowances for expected decreases in capacity are sometimes treated as a specific amount (percentage). Dawson and Bowman (1933) added an allowance of 15% friction loss to new pipe (equivalent to an 8% decrease in capacity). The *HDR Design Guide* (1981) increased the friction loss by 15 to 20% for closed piping systems and 75 to 90% for open systems. Carrier (1960) indicates a factor of approximately 1.75 between friction factors for closed and open systems.

Obrecht and Pourbaix (1967) differentiated between the corrosive potential of different metals in potable water systems and concluded that iron is the most severely attacked, then galvanized steel, lead, copper, and finally copper alloys (i.e., brass). Hunter (1941) and Freeman (1941) showed the same trend. After four years of cold and hot water use, copper pipe had a capacity loss of 25 to 65%. Aged ferrous pipe has a capacity loss of 40 to 80%. Smith (1983) recommended increasing the design discharge by 1.55 for uncoated cast iron, 1.08 for iron and steel, and 1.06 for cement or concrete.

The Plastic Pipe Institute (1971) found that corrosion is not a problem in plastic pipe; the capacity of plastic pipe in Europe and the United States remains essentially the same after 30 years in use.

Extensive age-related flow data are available for use with the Hazen-Williams empirical equation. Difficulties arise in its application, however, because the original Hazen-Williams roughness coefficients are valid only for the specific pipe diameters, water velocities, and water viscosities used in the original experiments. Thus, when the  $C_s$  are extended to different diameters, velocities, and/or water viscosities, errors of up to about 50% in pipe capacity can occur (Williams and Hazen 1933, Sanks 1978).

### Water Hammer

When any moving fluid (not just water) is abruptly stopped, as when a valve closes suddenly, large pressures can develop. While detailed analysis requires knowledge of the elastic properties of the pipe and the flow-time history, the limiting case of rigid pipe and instantaneous closure is simple to calculate. Under these conditions,

$$\Delta p_h = \rho c_s V \quad (10)$$

where

- $\Delta p_h$  = pressure rise caused by water hammer, Pa
- $\rho$  = fluid density,  $kg/m^3$
- $c_s$  = velocity of sound in fluid, m/s
- $V$  = fluid flow velocity, m/s

The  $c_s$  for water is 1439 m/s, although the elasticity of the pipe reduces the effective value.

**Example 3.** What is the maximum pressure rise if water flowing at 3 m/s is stopped instantaneously?

**Solution:**  $\Delta p_h = 1000 \times 1439 \times 3 = 4.32 \text{ MPa}$

**Other Considerations**

Not discussed in detail in this chapter, but of potentially great importance, are a number of physical and chemical considerations: pipe and fitting design, materials, and joining methods must be appropriate for working pressures and temperatures encountered, as well as being suitably resistant to chemical attack by the fluid.

**Other Piping Materials and Fluids**

For fluids not included in this chapter or for piping materials of different dimensions, manufacturers' literature frequently supplies pressure drop charts. The Darcy-Weisbach equation, with the Moody chart or the Colebrook equation, can be used as an alternative to pressure drop charts or tables.

**HYDRONIC SYSTEM PIPING**

The Darcy-Weisbach equation with friction factors from the Moody chart or Colebrook equation (or, alternatively, the Hazen-Williams equation) is fundamental to calculating pressure drop in hot and chilled water piping; however, charts calculated from these equations (such as Figures 1, 2, and 3) provide easy determination of pressure drops for specific fluids and pipe standards. In addition, tables of pressure drops can be found in Hydraulic Institute (1979) and Crane Co. (1976).

The Reynolds numbers represented on the charts in Figures 1, 2, and 3 are all in the turbulent flow regime. For smaller pipes and/or lower velocities, the Reynolds number may fall into the laminar regime, in which the Colebrook friction factors are no longer valid.

Most tables and charts for water are calculated for properties at 15°C. Using these for hot water introduces some error, although the answers are conservative (i.e., cold water calculations overstate the pressure drop for hot water). Using 15°C water charts for 90°C water should not result in errors in  $\Delta p$  exceeding 20%.

**Range of Usage of Pressure Drop Charts**

**General Design Range.** The general range of pipe friction loss used for design of hydronic systems is between 100 and 400 Pa/m of pipe. A value of 250 Pa/m represents the mean to which most systems are designed. Wider ranges may be used in specific designs if certain precautions are taken.

**Piping Noise.** Closed-loop hydronic system piping is generally sized below certain arbitrary upper limits, such as a velocity limit of 1.2 m/s for 50 mm pipe and under, and a pressure drop limit of 400 Pa/m for piping over 50 mm in diameter. Velocities in excess of 1.2 m/s can be used in piping of larger size. This limitation is generally accepted, although it is based on relatively inconclusive experience with noise in piping. **Water velocity noise** is not caused by water but by free air, sharp pressure drops, turbulence, or a combination of these, which in turn cause cavitation or flashing of water into steam.

Therefore, higher velocities may be used if proper precautions are taken to eliminate air and turbulence.

**Air Separation**

Air in hydronic systems is usually undesirable because it causes flow noise, allows oxygen to react with piping materials, and sometimes even prevents flow in parts of a system. Air may enter a system at an air-water interface in an open system or in an expansion tank in a closed system, or it may be brought in dissolved in makeup water. Most hydronic systems use air separation devices to remove air. The solubility of air in water increases with pressure and decreases with temperature; thus, separation of air from water is best achieved at the point of lowest pressure and/or highest temperature in a system. For more information, see Chapter 12 of the 2000 *ASHRAE Handbook—Systems and Equipment*.

In the absence of venting, air can be entrained in the water and carried to separation units at flow velocities of 0.5 to 0.6 m/s or more in pipe 50 mm and under. Minimum velocities of 0.6 m/s are therefore recommended. For pipe sizes 50 mm and over, minimum velocities corresponding to a pressure loss of 75 Pa are normally used. Maintenance of minimum velocities is particularly important in the upper floors of high-rise buildings where the air tends to come out of solution because of reduced pressures. Higher velocities should be used in **downcomer** return mains feeding into air separation units located in the basement.

**Example 4.** Determine the pipe size for a circuit requiring 1.25 L/s flow.

**Solution:** Enter Figure 1 at 1.25 L/s, read up to pipe size within normal design range (100 to 400 Pa/m), and select 40 mm. Velocity is 1 m/s and pressure loss is 300 Pa/m.

**Valve and Fitting Pressure Drop**

Valves and fittings can be listed in elbow equivalents, with an elbow being equivalent to a length of straight pipe. Table 8 lists equivalent lengths of 90° elbows; Table 9 lists elbow equivalents for valves and fittings for iron and copper.

**Example 5.** Determine equivalent length of pipe for a 100 mm open gate valve at a flow velocity of approximately 1.33 m/s.

**Solution:** From Table 8, at 1.33 m/s, each elbow is equivalent to 3.2 m of 100 mm pipe. From Table 9, the gate valve is equivalent to 0.5 elbows. The actual equivalent pipe length (added to measured circuit length for pressure drop determination) will be  $3.2 \times 0.5$ , or 1.6 m of 100 mm pipe.

**Tee Fitting Pressure Drop.** Pressure drop through pipe tees varies with flow through the branch. Figure 4 illustrates pressure drops for nominal 25 mm tees of equal inlet and outlet sizes and for the flow patterns illustrated. Idelchik (1986) also presents data for threaded tees.

**Table 8 Equivalent Length in Metres of Pipe for 90° Elbows**

**Table 10 Proper Flow and Pressure Required During Flow for Different Fixtures**

Fixture	Flow Pressure, kPa (gage) <sup>a</sup>	Flow, L/s
Ordinary basin faucet	55	0.2
Self-closing basin faucet	85	0.2
Sink faucet—10 mm	70	0.3
Sink faucet—15 mm	35	0.3
Dishwasher	105 to 175	— <sup>b</sup>
Bathtub faucet	35	0.4
Laundry tube cock—8 mm	35	0.3
Shower	85	0.2 to 0.6
Ball cock for closet	105	0.2
Flush valve for closet	70 to 140	1.0 to 2.5 <sup>c</sup>
Flush valve for urinal	105	1.0
Garden hose, 15 m, and sill cock	210	0.3

<sup>a</sup>Flow pressure is the pressure in the pipe at the entrance to the particular fixture considered.  
<sup>b</sup>Varies; see manufacturers' data.  
<sup>c</sup>Wide range due to variation in design and type of flush valve closets.

Different investigators present tee loss data in different forms, and it is sometimes difficult to reconcile results from several sources. As an estimate of the upper limit to tee losses, a pressure or head loss coefficient of 1.0 may be assumed for entering and leaving flows (i.e.,  $\Delta p = 1.0\rho V_{in}^2/2 + 1.0\rho V_{out}^2/2$ ).

**Example 6.** Determine the pressure or energy losses for a 25 mm (all openings) threaded pipe tee flowing 25% to the side branch, 75% through. The entering flow is 1 L/s (1.79 m/s).

**Solution:** From Figure 4, bottom curve, the number of equivalent elbows for the through-flow is 0.15 elbows; the through-flow is 0.75 L/s (1.34 m/s); and the pressure loss is based on the exit flow rate. Table 8 gives the equivalent length of a 25 mm elbow at 1.33 m/s as 0.8 m. Using Equations (1) and (2) with friction factor  $f = 0.0263$  and diameter  $D = 26.6$  mm,

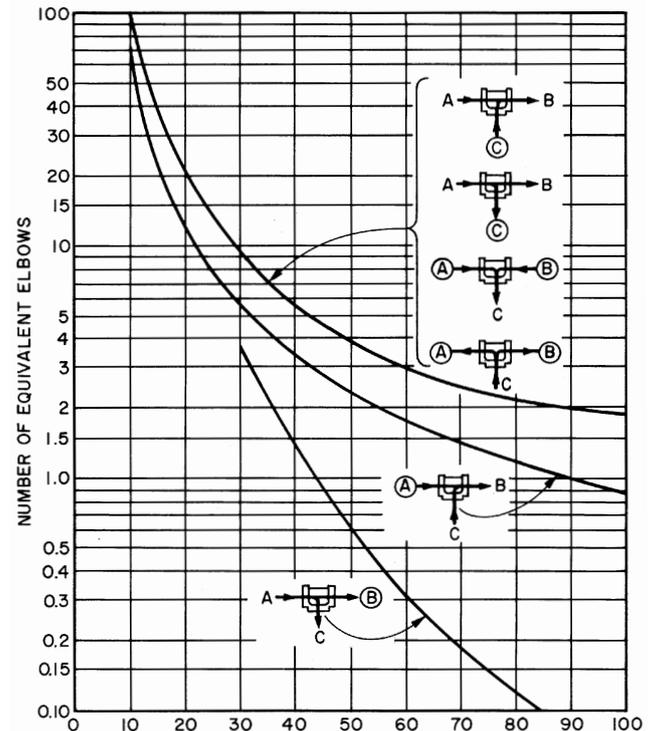

$$\Delta p = (0.15)(0.0263)(0.8/0.0266)(1000)(1.34^2)/2 = 0.107 \text{ kPa pressure drop, or}$$

$$\Delta h = (0.15)(0.0263)(0.8/0.0266)(1.34^2)/[(2)(9.8)] = 0.0109 \text{ m loss}$$

From Figure 4, top curve, the number of equivalent elbows for the branch flow of 25% is 13 elbows; the branch flow is 0.25 L/s (0.45 m/s); and the pressure loss is based on the exit flow rate. Interpolating from Table 8 gives the equivalent of a 25 mm elbow at 0.45 m/s as 0.75 m. Using Equations (1) and (2) with friction factor  $f = 0.0334$  and diameter = 26.6 mm,

$$\Delta p = (13)(0.0334)(0.75/0.0266)(1000)(0.45^2)/(2) = 1.24 \text{ kPa pressure drop, or}$$

$$\Delta h = (13)(0.0334)(0.75/0.0266)(0.45^2)/[(2)(9.8)]$$

- Notes: 1. Chart is based on straight tees (i.e., branches A, B, and C are the same size).  
 2. Pressure loss in desired circuit is obtained by selecting the proper curve according to illustrations, determining the flow at the circled branch, and multiplying the pressure loss for the same size elbow at the flow rate in the circled branch by the equivalent elbows indicated.  
 3. When the size of an outlet is reduced, the equivalent elbows shown in the chart do not apply. Therefore, the maximum loss for any circuit for any flow will not exceed 2 elbow equivalents at the maximum flow occurring in any branch of the tee.  
 4. Top curve is average of 4 curves, one for each circuit shown.

**Fig. 4 Elbow Equivalents of Tees at Various Flow Conditions** (Giesecke and Badgett 1931, 1932b)

### SERVICE WATER PIPING

Sizing of service water piping differs from sizing of process lines in that design flows in service water piping are determined by the probability of simultaneous operation of a multiplicity of individual loads such as water closets, urinals, lavatories, sinks, and showers. The full flow characteristics of each load device are readily obtained from manufacturers; however, service water piping sized to handle all load devices simultaneously would be seriously oversized. Thus, a major issue in sizing service water piping is to determine the diversity of the loads.

The procedure shown in this chapter uses the work of R.B. Hunter for estimating diversity (Hunter 1940, 1941). The present-day plumbing designer is usually constrained by building or plumbing codes, which specify the individual and collective loads to be used for pipe sizing. Frequently used codes (including the BOCA *National Plumbing Code*, *Standard Plumbing Code*, *Uniform Plumbing Code*, and *National Standard Plumbing Code*) contain procedures quite similar to those shown here. The designer must be aware of the applicable code for the location being considered.

Source: Hunter (1941).

<sup>a</sup>For supply outlets likely to impose continuous demands, estimate continuous supply separately, and add to total demand for fixtures.

<sup>b</sup>For fixtures not listed, weights may be assumed by comparing the fixture to a listed one using water in similar quantities and at similar rates.

<sup>c</sup>The given weights are for total demand. For fixtures with both hot and cold water supplies, the weights for maximum separate demands can be assumed to be 75% of the listed demand for the supply.

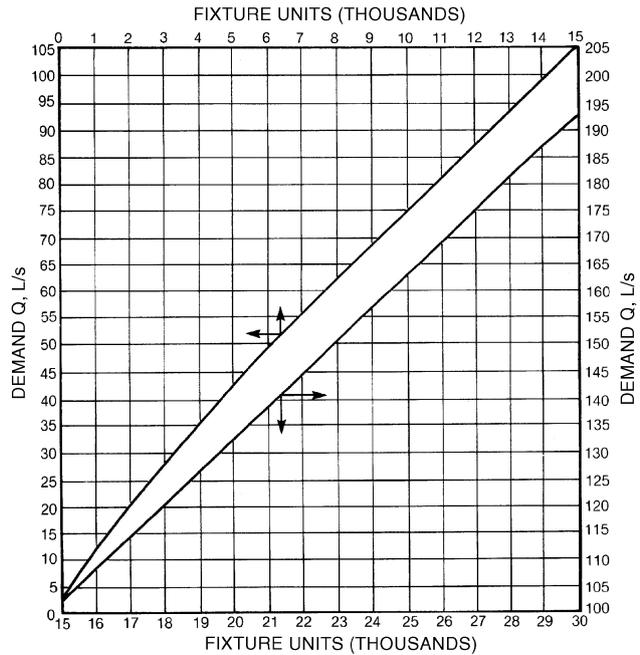

Federal mandates are forcing plumbing fixture manufacturers to reduce design flows to many types of fixtures, but these may not yet be included in locally adopted codes. Also, the designer must be aware of special considerations; for example, toilet usage at sports arenas will probably have much less diversity than the codes allow and thus may require larger supply piping than the minimum specified by the codes.

Table 10 gives the rate of flow desirable for many common fixtures and the average pressure necessary to give this rate of flow. The pressure varies with fixture design.

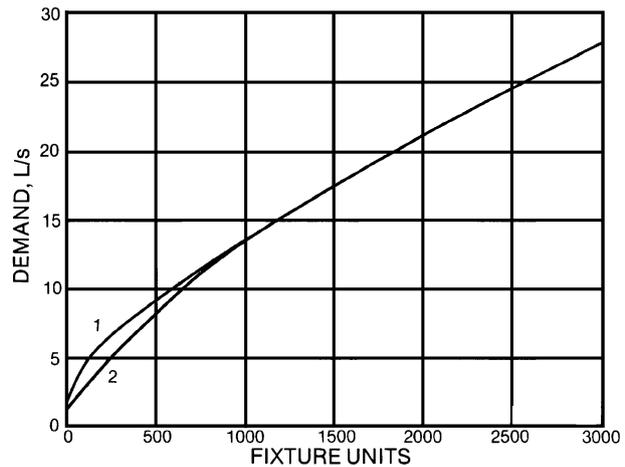

In estimating the load, the rate of flow is frequently computed in **fixture units**, which are relative indicators of flow. Table 11 gives the demand weights in terms of fixture units for different plumbing fixtures under several conditions of service, and Figure 5 gives the estimated demand in gallons per minute corresponding to any total number of fixture units. Figures 6 and 7 provide more accurate estimates at the lower end of the scale.

The estimated demand load for fixtures used intermittently on any supply pipe can be obtained by multiplying the number of each kind of fixture supplied through that pipe by its weight from Table 11, adding the products, and then referring to the appropriate curve of Figure 5, 6, or 7 to find the demand corresponding to the total fixture units. In using this method, note that the demand for fixture or supply outlets other than those listed in the table of fixture units is not yet included in the estimate. The demands for outlets (e.g., hose connections and air-conditioning apparatus) that are likely to impose continuous demand during heavy use of the weighted fixtures should be estimated separately and added to demand for fixtures used intermittently to estimate total demand.

The Hunter curves in Figures 5, 6, and 7 are based on use patterns in residential buildings and can be erroneous for other usages such as sports arenas. Williams (1976) discusses the Hunter assumptions and presents an analysis using alternative assumptions.

**Fig. 9 Variation of Pressure Loss with Flow Rate for Various Faucets and Cocks**

So far, the information presented shows the *design rate of flow* to be determined in any particular section of piping. The next step is to determine the *size* of piping. As water flows through a pipe, the pressure continually decreases along the pipe due to loss of energy from friction. The problem is then to ascertain the minimum pressure in the street main and the minimum pressure required to operate the top-most fixture. (A pressure of 100 kPa may be ample for most flush valves, but reference should be made to the manufacturers' requirements. Some fixtures require a pressure up to 175 kPa. A minimum of 55 kPa should be allowed for other fixtures.) The pressure differential overcomes pressure losses in the distributing system and the difference in elevation between the water main and the highest fixture.

The pressure loss (in kPa) resulting from the difference in elevation between the street main and the highest fixture can be obtained

by multiplying the difference in elevation in metres by the conversion factor 9.8.

Pressure losses in the distributing system consist of pressure losses in the piping itself, plus the pressure losses in the pipe fittings, valves, and the water meter, if any. Approximate design pressure losses and flow limits for disk-type meters for various rates of flow are given in Figure 8. Water authorities in many localities require compound meters for greater accuracy with varying flow; consult the local utility. Design data for compound meters differ from the data in Figure 8. Manufacturers give data on exact pressure losses and capacities.

Figure 9 shows the variation of pressure loss with rate of flow for various faucets and cocks. The water demand for hose bibbs or other large-demand fixtures taken off the building main frequently results in inadequate water supply to the upper floor of a building. This condition can be prevented by sizing the distribution system so that the pressure drops from the street main to all fixtures are the same. An ample building main (not less than 25 mm where possible) should be maintained until all branches to hose bibbs have been connected. Where the street main pressure is excessive and a pressure reducing valve is used to prevent water hammer or excessive pressure at the fixtures, the hose bibbs should be connected ahead of the reducing valve.

The principles involved in sizing upfeed and downfeed systems are the same. In the downfeed system, however, the difference in elevation between the overhead supply mains and the fixtures provides the pressure required to overcome pipe friction. Because friction pressure loss and height pressure loss are not additive, as in an upfeed system, smaller pipes may be used with a downfeed system.

### Plastic Pipe

The maximum safe water velocity in a thermoplastic piping system under most operating conditions is typically 1.5 m/s; however, higher velocities can be used in cases where the operating characteristics of valves and pumps are known so that sudden changes in flow velocity can be controlled. The total pressure in the system at any time (operating pressure plus surge of water hammer) should not exceed 150% of the pressure rating of the system.

### Procedure for Sizing Cold Water Systems

The recommended procedure for sizing piping systems is outlined below.

1. Sketch the main lines, risers, and branches, and indicate the fixtures to be served. Indicate the rate of flow of each fixture.
2. Using Table 11, compute the demand weights of the fixtures in fixture units.
3. Determine the total demand in fixture units and, using Figure 5, 6, or 7, find the expected demand.
4. Determine the equivalent length of pipe in the main lines, risers, and branches. Because the sizes of the pipes are not known, the exact equivalent length of various fittings cannot be determined. Add the equivalent lengths, starting at the street main and proceeding along the service line, the main line of the building, and up the riser to the top fixture of the group served.
5. Determine the average minimum pressure in the street main and the minimum pressure required for the operation of the topmost fixture, which should be 50 to 175 kPa above atmospheric.
6. Calculate the approximate design value of the average pressure drop per unit length of pipe in equivalent length determined in step 4.

$$\Delta p = (p_s - 9.8H - p_f - p_m) / L \quad (11)$$

where

- $\Delta p$  = average pressure loss per metre of equivalent length of pipe, kPa
- $p_s$  = pressure in street main, kPa
- $p_f$  = minimum pressure required to operate topmost fixture, kPa
- $p_m$  = pressure drop through water meter, kPa
- $H$  = height of highest fixture above street main, m
- $L$  = equivalent length determined in step 4, m

If the system is downfeed supply from a gravity tank, height of water in the tank, converted to kPa by multiplying by 9.8, replaces the street main pressure, and the term  $9.8H$  is added instead of subtracted in calculating  $\Delta p$ . In this case,  $H$  is the vertical distance of the fixture below the bottom of the tank.

7. From the expected rate of flow determined in step 3 and the value of  $\Delta p$  calculated in step 6, choose the sizes of pipe from Figure 1, 2, or 3.

**Example 7.** Assume a minimum street main pressure of 375 kPa; a height of topmost fixture (a urinal with flush valve) above street main of 15 m; an equivalent pipe length from water main to highest fixture of 30 m; a total load on the system of 50 fixture units; and that the water closets are flush valve operated. Find the required size of supply main.

**Solution:** From Figure 7, the estimated peak demand is 3.2 L/s. From Table 10, the minimum pressure required to operate the topmost fixture is 105 kPa. For a trial computation, choose the 40 mm meter. From Figure 8, the pressure drop through a 40 mm disk-type meter for a flow of 3.2 L/s is 45 kPa.

The pressure drop available for overcoming friction in pipes and fittings is  $375 - 9.8 \times 15 - 105 - 45 = 78$  kPa.

At this point, estimate the equivalent pipe length of the fittings on the direct line from the street main to the highest fixture. The exact equivalent length of the various fittings cannot be determined since the pipe sizes of the building main, riser, and branch leading to the highest fixture are not yet known, but a first approximation is necessary to tentatively select pipe sizes. If the computed pipe sizes differ from those used in determining the equivalent length of pipe fittings, a recalculation using the computed pipe sizes for the fittings will be necessary. For this example, assume that the total equivalent length of the pipe fittings is 15 m.

The permissible pressure loss per metre of equivalent pipe is  $78 / (30 + 15) = 1.7$  kPa/m. A 40 mm building main is adequate.

The sizing of the branches of the building main, the risers, and the fixture branches follows these principles. For example, assume that one of the branches of the building main carries the cold water supply for 3 water closets, 2 bathtubs, and 3 lavatories. Using the permissible pressure loss of 1.7 kPa/m, the size of branch (determined from Table 11 and Figures 1 and 7) is found to be 40 mm. Items included in the computation of pipe size are as follows:

Fixtures, No. and Type	Fixture Units (Table 11 and Note c)	Demand (Figure 7)	Pipe Size (Figure 1)
3 flush valves	$3 \times 6 = 18$		
2 bathtubs	$0.75 \times 2 \times 2 = 3$		
3 lavatories	$0.75 \times 3 \times 1 = 2.25$		
Total	$= 23.25$	2.4 L/s	40 mm

Table 12 is a guide to minimum pipe sizing where flush valves are used.

Velocities exceeding 3 m/s cause undesirable noise in the piping system. This usually governs the size of larger pipes in the system, while in small pipe sizes, the friction loss usually governs the selection because the velocity is low compared to friction loss. Velocity is the governing factor in downfeed systems, where friction loss is usually neglected. Velocity in branches leading to pump suction should not exceed 1.5 m/s.

If the street pressure is too low to adequately supply upper-floor fixtures, the pressure must be increased. Constant or variable speed

**Table 12 Allowable Number of 25 mm Flush Valves Served by Various Sizes of Water Pipe<sup>a</sup>**

Pipe Size, mm	No. of 25 mm Flush Valves
32	1
40	2-4
50	5-12
65	13-25
75	26-40
100	41-100

<sup>a</sup>Two 20 mm flush valves are assumed equal to one 25 mm flush valve but can be served by a 25 mm pipe. Water pipe sizing must consider demand factor, available pressure, and length of run.

**Table 13 Pressure Drops Used for Sizing Steam Pipe<sup>a</sup>**

Initial Steam Pressure, kPa <sup>b</sup>	Pressure Drop, Pa/m	Total Pressure Drop in Steam Supply Piping, kPa

790	450 to 1100	105 to 170
1140	450 to 2300	170 to 210

<sup>a</sup>Equipment, control valves, and so forth must be selected based on delivered pressures.

<sup>b</sup>Subtract 101 to convert to pressure above atmospheric.

booster pumps, alone or in conjunction with gravity supply tanks, or hydropneumatic systems may be used.

Flow control valves for individual fixtures under varying pressure conditions automatically adjust the flow at the fixture to a predetermined quantity. These valves allow the designer to (1) limit the flow at the individual outlet to the minimum suitable for the purpose, (2) hold the total demand for the system more closely to the required minimum, and (3) design the piping system as accurately as is practicable for the requirements.

## STEAM PIPING

Pressure losses in steam piping for flows of dry or nearly dry steam are governed by Equations (1) through (7) in the section on Pressure Drop Equations. This section incorporates these principles with other information specific to steam systems.

### Pipe Sizes

Required pipe sizes for a given load in steam heating depend on the following factors:

- The initial pressure and the total pressure drop that can be allowed between the source of supply and the end of the return system
- The maximum velocity of steam allowable for quiet and dependable operation of the system, taking into consideration the direction of condensate flow
- The equivalent length of the run from the boiler or source of steam supply to the farthest heating unit

**Initial Pressure and Pressure Drop.** Table 13 lists pressure drops commonly used with corresponding initial steam pressures for sizing steam piping.

Several factors, such as initial pressure and pressure required at the end of the line, should be considered, but it is most important that (1) the total pressure drop does not exceed the initial gage pres-

**Table 14 Comparative Capacity of Steam Lines at Various Pitches for Steam and Condensate Flowing in Opposite Directions**

Capacity in g/s; velocity in m/s.

sure of the system (and in practice it should never exceed one-half the initial gage pressure); (2) the pressure drop is not great enough to cause excessive velocities; (3) a constant initial pressure is maintained, except on systems specially designed for varying initial pressures (e.g., subatmospheric pressure), which normally operate under controlled partial vacuums; and (4) for gravity return systems, the pressure drop to the heating units does not exceed the water column available for removing condensate (i.e., the height above the boiler water line of the lowest point on the steam main, on the heating units, or on the dry return).

**Maximum Velocity.** For quiet operation, steam velocity should be 40 to 60 m/s, with a maximum of 75 m/s. The lower the velocity, the quieter the system. When the condensate must flow against the steam, even in limited quantity, the velocity of the steam must not exceed limits above which the disturbance between the steam and the counterflowing water may (1) produce objectionable sound, such as water hammer, or (2) result in the retention of water in certain parts of the system until the steam flow is reduced sufficiently to permit the water to pass. The velocity at which these dis-

turbances take place is a function of (1) pipe size; (2) the pitch of the pipe if it runs horizontally; (3) the quantity of condensate flowing against the steam; and (4) the freedom of the piping from water pockets that, under certain conditions, act as a restriction in pipe size. Table 14 lists maximum capacities for various size steam lines.

**Equivalent Length of Run.** All tables for the flow of steam in pipes based on pressure drop must allow for pipe friction, as well as for the resistance of fittings and valves. These resistances are generally stated in terms of straight pipe; that is, a certain fitting produces a drop in pressure equivalent to the stated number of feet of straight run of the same size of pipe. Table 15 gives the number of feet of straight pipe usually allowed for the more common types of fittings and valves. In all pipe sizing tables in this chapter, the *length of run* refers to the *equivalent length of run* as distinguished from the *actual length* of pipe. A common sizing method is to assume the length of run and to check this assumption after pipes are sized. For this purpose, the length of run is usually assumed to be double the actual length of pipe.

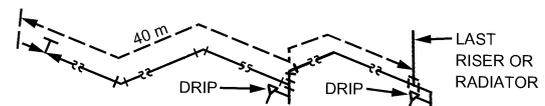

**Example 8.** Using Table 15, determine the equivalent length of pipe for the run illustrated.

**Table 15 Equivalent Length of Fittings to Be Added to Pipe Run**

Nominal Pipe Diameter, mm	Length to Be Added to Run, m

<sup>a</sup>Valve in full-open position.

<sup>b</sup>Values apply only to a tee used to divert the flow in the main to the last riser.

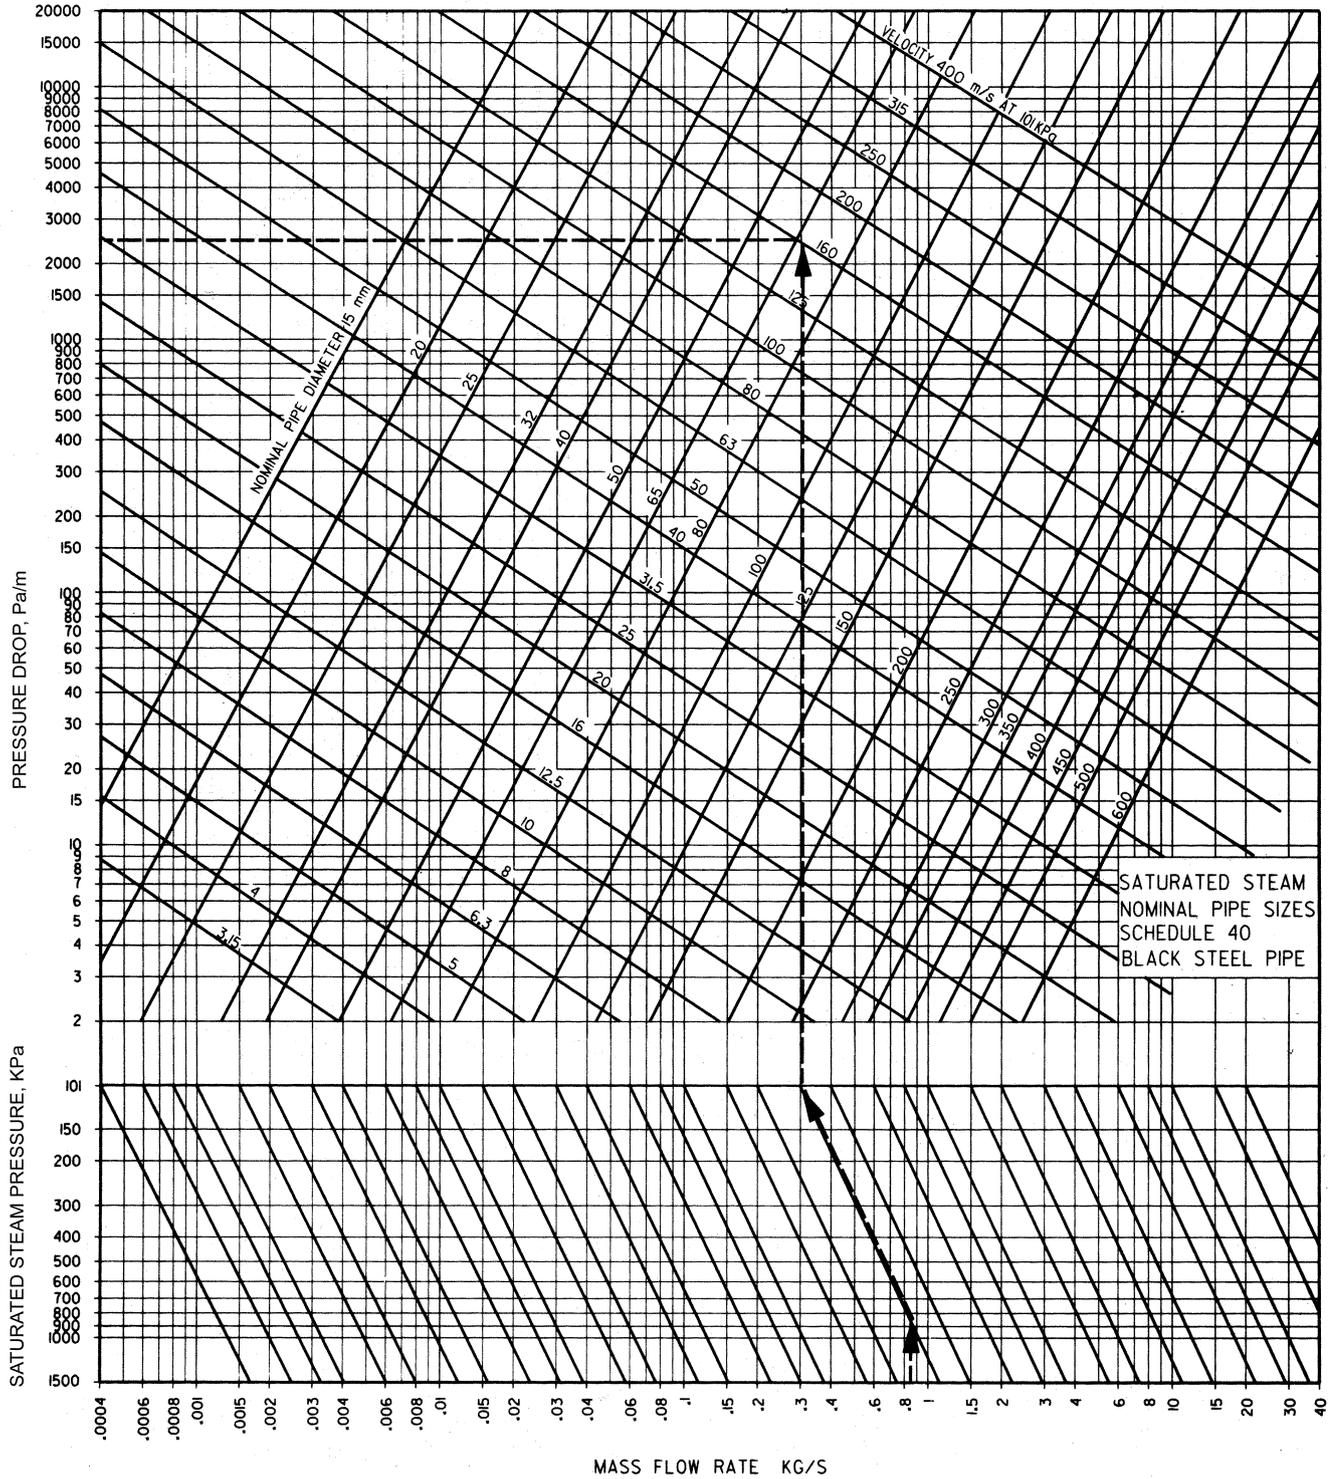

Measured length = 40.0 m  
 100 mm gate valve = 0.6 m  
 Four 100 mm elbows = 10.8 m  
 Two 100 mm tees = 11.0 m  
 Equivalent = 62.4 m

**Sizing Charts**

Figure 10 is the basic chart for determining the flow rate and velocity of steam in Schedule 40 pipe for various values of pressure drop per unit length, based on saturated steam at standard pressure (101.325 kPa). Using the multiplier chart (Figure 11), Figure 10 can be used at all saturation pressures between 101 and 1500 kPa (see Example 10).

**LOW-PRESSURE STEAM PIPING**

Values in Table 16 (taken from Figure 10) provide a more rapid means of selecting pipe sizes for the various pressure drops listed and for systems operated at 25 and 85 kPa (gage). The flow rates shown for 25 kPa can be used for saturated pressures from 7 to 41 kPa, and those shown for 85 kPa can be used for saturated pressures from 55 to 110 kPa with an error not exceeding 8%.

Notes: Based on Moody Friction Factor where flow of condensate does not inhibit the flow of steam. See Figure 11 for obtaining flow rates and velocities of all saturation pressures between 0 and 200 psig; see also Examples 9 and 10.

Fig. 10 Flow Rate and Velocity of Steam in Schedule 40 Pipe at Saturation Pressure of 0 psig

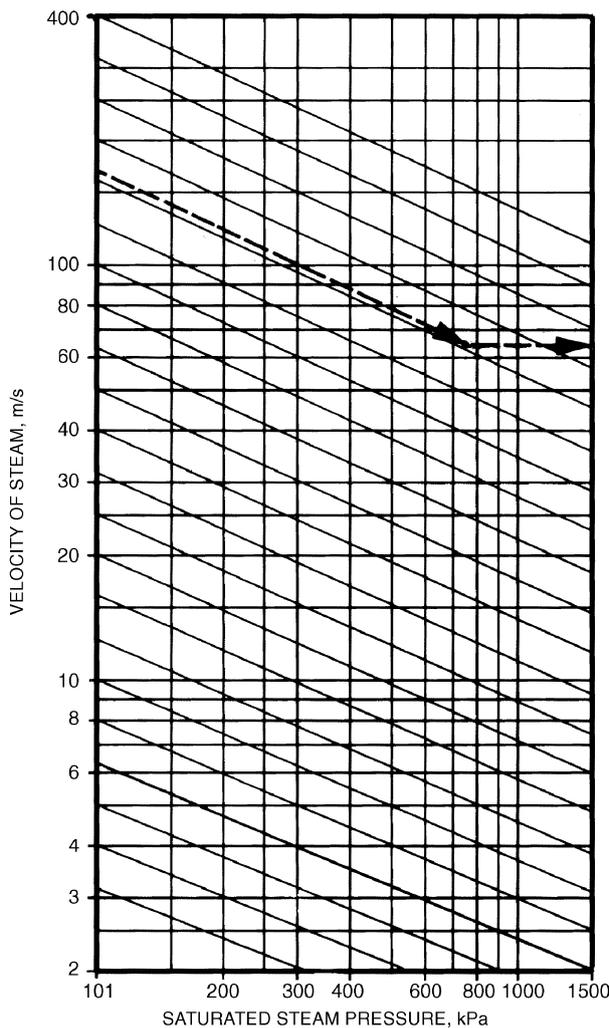

Fig. 11 Velocity Multiplier Chart for Figure 10

Both Figure 10 and Table 16 can be used where the flow of condensate does not inhibit the flow of steam. Columns B and C of Table 17 are used in cases where steam and condensate flow in opposite directions, as in risers or runouts that are not dripped. Columns D, E, and F are for one-pipe systems and include risers, radiator valves and vertical connections, and radiator and riser runout sizes, all of which are based on the critical velocity of the steam to permit the counterflow of condensate without noise.

Return piping can be sized using Table 18, in which pipe capacities for wet, dry, and vacuum return lines are shown for several values of pressure drop per metre of equivalent length.

**Example 9.** What pressure drop should be used for the steam piping of a system if the measured length of the longest run is 150 m, and the initial pressure must not exceed 14 kPa above atmospheric?

**Solution:** It is assumed, if the measured length of the longest run is 150 m, that when the allowance for fittings is added, the equivalent length of run does not exceed 300 m. Then, with the pressure drop not over one-half of the initial pressure, the drop could be 7 kPa or less. With a pressure drop of 7 kPa and a length of run of 300 m, the drop would be 23 Pa/m; if the total drop were 3.5 kPa, the drop would be 12 Pa/m. In both cases, the pipe could be sized for a desired capacity according to Figure 10.

On completion of the sizing, the drop could be checked by taking the longest line and actually calculating the equivalent length of run from the pipe sizes determined. If the calculated drop is less than that assumed, the pipe size is adequate; if it is more, an unusual number of fittings is probably involved, and either the lines must be straightened, or the next larger pipe size must be tried.

### HIGH-PRESSURE STEAM PIPING

Many heating systems for large industrial buildings use high-pressure steam [100 to 1000 kPa (gage)]. These systems usually have unit heaters or large built-up fan units with blast heating coils. Temperatures are controlled by a modulating or throttling thermostatic valve or by face or bypass dampers controlled by the room air temperature, fan inlet, or fan outlet.

Notes:

1. Flow rate is in g/s at initial saturation pressures of 25 and 85 kPa (gage). Flow is based on Moody friction factor, where the flow of condensate does not inhibit the flow of steam.

2. The flow rates at 25 kPa cover saturated pressure from 7 to 41 kPa, and the rates at 85 kPa cover saturated pressure from 55 to 110 kPa with an error not exceeding 8%.

3. The steam velocities corresponding to the flow rates given in this table can be found from Figures 10 and 11.

**Table 17 Steam Pipe Capacities for Low-Pressure Systems**

300	1450	1200	—	—	—
400	2770	2390	—	—	—

Notes:  
 1. For one- or two-pipe systems in which condensate flows against the steam flow.  
 2. Steam at average pressure of 7 kPa (gauge) is used as a basis of calculating capacities.  
<sup>a</sup>Do not use Column B for pressure drops of less than 13 Pa per metre of equivalent run. Use Figure 10 or Table 15 instead.  
<sup>b</sup>Pitch of horizontal runouts to risers and radiators should be not less than 40 mm/m. Where this pitch cannot be obtained, runouts over 2.5 m in length should be one pipe size larger than that called for in this table.  
<sup>c</sup>Do not use Column D for pressure drops of less than 9 Pa per metre of equivalent run, except on sizes 80 mm and over. Use Figure 10 or Table 15 instead.

**Use of Basic and Velocity Multiplier Charts**

**Example 10.** Given a flow rate of 0.85 kg/s, an initial steam pressure of 800 kPa, and a pressure drop of 2.5 kPa/m, find the size of Schedule 40 pipe required and the velocity of steam in the pipe.

**Solution:** The following steps are illustrated by the broken line on Figures 10 and 11.

1. Enter Figure 10 at a flow rate of 0.85 kg/s, and move vertically to the horizontal line at 800 kPa.
2. Follow along inclined multiplier line (upward and to the left) to horizontal 101 kPa line. The equivalent mass flow at 101 kPa is about 0.30 kg/s.
3. Follow the 0.30 kg/s line vertically until it intersects the horizontal line at 2500 Pa/m pressure drop. Nominal pipe size is 65 mm. The equivalent steam velocity at 101 kPa is about 165 m/s.
4. To find the steam velocity at 800 kPa, locate the value of 165 m/s on the ordinate of the velocity multiplier chart (Figure 11) at 101 kPa.
5. Move along the inclined multiplier line (downward and to the right) until it intersects the vertical 800 kPa pressure line. The velocity is about 65 m/s.

Note: Steps 1 through 5 would be rearranged or reversed if different data were given.

**STEAM CONDENSATE SYSTEMS**

The majority of steam systems used in heating applications are two-pipe systems, in which the two pipes are the “steam” pipe and the “condensate” pipe. This discussion is limited to the sizing of the condensate lines in two-pipe systems.

**Two-Pipe Systems**

When steam is used for heating a liquid to 102°C or less (e.g., in domestic water heat exchangers, domestic heating water converters, or air-heating coils), the devices are usually provided with a steam control valve. As the control valve throttles, the absolute

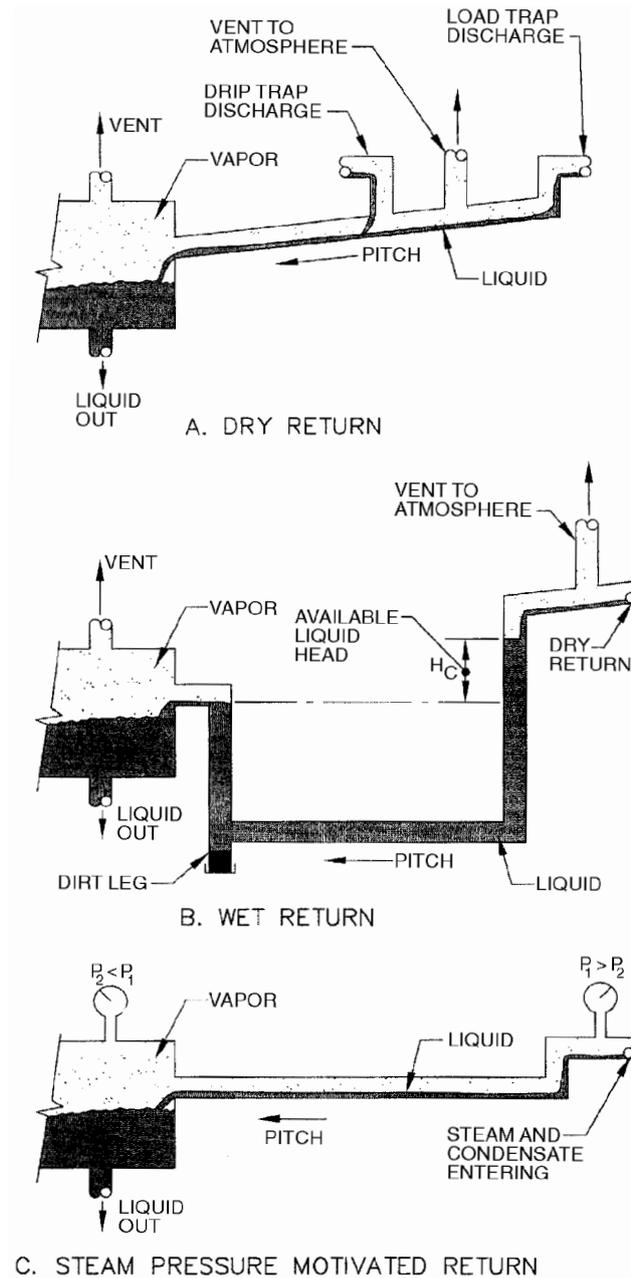

Fig. 12 Types of Condensate Return Systems

pressure in the load device decreases, removing all pressure motivation for flow in the condensate return system. In order to ensure the flow of steam condensate from the load device through the trap and into the return system, it is necessary to provide a vacuum breaker on the device ahead of the trap. This ensures a minimum pressure at the trap inlet of atmospheric pressure plus whatever liquid leg the designer has provided. Then, to ensure flow through the trap, it is necessary to design the condensate system so that it will never have a pressure above atmospheric in the condensate return line.

**Vented (Open) Return Systems.** To achieve this pressure requirement, the condensate return line is usually vented to the atmosphere (1) near the point of entrance of the flow streams from the load traps, (2) in proximity to all connections from drip traps, and (3) at transfer pumps or feedwater receivers.

Table 19 Vented Dry Condensate Return for Gravity Flow Based on Manning Equation

125	1270	1800	2540	3590
150	2070	2930	4150	5860

<sup>a</sup> Flow is in g/s of 82°C water for Schedule 40 steel pipes.

<sup>b</sup> Flow was calculated from Equation (12) and rounded.

With this design, the only motivation for flow in the return system is gravity. Return lines that are below the liquid level in the downstream receiver or boiler and are thus filled with liquid are called wet returns; those above the liquid level have both liquid and gas in the pipes and are called dry returns.

The dry return lines in a vented return system have flowing liquid in the bottom of the line and gas or vapor in the top (Figure 12A). The liquid is the condensate, and the gas may be steam, air, or a mixture of the two. The flow phenomenon for these dry return systems is open channel flow, which is best described by the **Manning equation**:

$$Q = \frac{1.00Ar^{2/3}S^{1/2}}{n} \quad (12)$$

where

- Q = volumetric flow rate, m<sup>3</sup>/s
- A = cross-sectional area of conduit, m<sup>2</sup>
- r = hydraulic radius of conduit, m
- n = coefficient of roughness (usually 0.012)
- S = slope of conduit, m/m

Table 19 is a solution to Equation (12) that shows pipe size capacities for steel pipes with various pitches. Recommended practice is to size vertical lines by the maximum pitch shown, although they would actually have a capacity far in excess of that shown. As the pitch increases, hydraulic jump that could fill the pipe and other transient effects that could cause water hammer should be avoided. Flow values in Table 19 are calculated for Schedule 40 steel pipe, with a factor of safety of 3.0, and can be used for copper pipes of the same nominal pipe size.

The flow characteristics of **wet return lines** (Figure 12B) are best described by the Darcy-Weisbach equation [Equation (1)]. The motivation for flow is the fluid pressure difference between the entering section of the flooded line and the leaving section. It is common practice, in addition to providing for the fluid pressure differential, to slope the return in the direction of flow to a collection point such as a dirt leg in order to clear the line of sediment or solids. Table 20 is a solution to Equation (1) that shows pipe size capacity for steel pipes with various available fluid pressures. Table 20 can also be used for copper tubing of equal nominal pipe size.

**Nonvented (Closed) Return Systems.** For those systems in which there is a continual steam pressure difference between the point where the condensate enters the line and the point where it leaves (Figure 12C), Table 18 or Table 21, as applicable, can be used for sizing the condensate lines. Although these tables express condensate capacity without slope, common practice is to slope the

<sup>a</sup>For these sizes and pressure losses, the velocity is above 35 m/s. Select another combination of size and pressure loss.

lines in the direction of flow to a collection point similar to wet returns to clear the lines of sediment or solids.

When saturated condensate at pressures above the return system pressure enters the return (condensate) mains, some of the liquid flashes to steam. This occurs typically at drip traps into a vented return system or at load traps leaving process load devices that are not valve-controlled and typically have no subcooling. If the return main is vented, the vent lines will relieve any excessive pressure and prevent a back pressure phenomenon that could restrict the flow through traps from valved loads; the pipe sizing would be as

described above for vented dry returns. If the return line is not vented, the flash steam results in a pressure rise at that point and the piping could be sized as described above for closed returns, and in accordance with Table 18 or Table 21, as applicable.

The passage of the fluid through the steam trap is a throttling or constant enthalpy process. The resulting fluid on the downstream side of the trap can be a mixture of saturated liquid and vapor. Thus, in nonvented returns, it is important to understand the condition of the fluid when it enters the return line from the trap.

**Table 22 Flash Steam from Steam Trap on Pressure Drop**

Supply Pressure, kPa (gage)	Return Pressure, kPa (gage)	$x$ , Fraction Vapor, Mass Basis	$V_c$ , Fraction Vapor, Volume Basis
35	0	0.016	0.962
103	0	0.040	0.985
207	0	0.065	0.991
345	0	0.090	0.994
690	0	0.133	0.996
1030	0	0.164	0.997
690	103	0.096	0.989
1030	103	0.128	0.992

The condition of the condensate downstream of the trap can be expressed by the quality  $x$ , defined as

$$x = \frac{m_v}{m_l + m_v} \quad (13)$$

where

$m_v$  = mass of saturated vapor in condensate  
 $m_l$  = mass of saturated liquid in condensate

Likewise, the volume fraction  $V_c$  of the vapor in the condensate is expressed as

$$V_c = \frac{V_v}{V_l + V_v} \quad (14)$$

where

$V_v$  = volume of saturated vapor in condensate  
 $V_l$  = volume of saturated liquid in condensate

The quality and the volume fraction of the condensate downstream of the trap can be estimated from Equations (13) and (14), respectively.

$$x = \frac{h_1 - h_{f_2}}{h_{g_2} - h_{f_2}} \quad (15)$$

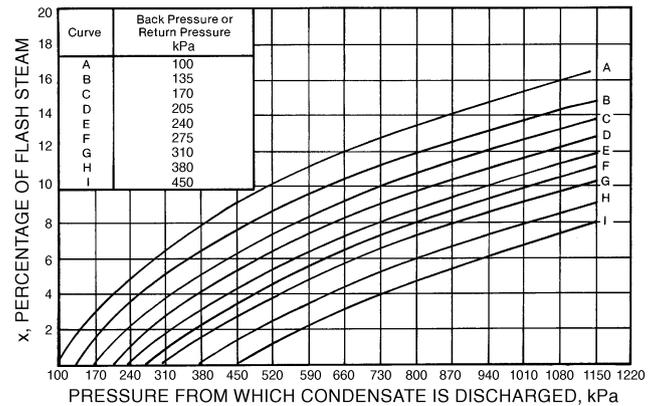

$$V_c = \frac{xv_{g_2}}{v_{f_2}(1-x) + xv_{g_2}} \quad (16)$$

where

$h_1$  = enthalpy of liquid condensate entering trap evaluated at supply pressure for saturated condensate or at saturation pressure corresponding to temperature of subcooled liquid condensate  
 $h_{f_2}$  = enthalpy of saturated liquid at return or downstream pressure of trap  
 $h_{g_2}$  = enthalpy of saturated vapor at return or downstream pressure of trap  
 $v_{f_2}$  = specific volume of saturated liquid at return or downstream pressure of trap  
 $v_{g_2}$  = specific volume of saturated vapor at return or downstream pressure of trap

Table 22 presents some values for quality and volume fraction for typical supply and return pressures in heating and ventilating systems. Note that the percent of vapor on a mass basis  $x$  is small, while the percent of vapor on a volume basis  $V_c$  is very large. This indicates that the return pipe cross section is predominantly occupied by vapor. Figure 13 is a working chart to determine the quality of the condensate entering the return line from the trap for various combinations of supply and return pressures. If the liquid is subcooled entering the trap, the saturation pressure corresponding to the liquid temperature should be used for the supply or upstream pressure.

$$Q = 0.0001d^{2.623}(\Delta p/CL)^{0.541} \quad (17)$$

**Fig. 13 Working Chart for Determining Percentage of Flash Steam (Quality)**

**Table 23 Estimated Return Line Pressures**

Pressure Drop, Pa/m	Pressure in Return Line, Pa (gage)

### One-Pipe Systems

Gravity one-pipe air vent systems in which steam and condensate flow in the same pipe, frequently in opposite directions, are considered obsolete and are no longer being installed. Chapter 33 of the 1993 *ASHRAE Handbook—Fundamentals* or earlier ASHRAE Handbooks include descriptions of and design information for one-pipe systems.

## GAS PIPING

Piping for gas appliances should be of adequate size and installed so that it provides a supply of gas sufficient to meet the maximum demand without undue loss of pressure between the point of supply (the meter) and the appliance. The size of gas pipe required depends on (1) maximum gas consumption to be provided, (2) length of pipe and number of fittings, (3) allowable pressure loss from the outlet of the meter to the appliance, and (4) specific gravity of the gas.

Insufficient gas flow from excessive pressure losses in gas supply lines can cause inefficient operation of gas-fired appliances and sometimes create hazardous operations. Gas-fired appliances are normally equipped with a data plate giving information on maximum gas flow requirements or Btu input as well as inlet gas pressure requirements. The gas utility in the area of installation can give the gas pressure available at the utility's gas meter. Using the information, the required size of gas piping can be calculated for satisfactory operation of the appliance(s).

Table 24 gives pipe capacities for gas flow for up to 60 m of pipe based on a specific gravity of 0.60. Capacities for pressures less than 10 kPa may also be determined by the following equation from NFPA/IAS *National Fuel Gas Code*:

where

$Q$  = flow rate at 15°C and 101 kPa, L/s

**Table 24 Maximum Capacity of Gas Pipe in Litres per Second**

Nominal Iron Pipe Size, mm	Internal Diameter, mm	Length of Pipe, m

- $d$  = inside diameter of pipe, mm
- $\Delta p$  = pressure drop, Pa
- $C$  = factor for viscosity, density, and temperature  
 $= 0.00223(t + 273)s^{0.848}\mu^{0.152}$
- $t$  = temperature, °C
- $s$  = ratio of density of gas to density of air at 15°C and 101 kPa
- $\mu$  = viscosity of gas,  $\mu\text{Pa}\cdot\text{s}$  (12 for natural gas, 8 for propane)
- $L$  = pipe length, m

Gas service in buildings is generally delivered in the “low-pressure” range of 1.7 kPa (gage). The maximum pressure drop allowable in piping systems at this pressure is generally 125 Pa but is subject to regulation by local building, plumbing, and gas appliance codes (see also the NFPA/IAS *National Fuel Gas Code*).

Where large quantities of gas are required or where long lengths of pipe are used (e.g., in industrial buildings), low-pressure limitations result in large pipe sizes. Local codes may allow and local gas companies may deliver gas at higher pressures [e.g., 15, 35, or 70 kPa (gage)]. Under these conditions, an allowable pressure drop of 10% of the initial pressure is used, and pipe sizes can be reduced significantly. Gas pressure regulators at the appliance must be specified to accommodate higher inlet pressures. NFPA/IAS (1992) provides information on pipe sizing for various inlet pressures and pressure drops at higher pressures.

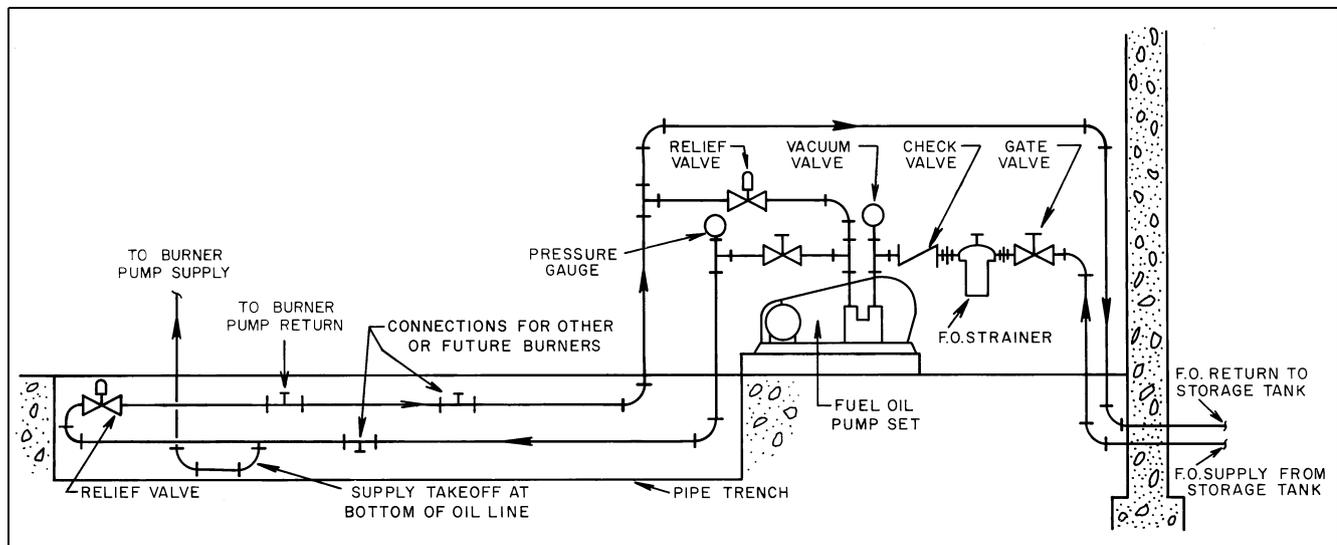

More complete information on gas piping can be found in the *Gas Engineers’ Handbook* (1970).

## FUEL OIL PIPING

The pipe used to convey fuel oil to oil-fired appliances must be large enough to maintain low pump suction pressure and, in the case of circulating loop systems, to prevent overpressure at the burner oil pump inlet. Pipe materials must be compatible with the fuel and must be carefully assembled to eliminate all leaks. Leaks in suction lines cause pumping problems that result in unreliable burner operation. Leaks in pressurized lines create fire hazards. Cast-iron or aluminum fittings and pipe are unacceptable. Pipe joint compounds must be selected carefully.

Oil pump suction lines should be sized so that at maximum suction line flow conditions, the maximum vacuum will not exceed 34 kPa for distillate grade fuels and 50 kPa for residual oils. Oil supply lines to burner oil pumps should not be pressurized by circulating loop systems or aboveground oil storage tanks to more than 34 kPa, or pump shaft seals may fail. A typical oil circulating loop system is shown in Figure 14.

In assembling long fuel pipe lines, care should be taken to avoid air pockets. On overhead circulating loops, the line should vent air at all high points. Oil supply loops for one or more burners should

**Fig. 14 Typical Oil Circulating Loop**

**Table 25 Recommended Nominal Size for Fuel Oil Suction Lines from Tank to Pump (Residual Grades No. 5 and No. 6)**

Pumping Rate, L/h	Length of Run in Metres at Maximum Suction Lift of 4.5 kPa									
	10	20	30	40	50	60	70	80	90	100
50	40	40	40	50	50	50	65	65	65	80
100	40	40	50	50	65	65	65	65	80	80
200	40	50	50	50	65	65	65	80	80	80
300	50	50	65	65	65	80	80	80	80	80
400	50	50	65	65	80	80	80	80	80	100
500	50	65	65	65	80	80	80	80	100	100
600	65	65	65	80	80	80	100	100	100	100
700	65	65	65	80	80	100	100	100	100	100
800	65	65	80	80	100	100	100	100	100	100

**Notes:**

- Sizes (in millimetres) are nominal.
- Pipe sizes smaller than 25 mm ISO are not recommended for use with residual grade fuel oils.
- Lines conveying fuel oil from pump discharge port to burners and tank return may be reduced by one or two sizes, depending on piping length and pressure losses.

**Table 26 Recommended Nominal Size for Fuel Oil Suction Lines from Tank to Pump (Distillate Grades No. 1 and No. 2)**

Pumping Rate, L/h	Length of Run in Metres at Maximum Suction Lift of 9.0 kPa

700	20	25	25	25	25	32	32	32	50	50
800	20	25	25	25	32	32	32	32	50	50

Note: Sizes (in millimetres) are nominal.

be the continuous circulation type, with excess fuel returned to the storage tank. Dead-ended pressurized loops can be used, but air or vapor venting is more problematic.

Where valves are used, select ball or gate valves. Globe valves are not recommended because of their high pressure drop characteristics.

Oil lines should be tested after installation, particularly if they are buried, enclosed, or otherwise inaccessible. Failure to perform this test is a frequent cause of later operating difficulties. A suction line can be hydrostatically tested at 1.5 times its maximum operating pressure or at a vacuum of not less than 70 kPa. Pressure or vacuum tests should continue for at least 60 min. If there is no noticeable drop in the initial test pressure, the lines can be considered tight.

### Pipe Sizes for Heavy Oil

Table 25 and Table 26 give recommended pipe sizes for handling No. 5 and No. 6 oils (residual grades) and No. 1 and No. 2 oils (distillate grades), respectively.

Storage tanks and piping and pumping facilities for delivering the oil from the tank to the burner are important considerations in the design of an industrial oil-burning system.

The construction and location of the tank and oil piping are usually subject to local regulations and National Fire Protection Association (NFPA) *Standards* 30 and 31.

## CHAPTER 36

# ABBREVIATIONS AND SYMBOLS

<i>Abbreviations for Text, Drawings, and Computer Programs</i> .....	36.1
<i>Letter Symbols</i> .....	36.1
<i>Dimensionless Numbers</i> .....	36.4

<i>Mathematical Symbols</i> .....	36.4
<i>Subscripts</i> .....	36.5
<i>Graphical Symbols for Drawings</i> .....	36.5
<i>Piping System Identification</i> .....	36.10

**T**HIS CHAPTER contains information about abbreviations and symbols for heating, ventilating, air-conditioning, and refrigerating (HVAC&R) engineers.

**Abbreviations** are shortened forms of names and expressions used in text, drawings, and computer programs. This chapter discusses conventional English language abbreviations that may be different in other languages. A **letter symbol** represents a quantity or a unit, not its name, and is independent of language. Because of this, use of a letter symbol is preferred over abbreviations for unit or quantity terms. Letter symbols necessary for individual chapters are defined in the chapters where they occur.

Abbreviations are never used for mathematical signs, such as the equality sign (=) or division sign (/), except in computer programming, where the abbreviation functions as a letter symbol. Mathematical operations are performed only with symbols. Abbreviations should be used only where necessary to save time and space; avoid their usage in documents circulated in foreign countries.

Graphical symbols in this chapter of piping, ductwork, fittings, and in-line accessories can be used on scale drawings and diagrams.

Identifying piping by legend and color promotes greater safety and lessens the chance of error in emergencies. Piping identification is now required throughout the United States by the Occupational Safety and Health Administration (OSHA) for some industries and by many federal, state, and local codes.

### ABBREVIATIONS FOR TEXT, DRAWINGS, AND COMPUTER PROGRAMS

Table 1 gives some abbreviations, as well as others commonly found on mechanical drawings and abbreviations (symbols) used in computer programming. Abbreviations specific to a single subject are defined in the chapters in which they appear. Additional abbreviations used on drawings can be found in the section on Graphical Symbols for Drawings.

The abbreviations (symbols) used for computer programming for the HVAC&R industries have been developed by ASHRAE Technical Committee 1.5, Computer Applications. These symbols identify computer variables, subprograms, subroutines, and functions commonly applied in the industry. Using these symbols enhances comprehension of the program listings and provides a clearly defined nomenclature in applicable computer programs.

Certain programming languages differentiate between real numbers (numbers with decimals) and integers (numbers without decimals) by reserving certain initial letters of a variable for integer numbers. Many of the symbols listed in this chapter begin with these letters and, in order to make them real numbers, must be prefixed with a noninteger letter.

Some symbols have two or more options listed. The longest abbreviation is preferred and should be used if possible. However,

it is sometimes necessary to shorten the symbol to further identify the variable. For instance, the area of a wall cannot be defined as WALLAREA because some computer languages restrict the number of letters in a variable name. Therefore, a shorter variable symbol is applied, and WALLAREA becomes WALLA or WAREA.

Many advanced computer programming languages such as Basic, C, and C++ do not have the limitations of older computer language compilers. It is good programming practice to include the complete name of each variable and to define any abbreviations in the comments section at the beginning of each module of code. Abbreviations should be used to help clarify the variables in an equation and not to obscure the readability of the code.

In Table 1, the same symbol is sometimes used for different terms. This liberty is taken because it is unlikely that the two terms would be used in the same program. If such were the case, one of the terms would require a suffix or prefix to differentiate it from the other.

### LETTER SYMBOLS

Letter symbols include symbols for physical quantities (quantity symbols) and symbols for the units in which these quantities are measured (unit symbols). **Quantity symbols**, such as *I* for electric current, are listed in this chapter and are printed in italic type. A **unit symbol** is a letter or group of letters such as mm for millimetre or a special sign such as ° for degrees and is printed in Roman type. Subscripts and superscripts are governed by the same principles. Letter symbols are restricted mainly to the English and Greek alphabets.

Quantity symbols may be used in mathematical expressions in any way consistent with good mathematical usage. The product of two quantities, *a* and *b*, is indicated by *ab*. The quotient is *a/b*, or *ab<sup>-1</sup>*. To avoid misinterpretation, parentheses must be used if more than one slash (/) is employed in an algebraic term; for example, (*a/b*)/*c* or *a/(b/c)* is correct, but not *a/b/c*.

Subscripts and superscripts, or several of them separated by commas, may be attached to a single basic letter (kernel), but not to other subscripts or superscripts. A symbol that has been modified by a superscript should be enclosed in parentheses before an exponent is added (*X<sub>a</sub>*)<sup>3</sup>. Symbols can also have alphanumeric marks such as ' (prime), + (plus), and \* (asterisk).

More detailed information on the general principles of letter symbol standardization are in standards listed at the end of this chapter. The letter symbols, in general, follow these standards, which are out of print:

Y10.3M	Letter Symbols for Mechanics and Time-Related Phenomena
Y10.4-82	Letter Symbols for Heat and Thermodynamics

Other symbols chosen by an author for a physical magnitude not appearing in any standard list should be ones that do not already have different meanings in the field of the text.

The preparation of this chapter is assigned to TC 1.6, Terminology.

**Table 1 Abbreviations for Text, Drawings, and Computer Programs**

Term	Text	Drawings	Program
above finished floor	—	AFF	—
absolute	abs	ABS	ABS
accumulat(e, -or)	acc	ACCUM	ACCUM
air condition(-ing, -ed)	—	AIR COND	—
air-conditioning unit(s)	—	ACU	ACU
air-handling unit	—	AHU	AHU
alteration	altrn	ALTRN	—
alternating current	ac	AC	AC
altitude	alt	ALT	ALT
ambient	amb	AMB	AMB
American National Standards Institute <sup>1</sup>	ANSI	ANSI	—
American wire gage	AWG	AWG	—
ampere	amp	AMP	AMP, AMPS
angle	—	—	ANG
angle of incidence	—	—	ANGI
apparatus dew point	adp	ADP	ADP
approximate	approx.	APPROX	—
area	—	—	A
atmosphere	atm	ATM	—
average	avg	AVG	AVG
azimuth	az	AZ	AZ
azimuth, solar	—	—	SAZ
azimuth, wall	—	—	WAZ
barometer(-tric)	baro	BARO	—
bill of material	b/m	BOM	—
boiling point	bp	BP	BP
Brown & Sharpe wire gage	B&S	B&S	—
Celsius	°C	°C	°C
center to center	c to c	C TO C	—
circuit	ckt	CKT	CKT
clockwise	cw	CW	—
coefficient	coeff.	COEF	COEF
coefficient, valve flow	C <sub>v</sub>	C <sub>v</sub>	CV
coil	—	—	COIL
compressor	cprsr	CMPR	CMPR
condens(-er, -ing, -ation)	cond	COND	COND
conductance	—	—	C
conductivity	condct	CNDCT	K
conductors, number of (3)	3/c	3/c	—
contact factor	—	—	CF
cooling load	clg load	CLG LOAD	CLOAD
counterclockwise	ccw	CCW	—
cubic centimeter	cm <sup>3</sup>	CC	CC
cubic metre	m <sup>3</sup>	CU M	CU M
decibel	dB	DB	DB
degree	deg. or °	DEG or °	DEG
density	dens	DENS	RHO
depth or deep	dp	DP	DPTH
dew-point temperature	dpt	DPT	DPT
diameter	dia.	DIA	DIA
diameter, inside	ID	ID	ID
diameter, outside	OD	OD	OD
difference or delta	diff., Δ	DIFF	D, DELTA
diffuse radiation	—	—	DFRAD
direct current	dc	DC	DC
direct radiation	dir radn	DIR RADN	DIRAD
dry	—	—	DRY
dry-bulb temperature	dbt	DBT	DB, DBT
effectiveness	—	—	EFT
effective temperature <sup>2</sup>	ET*	ET*	ET
efficiency	eff	EFF	EFF
efficiency, fin	—	—	FEFF
efficiency, surface	—	—	SEFF

Term	Text	Drawings	Program
electromotive force	emf	EMF	—
elevation	elev.	EL	ELEV
entering	entr	ENT	ENT
entering water temperature	EWT	EWT	EWT
entering air temperature	EAT	EAT	EAT
enthalpy	—	—	H
entropy	—	—	S
equivalent direct radiation	edr	EDR	—
evaporat(-e, -ing, -ed, -or)	evap	EVAP	EVAP
expansion	exp	EXP	XPAN
face area	fa	FA	FA
face to face	f to f	F to F	—
face velocity	fvcl	FVEL	FV
factor, correction	—	—	CFAC, CFACT
factor, friction	—	—	FFACT, FF
fan	—	—	FAN
film coefficient, <sup>3</sup> inside	—	—	FI, HI
film coefficient, <sup>3</sup> outside	—	—	FO, HO
flow rate, air	—	—	QAR, QAIR
flow rate, fluid	—	—	QFL
flow rate, gas	—	—	QGA, QGAS
freezing point	fp	FP	FP
frequency	Hz	HZ	—
gage or gauge	ga	GA	GA, GAGE
gram	g	g	G
gravitational constant	g	G	G
greatest temp difference	GTD	GTD	GTD
heat	—	—	HT
heater	—	—	HTR
heat gain	HG	HG	HG, HEATG
heat gain, latent	LHG	LHG	HGL
heat gain, sensible	SHG	SHG	HGS
heat loss	—	—	HL, HEATL
heat transfer	—	—	Q
heat transfer coefficient	U	U	U
height	hgt	HGT	HGT, HT
high-pressure steam	hps	HPS	HPS
high-temperature hot water	hthw	HTHW	HTHW
horsepower	hp	HP	HP
hour(s)	h	h	HR
humidity, relative	rh	RH	RH
humidity ratio	W	W	W
incident angle	—	—	INANG
indicated kilowatt	lkW	lkW	—
International Pipe Std	IPS	IPS	—
iron pipe size	ips	IPS	—
joule	J	J	J
kelvin	K	K	K
kilograms	kg	kg	KG
kilojoules	kJ	kJ	KJ
kilometres per hour	km/h	km/h	KPH
kilopascals	kPa	kPa	KPA
kilowatt	kW	kW	KW
kilowatt hour	kWh	kWh	KWH
latent heat	LH	LH	LH, LHEAT
least mean temp. difference <sup>4</sup>	LMTD	LMTD	LMTD
least temp. difference <sup>4</sup>	LTD	LTD	LTD
leaving air temperature	lat	LAT	LAT
leaving water temperature	lwt	LWT	LWT
length	lg	LG	LG, L
liquid	liq	LIQ	LIQ
litre	L	L	L
litres per second	L/s	L/s	LPS
logarithm (natural)	ln	LN	LN

Term	Text	Drawings	Program
logarithm to base 10	log	LOG	LOG
low-pressure steam	lps	LPS	LPS
low-temp. hot water	lthw	LTHW	LTHW
Mach number	Mach	MACH	—
mass flow rate	mfr	MFR	MFR
maximum	max.	MAX	MAX
mean effective temp.	MET	MET	MET
mean temp. difference	MTD	MTD	MTD
medium-pressure steam	mps	MPS	MPS
medium-temp. hot water	mthw	MTHW	MTHW
mercury	Hg	HG	HG
metre	m	m	M
metres per second	m/s	m/s	M/S
millilitres per second	mL/s	mL/s	MLPS
mL/s standard	mL/sS	mL/sS	MLPSS
minimum	min.	MIN	MIN
noise criteria	NC	NC	—
normally open	n o	N O	—
normally closed	n c	N C	—
not applicable	na	N/A	—
not in contract	n i c	N I C	—
not to scale	—	N T S	—
number	no.	NO	N, NO
number of circuits	—	—	NC
number of tubes	—	—	NT
outside air	oa	OA	OA
parts per million	ppm	PPM	PPM
Pascal	Pa	Pa	PA
Pa (absolute)	Pa (abs)	Pa A	PAA
Pa (gage)	Pa (gage)	Pa G	PAG
percent	%	%	PCT
phase (electrical)	ph	PH	—
pipe	—	—	PIPE
pressure	—	PRESS	PRES, P
pressure, barometric	baro pr	BARO PR	BP
critical pressure	—	—	CRIP
pressure, dynamic (velocity)	vp	VP	VP
pressure drop or difference	PD	PD	PD, DELTP
pressure, static	sp	SP	SP
pressure, vapor	vap pr	VAP PR	VAP
primary	pri	PRI	PRIM
radian	—	—	RAD
radiat(-e, -or)	—	RAD	—
radiation	—	RADN	RAD
radius	—	—	R
receiver	rcvr	RCVR	REC
recirculate	recirc.	RECIRC	RCIR, RECIR
refrigerant (12, 22, etc.)	R-12, R-22	R12, R22	R12, R22
relative humidity	rh	RH	RH
resist(-ance, -ivity, -or)	res	RES	RES, OHMS
return air	ra	RA	RA
revolutions	rev	REV	REV
revolutions per minute	rpm	RPM	RPM
revolutions per second	rps	RPS	RPS
roughness	rgH	RGH	RGH, E
safety factor	sf	SF	SF
saturation	sat.	SAT	SAT
Saybolt seconds Furol	ssf	SSF	SSF
Saybolt seconds Universal	ssu	SSU	SSU
sea level	sl	SL	SE
second	s	s	SEC
sensible heat	SH	SH	SH
sensible heat gain	SHG	SHG	SHG
sensible heat ratio	SHR	SHR	SHR
shading coefficient	—	—	SC
solar	—	—	SOL

Term	Text	Drawings	Program
specification	spec	SPEC	—
specific gravity	SG	SG	—
specific heat	sp ht	SP HT	C
sp ht at constant pressure	$c_p$	$c_p$	CP
sp ht at constant volume	$c_v$	$c_v$	CV
specific volume	sp vol	SP VOL	V, CVOL
square	sq.	SQ	SQ
standard	std	STD	STD
standard time meridian	—	—	STM
static pressure	SP	SP	SP
suction	suct.	SUCT	SUCT, SUC
summ(-er, -ary, -ation)	—	—	SUM
supply	sply	SPLY	SUP, SPLY
supply air	sa	SA	SA
surface	—	—	SUR, S
surface, dry	—	—	SURD
surface, wet	—	—	SURW
system	—	—	SYS
tabulat(-e, -ion)	tab	TAB	TAB
tee	—	—	TEE
temperature	temp.	TEMP	T, TEMP
temperature difference	TD, $\Delta t$	TD	TD, TDIF
temperature entering	TE	TE	TE, TENT
temperature leaving	TL	TL	TL, TLEA
thermal conductivity	$k$	K	K
thermal expansion coeff.	—	—	TXPC
thermal resistance	$R$	R	RES, R
thermocouple	tc	TC	TC, TCPL
thermostat	T STAT	T STAT	T STAT
thick(-ness)	thkns	THKNS	THK
total	—	—	TOT
total heat	tot ht	TOT HT	—
transmissivity	—	—	TAU
U-factor	—	—	U
unit	—	—	UNIT
vacuum	vac	VAC	VAC
valve	v	V	VLV
vapor proof	vap prf	VAP PRF	—
variable	var	VAR	VAR
variable air volume	VAV	VAV	VAV
velocity	vel.	VEL	VEL, V
velocity, wind	w vel.	W VEL	W VEL
ventilation, vent	vent	VENT	VENT
vertical	vert.	VERT	VERT
viscosity	visc	VISC	MU, VISC
volt	V	V	E, VOLTS
volt ampere	VA	VA	VA
volume	vol.	VOL	VOL
volumetric flow rate	—	—	VFR
wall	—	—	W, WAL
water	—	—	WTR
watt	W	W	WAT, W
wet bulb	wb	WB	WB
wet-bulb temperature	wbt	WBT	WBT
width	—	—	WI
wind	—	—	WD
wind direction	wdir	WDIR	WDIR
wind pressure	wpr	WPR	WP, WPRES
year	yr	YR	YR
zone	z	Z	Z, ZN

<sup>1</sup>Abbreviations of most proper names use capital letters in both text and drawings.  
<sup>2</sup>The asterisk (\*) is used with ET\*, effective temperature, as in Chapter 8 of this volume.  
<sup>3</sup>These are surface heat transfer coefficients.  
<sup>4</sup>Letter L also used for *Logarithm* of these temperature differences in computer programming.

LETTER SYMBOLS

Symbol	Description of Item	Typical Units
<i>a</i>	acoustic velocity	m/s
<i>A</i>	area	m <sup>2</sup>
<i>b</i>	breadth or width	m
<i>B</i>	barometric pressure	kPa
<i>c</i>	concentration	kg/m <sup>3</sup>
<i>c</i>	specific heat	kJ/(kg·K)
<i>c<sub>p</sub></i>	specific heat at constant pressure	kJ/(kg·K)
<i>c<sub>v</sub></i>	specific heat at constant volume	kJ/(kg·K)
<i>C</i>	coefficient	—
<i>C</i>	fluid capacity rate	W/K
<i>C</i>	thermal conductance	W/(m <sup>2</sup> ·K)
<i>C<sub>L</sub></i>	loss coefficient	—
<i>C<sub>P</sub></i>	coefficient of performance	—
<i>d</i>	prefix meaning differential	—
<i>d</i> or <i>D</i>	diameter	m
<i>D<sub>e</sub></i> or <i>D<sub>h</sub></i>	equivalent or hydraulic diameter	m
<i>D<sub>v</sub></i>	mass diffusivity	mm <sup>2</sup> /s
<i>e</i>	base of natural logarithms	—
<i>E</i>	energy	kJ
<i>E</i>	electrical potential	V
<i>f</i>	film conductance (alternate for <i>h</i> )	W/(m <sup>2</sup> ·K)
<i>f</i>	frequency	Hz
<i>f<sub>D</sub></i>	friction factor, Darcy-Weisbach formulation	—
<i>f<sub>F</sub></i>	friction factor, Fanning formulation	—
<i>F</i>	force	N
<i>F<sub>ij</sub></i>	angle factor (radiation)	—
<i>g</i>	gravitational acceleration	m/s <sup>2</sup>
<i>G</i>	mass velocity	kg/(s·m <sup>2</sup> )
<i>h</i>	heat transfer coefficient	W/(m <sup>2</sup> ·K)
<i>h</i>	hydraulic head	m
<i>h</i>	specific enthalpy	kJ/kg
<i>h<sub>a</sub></i>	enthalpy of dry air	kJ/kg
<i>h<sub>D</sub></i>	mass transfer coefficient	m/s
<i>h<sub>s</sub></i>	enthalpy of moist air at saturation	kJ/kg
<i>H</i>	total enthalpy	kJ
<i>I</i>	electric current	A
<i>k</i>	thermal conductivity	W/(m·K)
<i>k</i> (or <i>γ</i> )	ratio of specific heats, <i>c<sub>p</sub>/c<sub>v</sub></i>	—
<i>K</i>	proportionality constant	—
<i>K<sub>D</sub></i>	mass transfer coefficient	kg/(h·m <sup>2</sup> )
<i>l</i> or <i>L</i>	length	m
<i>L<sub>p</sub></i>	sound pressure	dB
<i>L<sub>w</sub></i>	sound power	dB
<i>m</i> or <i>M</i>	mass	kg
<i>M</i>	relative molecular mass	kg/kg mol
<i>n</i> or <i>N</i>	number in general	—
<i>N</i>	rate of rotation	rad/s
<i>p</i> or <i>P</i>	pressure	kPa
<i>p<sub>a</sub></i>	partial pressure of dry air	kPa
<i>p<sub>s</sub></i>	partial pressure of water vapor in moist air	kPa
<i>p<sub>w</sub></i>	vapor pressure of water in saturated moist air	kPa
<i>P</i>	power	kW
<i>q</i>	time rate of heat transfer	W
<i>Q</i>	total heat transfer	kJ
<i>Q</i>	volumetric flow rate	L/s
<i>r</i>	radius	m
<i>r</i> or <i>R</i>	thermal resistance	m <sup>2</sup> ·K/W
<i>R</i>	gas constant	J/(kg·K)
<i>s</i>	specific entropy	kJ/(kg·K)
<i>S</i>	total entropy	kJ/K
<i>t</i>	temperature	°C
<i>Δt<sub>m</sub></i> or <i>ΔT<sub>m</sub></i>	mean temperature difference	K
<i>T</i>	absolute temperature	K
<i>u</i>	specific internal energy	kJ/kg
<i>U</i>	total internal energy	kJ
<i>U</i>	overall heat transfer coefficient	W/(m <sup>2</sup> ·K)
<i>v</i>	specific volume	m <sup>3</sup> /kg
<i>V</i>	total volume	m <sup>3</sup>

Symbol	Description of Item	Typical Units
<i>V</i>	linear velocity	m/s
<i>w</i>	mass rate of flow	g/s
<i>W</i>	weight	N
<i>W</i>	humidity ratio of moist air (dry air basis)	g/kg
<i>W</i>	work	J
<i>W<sub>s</sub></i>	humidity ratio of moist air at saturation (dry air basis)	g/kg
<i>x</i>	mole fraction	—
<i>x</i>	quality, mass fraction of vapor	—
<i>x, y, z</i>	lengths along principal coordinate axes	m
<i>Z</i>	figure of merit	—
<i>α</i>	absolute Seebeck coefficient	V/K
<i>α</i>	absorptivity, absorptance radiation	—
<i>α</i>	linear coefficient of thermal expansion	1/K
<i>α</i>	thermal diffusivity	m <sup>2</sup> /s
<i>β</i>	volume coefficient of thermal expansion	1/K
<i>γ</i> (or <i>k</i> )	ratio of specific heats, <i>c<sub>p</sub>/c<sub>v</sub></i>	—
<i>γ</i>	specific weight	N/m <sup>3</sup>
<i>Δ</i>	difference between values	—
<i>ε</i>	emissivity, emittance (radiation)	—
<i>θ</i>	time	s, h
<i>η</i>	efficiency or effectiveness	—
<i>λ</i>	wavelength	nm
<i>μ</i>	degree of saturation	—
<i>μ</i>	dynamic viscosity	mPa·s
<i>ν</i>	kinematic viscosity	m <sup>2</sup> /s
<i>ρ</i>	density	kg/m <sup>3</sup>
<i>ρ</i>	reflectivity, reflectance (radiation)	—
<i>ρ</i>	volume resistivity	Ω·m
<i>σ</i>	Stefan-Boltzmann constant	W/(m <sup>2</sup> ·K <sup>4</sup> )
<i>σ</i>	surface tension	N/m
<i>τ</i>	stress	N/m <sup>2</sup>
<i>τ</i>	time	s
<i>τ</i>	transmissivity, transmittance (radiation)	—
<i>φ</i>	relative humidity	—

DIMENSIONLESS NUMBERS

<i>Fo</i>	Fourier number	$\alpha t/L^2$
<i>Gr</i>	Grashof number	$L^3 \rho^2 \beta g (\Delta t) / \mu^2$
<i>Gz</i>	Graetz number	$w c_p / k L$
<i>j<sub>D</sub></i>	Colburn mass transfer	$Sh / Re Sc^{1/3}$
<i>j<sub>H</sub></i>	Colburn heat transfer	$Nu / Re Pr^{1/3}$
<i>Le</i>	Lewis number	$\alpha / D_v$
<i>M</i>	Mach number	$V/a$
<i>Nu</i>	Nusselt number	$h D / k$
<i>Pe</i>	Peclet number	$GD c_p / k$
<i>Pr</i>	Prandtl number	$c_p \mu / k$
<i>Re</i>	Reynolds number	$\rho V D / \mu$
<i>Sc</i>	Schmidt number	$\mu / \rho D_v$
<i>Sh</i>	Sherwood number	$h_D L / D_v$
<i>St</i>	Stanton number	$h / G c_p$
<i>Str</i>	Strouhal number	$f d / V$

MATHEMATICAL SYMBOLS

equal to	=
not equal to	≠
approximately equal to	≈
greater than	>
less than	<
greater than or equal to	≥
less than or equal to	≤
plus	+
minus	−
plus or minus	±
<i>a</i> multiplied by <i>b</i>	$ab, a \cdot b, a \times b$
<i>a</i> divided by <i>b</i>	$\frac{a}{b}, a/b, ab^{-1}$
ratio of the circumference of a circle to its diameter	$\pi$

$a$ raised to the power $n$	$a^n$
square root of $a$	$\sqrt{a}$ , $a^{0.5}$
infinity	$\infty$
percent	%
summation of	$\Sigma$
natural log	ln
logarithm to base 10	log

**SUBSCRIPTS**

These are to be affixed to the appropriate symbols. Several subscripts may be used together to denote combinations of various states, points, or paths. Often the subscript indicates that a particular property is to be kept constant in a process.

$a, b, \dots$	referring to different phases, states or physical conditions of a substance, or to different substances
$a$	air
$a$	ambient
$b$	barometric (pressure)
$c$	referring to critical state or critical value
$c$	convection
$db$	dry bulb
$dp$	dew point
$e$	base of natural logarithms
$f$	referring to saturated liquid
$f$	film
$fg$	referring to evaporation or condensation
$F$	friction
$g$	referring to saturated vapor
$h$	referring to change of phase in evaporation
$H$	water vapor
$i$	referring to saturated solid
$i$	internal
$if$	referring to change of phase in melting
$ig$	referring to change of phase in sublimation
$k$	kinetic
$L$	latent
$m$	mean value
$M$	molar basis
$o$	referring to initial or standard states or conditions
$p$	referring to constant pressure conditions or processes
$p$	potential
$r$	refrigerant
$r$	radiant or radiation
$s$	referring to moist air at saturation
$s$	sensible
$s$	referring to isentropic conditions or processes
$s$	static (pressure)
$s$	surface
$t$	total (pressure)
$T$	referring to isothermal conditions or processes
$v$	referring to constant volume conditions or processes
$v$	vapor
$v$	velocity (pressure)
$w$	wall
$w$	water
$wb$	wet bulb
1, 2, ...	different points in a process, or different instants of time

**GRAPHICAL SYMBOLS FOR DRAWINGS**

Graphical symbols have been extracted from ASME *Standard* Y32.2.3 and ASME *Standard* Y32.2.4. Some of these symbols have been modified, and others have been added to reflect current practice. Symbols and quotations are used with permission of the publisher, the American Society of Mechanical Engineers.

Solenoid	
Pneumatic Motor	
Diaphragm	

**Valves, Special Duty**

Check, swing gate	
Check, spring	
Control, electric-pneumatic	
Control, pneumatic-electric	
Hose end drain	
Lock shield	
Needle	
Pressure reducing (number and specify)	
Quick opening	

Quick closing, fusible link

Relief (R) or safety (S)

Solenoid

Square head cock

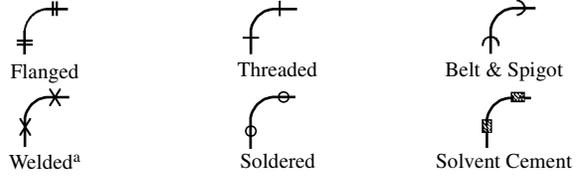

Unclassified (number and specify)

**Fittings**

The following fittings are shown with screwed connections. The symbol for the body of a fitting is the same for all types of connections, unless otherwise specified. The types of connections are often specified for a range of pipe sizes, but are shown with the fitting symbol where required. For example, an elbow would be:

Fitting	Symbol
Bushing	
Cap	
Connection, bottom	
Connection, top	
Coupling (joint)

Intercooler/desuperheater

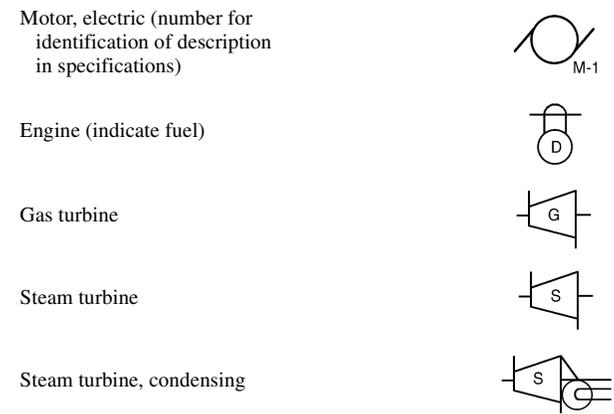

<sup>a</sup> Frequently used diagrammatically as evaporator and/or condenser with label indicating name and type.

<sup>b</sup> L = Liquid being cooled, RL = Refrigerant liquid, RS = Refrigerant suction.

**Energy Recovery Equipment**

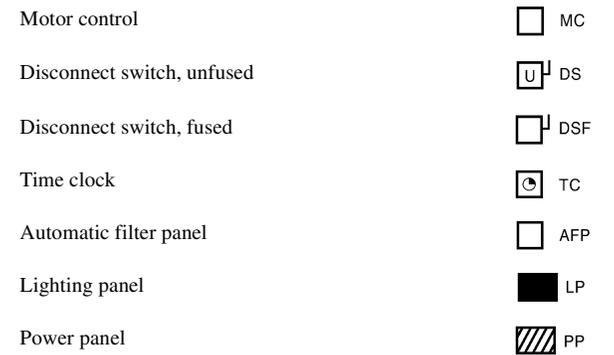

**Power Sources**

**Electrical Equipment<sup>a</sup>**

Symbols for electrical equipment shown on mechanical drawings are usually geometric figures with an appropriate name or abbreviation, with details described in the specifications. The following are some common examples.<sup>b</sup>

<sup>a</sup> See ARI Standard 130 for preferred symbols of common electrical parts.  
<sup>b</sup> Number each symbol if more than one; see ASME Standard Y32.4.

**PIPING SYSTEM IDENTIFICATION**

The material in piping systems is identified to promote greater safety and lessen the chances of error, confusion, or inaction in times of emergency. Primary identification should be by means of a lettered legend naming the material conveyed by the piping. In addition to, but not instead of lettered identification, color can be used to identify the hazards or use of the material.

The data in this section have been extracted from ASME Standard A13.1.

**Definitions**

**Piping Systems.** Piping systems include pipes of any kind, fittings, valves, and pipe coverings. Supports, brackets, and other accessories are not included. Pipes are defined as conduits for the transport of gases, liquids, semiliquids, or fine particulate dust.

**Materials Inherently Hazardous to Life and Property.** There are four categories of hazardous materials:

- Flammable or explosive materials that are easily ignited, including materials known as fire producers or explosives
- Chemically active or toxic materials that are corrosive or are in themselves toxic or productive of poisonous gases
- Materials at extreme temperatures or pressures that, when released from the piping, cause a sudden outburst with the potential for inflicting injury or property damage by burns, impingement, or flashing to vapor state
- Radioactive materials that emit ionizing radiation

**Materials of Inherently Low Hazard.** All materials that are not hazardous by nature, and are near enough to ambient pressure and temperature that people working on systems carrying these materials run little risk through their release.

**Fire Quenching Materials.** This classification includes sprinkler systems and other piped fire fighting or fire protection equipment. This includes water (for fire fighting), chemical foam, CO<sub>2</sub>, Halon, and so forth.

**Method of Identification**

**Legend.** The legend is the primary and explicit identification of content. Positive identification of the content of the piping system is by lettered legend giving the name of the contents, in full or abbreviated form, as shown in Table 2. Arrows should be used to indicate the direction of flow. Use the legend to identify contents exactly and to provide temperature, pressure, and other details necessary to identify the hazard.

The legend shall be brief, informative, pointed, and simple. Legends should be applied close to valves and adjacent to changes in direction, branches, and where pipes pass through walls or floors, and as frequently as needed along straight runs to provide clear and positive identification. Identification may be applied by stenciling, tape, or markers (see Figure 1). The number and location of identification markers on a particular piping system is based on judgment.

**Color.** Colors listed in Table 3 are used to identify the characteristic properties of the contents. Color can be shown on or contiguous to the piping by any physical means, but it should be used in combination with a legend. Color can be used in continuous total length coverage or in intermittent displays.

**Table 2 Examples of Legends**

HOT WATER
AIR 700 kPa
H.P. RETURN
STEAM 700 kPa (gage)

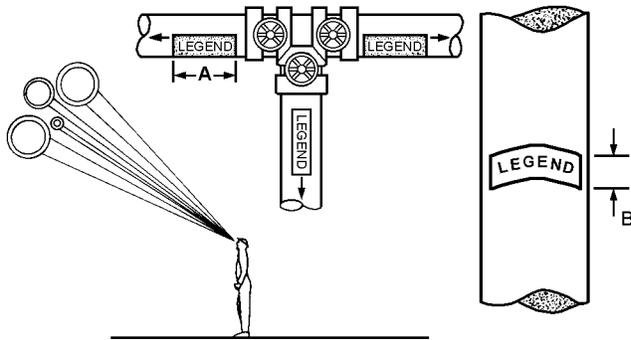

Fig. 1 Visibility of Pipe Markings

**Visibility.** Pipe markings should be highly visible. If pipe lines are above the normal line of vision, the lettering is placed below the horizontal centerline of the pipe (Figure 1).

**Type and Size of Letters.** Provide the maximum contrast between color field and legend (Table 3). Table 4 shows the size of letters recommended. Use of standard size letters of 1/2 in. or larger is recommended. For identifying materials in pipes of less than 3/4 in. in diameter and for valve and fitting identification, use a permanently legible tag.

**Unusual or Extreme Situations.** When the piping layout occurs in or creates an area of limited accessibility or is extremely complex, other identification techniques may be required. While a certain amount of imagination may be needed, the designer should always clearly identify the hazard and use the recommended color and legend guidelines.

Table 3 Classification of Hazardous Materials and Designation of Colors<sup>a</sup>

Classification	Color Field	Colors of Letters for Legend
<b>Materials Inherently Hazardous</b>		
Flammable or explosive	Yellow	Black
Chemically active or toxic	Yellow	Black
Extreme temperatures or pressures	Yellow	Black
Radioactive <sup>b</sup>	Purple	Yellow
<b>Materials of Inherently Low Hazard</b>		
Liquid or liquid admixture <sup>c</sup>	Green	Black
Gas or gaseous admixture	Blue	White
<b>Fire Quenching Materials</b>		
Water, foam, CO <sub>2</sub> , Halon, etc.	Red	White

<sup>a</sup>When the color scheme above is used, the colors should be as recommended in the latest revision of NEMA *Standard Z535.1*.

<sup>b</sup>Previously specified radioactive markers using yellow or purple are acceptable if already installed and/or until existing supplies are depleted, subject to applicable federal regulations.

<sup>c</sup>Markers with black letters on a green color field are acceptable if already installed and/or until existing supplies are depleted.

Table 4 Size of Legend Letters

Outside Diameter of Pipe or Covering, mm	Length of Color Field A, mm	Size of Letters B, mm.
20 to 32	200	13
40 to 50	200	20
65 to 150	300	32
200 to 250	600	65
over 250	800	90

Rankine	x°R = x/1.8	(x - 491.67)/1.8	x	x - 459.67	1°R = 5/9	5/9	1	1
Fahrenheit	x°F = (x + 459.67)/1.8	(x - 32)/1.8	x + 459.67	x	1°F = 5/9	5/9	1	1

Notes: Conversions with \* are exact. The Btu and calorie are based on the International Table.

All temperature conversions and factors are exact. The term centigrade is obsolete and should not be used.

When making conversions, remember that a converted value is no more precise than the original value. For many applications, rounding off the converted value to the same number of significant figures as those in the original value provides sufficient accuracy.

Caution: The conversion values in Table 1 are rounded to three or four significant figures, which is sufficiently accurate for most applications. See ANSI Standard SI-10 (available from ASTM or IEEE) for additional conversions with more significant figures.

## CHAPTER 38

# PHYSICAL PROPERTIES OF MATERIALS

**V**ALUES in the following tables are in consistent units to assist the engineer looking for approximate values. For data on refrigerants, see Chapter 19; for secondary coolants, see Chapter 21. Chapter 25 gives more information on the values for

materials used in building construction and insulation. Many properties vary with temperature, material density, and composition. The references document the source of the values and provide more detail or values for materials not listed here.

**Table 1 Properties of Vapor**

Material	Relative Molecular Mass	Normal Boiling Point, °C	Critical Temperature, °C	Critical Pressure, kPa	Density, kg/m <sup>3</sup>	Specific Heat, J/(kg·K)	Thermal Conductivity, W/(m·K)	Viscosity, μPa·s
Alcohol, Ethyl	46.07 <sup>a</sup>	78.6 <sup>a</sup>	243.2 <sup>b</sup>	6 394 <sup>b</sup>		1520 <sup>j</sup>	0.013 <sup>a</sup>	14.2 <sup>j</sup> (289)
Alcohol, Methyl	32.04 <sup>a</sup>	65.0 <sup>a</sup>	240.1 <sup>b</sup>	7 977 <sup>b</sup>		1350 <sup>j</sup>	0.0301 <sup>f</sup>	14.8 <sup>j</sup> (272)

Table 3 Properties of Solids

Material Description	Specific Heat, J/(kg·K)	Density, kg/m <sup>3</sup>	Thermal Conductivity, W/(m·K)	Emissivity	
				Ratio	Surface Condition
Aluminum (alloy 1100)	896 <sup>b</sup>	2 740 <sup>u</sup>	221 <sup>u</sup>	0.09 <sup>n</sup> 0.20 <sup>n</sup>	Commercial sheet Heavily oxidized
Aluminum bronze (76% Cu, 22% Zn, 2% Al)	400 <sup>n</sup>	8 280 <sup>u</sup>	100 <sup>u</sup>		
Asbestos: Fiber Insulation	1050 <sup>b</sup> 800 <sup>t</sup>	2 400 <sup>u</sup> 580 <sup>b</sup>	0.170 <sup>u</sup> 0.16 <sup>b</sup>	0.93 <sup>b</sup>	“Paper”
Ashes, wood	800 <sup>t</sup>	640 <sup>b</sup>	0.071 <sup>b</sup> (50)		
Asphalt	920 <sup>b</sup>	2 110 <sup>b</sup>	0.74 <sup>b</sup>		
Bakelite	1500 <sup>b</sup>	1 300 <sup>u</sup>	17 <sup>u</sup>		
Bell metal	360 <sup>t</sup> (50)				
Bismuth tin	170 <sup>*</sup>		65.0 <sup>*</sup>		
Brick, building	800 <sup>b</sup>	1 970 <sup>u</sup>	0.7 <sup>b</sup>	0.93 <sup>*</sup>	
Brass: Red (85% Cu, 15% Zn)	400 <sup>u</sup>	8 780 <sup>u</sup>	150 <sup>u</sup>	0.030 <sup>b</sup>	Highly polished
Yellow (65% Cu, 35% Zn)	400 <sup>u</sup>	8 310 <sup>u</sup>	120 <sup>u</sup>	0.033 <sup>b</sup>	Highly polished
Bronze	435 <sup>t</sup>	8 490 <sup>f</sup>	29 <sup>d</sup> (0)		
Cadmium	230 <sup>a</sup>	8 650 <sup>f</sup>	92.9 <sup>b</sup>	0.02 <sup>d</sup>	
Carbon (gas retort)	710 <sup>a</sup>		0.35 <sup>b</sup> (−17)	0.81 <sup>a</sup>	
Cardboard			0.07 <sup>b</sup>		
Cellulose	1300 <sup>b</sup>	54 <sup>t</sup>	0.057 <sup>t</sup>		
Cement (Portland clinker)	670 <sup>b</sup>	1 920 <sup>j</sup>	0.029 <sup>i</sup>		
Chalk	900 <sup>t</sup>	2 290 <sup>t</sup>	0.83 <sup>*</sup>	0.34 <sup>*</sup>	About 120°C
Charcoal (wood)	840 <sup>t</sup>	240 <sup>a</sup>	0.05 <sup>a</sup> (200)		
Chrome brick	710 <sup>b</sup>	3 200 <sup>b</sup>	1.2 <sup>b</sup>		
Clay	920 <sup>b</sup>	1 000 <sup>f</sup>			
Coal	1000 <sup>b</sup>	1 400 <sup>f</sup>	0.17 <sup>f</sup> (0)		
Coal tars	1500 <sup>b</sup> (40)	1 200 <sup>b</sup>	0.1 <sup>b</sup>		
Coke (petroleum, powdered)	1500 <sup>b</sup> (400)	990 <sup>b</sup>	0.95 <sup>b</sup> (400)		
Concrete (stone)	653 <sup>b</sup> (200)	2 300 <sup>b</sup>	0.93 <sup>b</sup>		
Copper (electrolytic)	390 <sup>u</sup>	8 910 <sup>u</sup>	393 <sup>u</sup>	0.072 <sup>n</sup>	commercial, shiny
Cork (granulated)	2030 <sup>t</sup>	86 <sup>t</sup>	0.048 <sup>t</sup> (−5)		
Cotton (fiber)	1340 <sup>u</sup>	1 500 <sup>u</sup>	0.042 <sup>u</sup>		
Cryolite (AlF <sub>3</sub> ·3NaF)	1060 <sup>b</sup>	2 900 <sup>b</sup>			
Diamond	616 <sup>b</sup>	2 420 <sup>f</sup>	47 <sup>t</sup>		
Earth (dry and packed)		1 500 <sup>f</sup>	0.064 <sup>*</sup>	0.41 <sup>*</sup>	
Felt		330 <sup>b</sup>	0.05 <sup>b</sup>		
Fireclay brick	829 <sup>b</sup> (100)	1 790 <sup>f</sup>	1 <sup>b</sup> (200)	0.75 <sup>n</sup>	At 1000°C
Fluorspar (CaF <sub>2</sub> )	880 <sup>b</sup>	3 190 <sup>v</sup>	1.1 <sup>v</sup>		
German silver (nickel silver)	400 <sup>u</sup>	8 730 <sup>u</sup>	33 <sup>u</sup>	0.135 <sup>n</sup>	Polished
Glass: Crown (soda-lime)	750 <sup>b</sup>	2 470 <sup>u</sup>	1.0 <sup>f</sup> (93)	0.94 <sup>n</sup>	Smooth
Flint (lead)	490 <sup>b</sup>	4 280 <sup>u</sup>	1.4 <sup>f</sup>		
Heat-resistant “Wool”	840 <sup>b</sup> 657 <sup>b</sup>	2 230 <sup>f</sup> 52.0 <sup>f</sup>	1.0 <sup>f</sup> (93) 0.038 <sup>t</sup>		
Gold	131 <sup>u</sup>	19 350 <sup>u</sup>	297 <sup>t</sup>	0.02 <sup>n</sup>	Highly polished
Graphite: Powder	691 <sup>*</sup>		0.183 <sup>*</sup>		
Impervious	670 <sup>u</sup>	1 870 <sup>u</sup>	130 <sup>u</sup>	0.75 <sup>n</sup>	
Gypsum	1080 <sup>b</sup>	1 200 <sup>b</sup>	0.43 <sup>b</sup>	0.903 <sup>b</sup>	On a smooth plate
Hemp (fiber)	1352.3 <sup>u</sup>	1 500 <sup>u</sup>			
Ice: 0°C	2040 <sup>t</sup>	921 <sup>b</sup>	2.24 <sup>b</sup>	0.95 <sup>*</sup>	
−20°C	1950 <sup>t</sup>		2.44 <sup>*</sup>		
Iron: Cast	500 <sup>v</sup> (100)	7 210 <sup>f</sup>	47.7 <sup>b</sup> (54)	0.435 <sup>b</sup>	Freshly turned
Wrought		7 700 <sup>b</sup>	60.4 <sup>b</sup>	0.94 <sup>b</sup>	Dull, oxidized
Lead	129 <sup>u</sup>	11 300 <sup>u</sup>	34.8 <sup>u</sup>	0.28 <sup>n</sup>	Gray, oxidized
Leather (sole)		1 000 <sup>b</sup>	0.16 <sup>b</sup>		
Limestone	909 <sup>b</sup>	1 650 <sup>b</sup>	0.93 <sup>b</sup>	0.36 <sup>*</sup> to 0.90	At 63 to 193°C
Linen			0.09 <sup>b</sup>		
Litharge (lead monoxide)	230 <sup>b</sup>	7 850 <sup>b</sup>			
Magnesia: Powdered	980 <sup>b</sup> (100)	796 <sup>b</sup>	0.61 <sup>b</sup> (47)		
Light carbonate		210 <sup>b</sup>	0.059 <sup>b</sup>		
Magnesite brick	930 <sup>b</sup> (100)	2 530 <sup>b</sup>	3.8 <sup>b</sup> (204)		
Magnesium	1000 <sup>b</sup>	1 730 <sup>u</sup>	160 <sup>u</sup>	0.55 <sup>n</sup>	Oxidized
Marble	880 <sup>b</sup>	2 600 <sup>b</sup>	2.6 <sup>b</sup>	0.931 <sup>b</sup>	Light gray, polished
Nickel, polished	440 <sup>u</sup>	8 890 <sup>u</sup>	59.5 <sup>u</sup>	0.045 <sup>n</sup>	Electroplated
Paints: White lacquer				0.80 <sup>n</sup>	
White enamel				0.91 <sup>n</sup>	On rough plate
Black lacquer				0.80 <sup>n</sup>	
Black shellac		1 000 <sup>u</sup>		0.91 <sup>n</sup>	“Matte” finish
Flat black lacquer			0.26 <sup>u</sup>	0.96 <sup>n</sup>	
Aluminum lacquer				0.39 <sup>n</sup>	On rough plate

Table 3 Properties of Solids (Continued)

Material Description	Specific Heat, J/(kg·K)	Density, kg/m <sup>3</sup>	Thermal Conductivity, W/(m·K)	Emissivity	
				Ratio	Surface Condition
Paper	1300*	930 <sup>b</sup>	0.13 <sup>b</sup>	0.92 <sup>b</sup>	Pasted on tinned plate
Paraffin	1670 <sup>bb</sup>	749 <sup>bb</sup>	0.24 <sup>b</sup> (0)		
Plaster		2 110 <sup>b</sup>	0.74 <sup>b</sup> (75)	0.91 <sup>b</sup>	Rough
Platinum	130 <sup>u</sup>	21 470 <sup>u</sup>	69.0 <sup>u</sup>	0.054 <sup>b</sup>	Polished
Porcelain	750*	260 <sup>u</sup>	2.2 <sup>u</sup>	0.92 <sup>b</sup>	Glazed
Pyrites (copper)	549 <sup>b</sup>	4 200 <sup>b</sup>			
Pyrites (iron)	569 <sup>b</sup> (69)	4 970 <sup>v</sup>			
Rock Salt	917 <sup>u</sup>	2 180 <sup>u</sup>			
Rubber, vulcanized: Soft	2000*	1 100 <sup>t</sup>	0.1 <sup>t</sup>	0.86 <sup>b</sup>	Rough
Hard		1 190 <sup>t</sup>	0.16 <sup>t</sup>	0.95 <sup>b</sup>	Glossy
Sand	800 <sup>b</sup>	1 520 <sup>b</sup>	0.33 <sup>b</sup>		
Sawdust		190 <sup>b</sup>	0.05 <sup>b</sup>		
Silica	1320 <sup>b</sup>	2 240 <sup>v</sup>	1.4 <sup>t</sup> (93)		
Silver	235 <sup>u</sup>	10 500 <sup>u</sup>	424 <sup>u</sup>	0.02 <sup>n</sup>	Polished and at 227°C
Snow: Freshly fallen		100 <sup>v</sup>	0.598 <sup>t</sup>		
At 0°C		500 <sup>t</sup>	2.2 <sup>t</sup>		
Steel (mild)	500 <sup>b</sup>	7 830 <sup>b</sup>	45.3 <sup>b</sup>	0.12 <sup>n</sup>	Cleaned
Stone (quarried)	800 <sup>b</sup>	1 500 <sup>t</sup>			
Tar: Pitch	2500 <sup>v</sup>	1 100 <sup>u</sup>	0.88 <sup>v</sup>		
Bituminous		1 200 <sup>t</sup>	0.71 <sup>u</sup>		
Tin	233 <sup>u</sup>	7 290 <sup>u</sup>	64.9 <sup>u</sup>	0.06 <sup>h</sup>	Bright and at 50°C
Tungsten	130 <sup>u</sup>	19 400 <sup>u</sup>	201 <sup>u</sup>	0.032 <sup>n</sup>	Filament at 27°C
Wood: Hardwoods—	1900/2700 <sup>b</sup>	370/1100 <sup>z</sup>	0.11/0.255 <sup>z</sup>		
Ash, white		690 <sup>z</sup>	0.172 <sup>z</sup>		
Elm, American		580 <sup>z</sup>	0.153 <sup>z</sup>		
Hickory		800 <sup>z</sup>			
Mahogany		550 <sup>u</sup>	0.13 <sup>u</sup>		
Maple, sugar		720 <sup>z</sup>	0.187 <sup>z</sup>		
Oak, white	2390 <sup>b</sup>	750 <sup>z</sup>	0.176 <sup>z</sup>	0.90 <sup>n</sup>	Planed
Walnut, black		630 <sup>z</sup>			
Softwoods—	See Table 4,	350/740 <sup>z</sup>	0.11/0.16 <sup>z</sup>		
Fir, white	Chapter 24	430 <sup>z</sup>	0.12 <sup>z</sup>		
Pine, white		430 <sup>z</sup>	0.11 <sup>z</sup>		
Spruce		420 <sup>z</sup>	0.11 <sup>z</sup>		
Wool: Fiber	1360 <sup>u</sup>	1 300 <sup>u</sup>			
Fabric		110/330 <sup>u</sup>	0.036/0.063 <sup>u</sup>		
Zinc: Cast	390 <sup>u</sup>	7 130 <sup>u</sup>	110 <sup>u</sup>	0.05 <sup>n</sup>	Polished
Hot-rolled	390 <sup>b</sup>	7 130 <sup>b</sup>	110 <sup>b</sup>		
Galvanizing				0.23 <sup>n</sup>	Fairly bright
